In Vitro Potentiation of Human Natural Killer Cell Activity by a Streptococcal Preparation, OK-432: Interferon and Interleukin-2 Participation in the Stimulation With OK-432[1,2]

Hiro Wakasugi, *M.D.*,[3] Tadashi Kasahara, *Ph.D.*,[4] Nagahiro Minato, *M.D.*,[5] Junji Hamuro, *Ph.D.*,[6] Michio Miyata, *M.D.*,[3] *and* Yasuhiko Morioka, *M.D.*[3,7]

ABSTRACT—Inasmuch as human natural killer (NK) cell activity was markedly augmented by a streptococcal immunopotentiator, OK-432, both in vivo and in vitro, the mechanism in which OK-432 augmented human NK cell activity was analyzed. Culture supernatants of nonadherent lymphocytes stimulated with OK-432 significantly augmented NK cell activity. Significant activity of both interferon (IFN) (both α- and γ-types) and interleukin-2 (IL-2) was detected in the culture supernatants from nonadherent lymphocytes. Concomitant treatment of supernatants with anti-IFN-α antiserum and pH-2 glycine–HCl buffer or the absorption of supernatants with an IL-2-dependent cell line completely abrogated the NK-augmenting activity, whereas the treatment with either one of these resulted in only partial elimination of the activity. These results indicate that OK-432 stimulates human nonadherent lymphocytes to produce IFN and IL-2 and that both factors are primarily responsible for the NK augmentation by OK-432.—JNCI 1982; 69:807–812.

Lymphoid cells from healthy, previously unsensitized experimental animals and humans are capable of mediating cytotoxicity against a variety of tumors and virus-infected cells. This phenomenon has been called "natural killing" (*1*, *2*). NK effector cells in humans have been characterized as NAdL expressing low-affinity receptors for SRBC and Fc-γR (*3*, *4*). NK cells have received considerable attention because of their potential role in resistance to cancer (*5*). NK cell activity has been reported to be augmented by a number of agents such as virus (*6*), tumor cells (*7*), BCG (*8*), *Corynebacterium parvum* (*9*), and IFN (*10*). Because most of these agents are also known to be able to induce IFN, the augmentation of NK cell activity by these agents has been proposed to be mediated by IFN production (*6*, *7*, *9*). More recently, however, IL-2, which is primarily involved in T-cell growth regulation, also has been shown to be able to augment NK cell activity (*11*).

Some of us have reported (*12*, *13*) that a streptococcal preparation, OK-432, which is widely used as an immunopotentiator with considerable success in patients with malignant diseases in Japan, strongly augmented human NK cell activity in vivo (*12*) as well as in vitro (*13*). In this paper we present evidence that both IFN and IL-2 produced by the lymphocytes stimulated with OK-432 play an essential role in the augmentation of NK cell activity.

MATERIALS AND METHODS

Cell separation.—Cell-separation procedures have been described in (*13*). Peripheral blood from normal donors was diluted with equal volumes of phosphate-buffered saline, and UFC were separated by the Ficoll-Conrey (d=1.078; Daiichi Seiyaku Co., Ltd., Tokyo, Japan) density gradient centrifugation method. Monocyte-rich and lymphocyte-rich cell fractions were separated with adherent properties. UFC suspended in a RPMI-1640 tissue culture medium (Flow Laboratories, Inc., Rockville, Md.) supplemented with 6% FCS (Flow Laboratories, Inc.,) were incubated at 37°C for 12 hours in plastic dishes (LUX Scientific Corp., Newburg Park, Calif.). NAdC were harvested with gentle pipetting and further purified on a Sephadex G-10 column. These procedures reduced the number of monocytes to less than 2%. After harvesting NAdC, the dishes were repeatedly washed, and remaining AdC were detached from the dishes by rubber policemen. AdC usually contained nearly 90% peroxidase-positive monocytes. In some experiments, T-cells (erythrocyte rosette-positive) and non-T-cells (erythrocyte rosette-negative) were separated by being rosetted with AET (2-aminoethylisothiouronium bromide hydrobromide)-treated SRBC. FcγR-positive (erythrocyte–antibody rosette-positive) and FcγR-negative (erythrocyte–antibody rosette-negative) cells were also separated by being rosetted with rabbit IgG anti-SRBC-sensitized SRBC. Cells thus obtained were usually treated with distilled water for 20 seconds for removal of contaminating red blood cells. In all

experiments, viability of the preparations before and after incubation was tested by trypan blue exclusion. The viability of the cells exceeded 90% in every fraction.

Preparation of culture supernatants.—The incubation of 2×10^6 UFC, NAdC, or AdC/ml with 0.2 KE OK-432/ml, 10 μg SpA/ml, 0.005% SpA-CoI bacteria, or 1×10^3IU IFN-α/ml was in RPMI-1640 medium supplemented with 6% FCS. After a 24-hour incubation, the culture supernatants were collected by centrifugation at 2,000 rpm for 5 minutes, were then filtered through a Millipore membrane (0.45 μm; Millipore Corp., Bedford, Mass.) for removal of the streptococcal or staphylococcal bacteria, and were stored at 4°C for later use. In all experiments, supernatants from unstimulated cultures were used as a control.

Assay of cytotoxic activity.—An erythroleukemic cell line, K562, was maintained in RPMI-1640 medium containing 7% FCS. Cells were labeled with 100 μCi of $Na_2{}^{51}CrO_4$ (300–400 μCi/mg; New England Nuclear Corp., Boston, Mass.) by incubation at 37°C for 90 minutes. After being washed four times, the serially diluted lymphoid cells (0.1 ml) and the ^{51}Cr-labeled K562 target cells (10^4 cells/0.1 ml) were mixed in a round-bottom tissue culture plate (Linbro Scientific Inc., Hamden, Conn.) and were incubated for 5 hours in a 5% CO_2–air incubator at 37°C. After incubation, the plates were centrifuged, and 0.1 ml of the supernatants was removed. The radioactivity in the supernatants was counted in a gamma well counter. The specific ^{51}Cr release was calculated as decribed in (*13*).

Determination of antiviral (*IFN*) *activity.*—The culture supernatants were assayed for antiviral activity by the cytopathic effect inhibition method in which FL cells were used as indicator cells and vesicular stomatitis virus (New Jersey strain) was used as challenge virus (*14*). IFN titer expressed in IU was determined by comparison with a standard international reference IFN-α (NIH human reference IFN-G-023-901-527).

Acid treatment of cultured supernatants.—The samples were dialyzed in 0.05 *M* pH 2.0 glycine-HCl buffer at 4°C for 24 hours. An additional dialysis in RPMI-1640 medium at 4°C for 24 hours brought the pH of the samples back to 7.2. Samples were stored at 4°C for later use.

Anti-IFN antiserum.—Sheep anti-human-IFN-α antiserum was provided by Dr. M. Imai. Anti-IFN-α serum at a 1:10,000 dilution was capable of neutralizing 10 IU of IFN-α.

Determination of IL-2 activity.—IL-2 activity in the cultured supernatants was determined according to the methods of Baker et al. (*15*) and Gillis et al. (*16*). Murine (C57BL/6) tumor-specific cytotoxic T-lymphocyte line (CTLL-2) was used as an indicator cell in IL-2 microassays. The cells were washed extensively three times with DMEM (GIBCO, Grand Island, N.Y.) and were resuspended in the DMEM supplemented with 2% FCS. Cells (0.1 ml) were placed in 96-well Microplates, and serial dilutions of the IL-2 sample (0.1 ml) to be assayed were then added. Microplates were incubated at 37°C in an atmosphere of 5% CO_2 in air. Following a 24-hour incubation, 0.5 μCi of [^{3}H]dThd (5 mCi/mmol; New England Nuclear Corp.) was added to each well and incubated for an additional 4 hours. Cultures were harvested, and [^{3}H]dThd incorporation was determined by a scintillation counter.

Preparation of IL-2-absorbed supernatants.—The IL-2-dependent cell line CTLL-2 was washed repeatedly with IL-2-free, fresh RPMI-1640 medium, which removed the remaining IL-2. Then 1×10^7 CTLL-2 cells were incubated with 1 ml of the cultured supernatants at 4°C for 24 hours. The supernatants were collected by sedimentation, filtered through a Millipore membrane (0.45 μm), and stored at 4°C for later use. The procedure completely eliminated IL-2 activity in the culture supernatants.

Stimulants.—OK-432, a penicillin- and heat-treated lyophilized preparation of the low-virulence strain SU of *Streptococcus pyogenes* (group A3), was provided by Chugai Seiyaku (Tokyo, Japan). One KE of OK-432 contained 0.1 mg of dried cocci (10^7–10^8), which was used as a suspension in physiologic saline. SpA-CoI bacteria killed by 0.5% of formaldehyde and heat treatment at 80°C for 5 minutes were used as a stimulant of IFN-α induction (*17*). SpA (Pharmacia Chemicals AB, Uppsala, Sweden) was purchased commercially.

RESULTS

Effect of OK-432-Stimulated Supernatants on the NK Cell Activity

Some of us have previously reported (*12*) that OK-432

[a] Effect of OK-432-stimulated PBL supernatants on the cytotoxicity of both autologous and allogeneic cells was examined with K562 target cells. Fresh autologous or allogeneic PBL were incubated for 24 hr with medium alone, culture supernatants from unstimulated PBL (supernatants at a final concentration of 50%), or with culture supernatants from OK-432-stimulated PBL (supernatants at a final concentration of 50%). Cells were washed and assayed for the cytotoxicity against ^{51}Cr-labeled K562 cells in the 4-hr ^{51}Cr release assay.

[b] $P<0.01$, when compared with above two values.

[c] $P<0.001$, when compared with above two values.

[a] Effector cells were all allogeneic UFC. Fresh PBL were separated into AdL and NAdL fractions as described in "Materials and Methods." UFC, NAdC, or AdC were then cultured with or without OK-432, and the culture supernatants were harvested 24 hr later. The effect of each supernatant on NK activity was examined as described in table 1.

strongly augmented cytotoxic activity against K562 target cells in vitro. The augmented cytotoxic activity was considered to be mainly mediated by nonadherent, FcγR-positive, and non-erythrocyte-rosetting lymphocytes, which were the same characteristics as the characteristics of endogenous NK cells. Our preliminary results indicated that AdC were not required for NK cell augmentation (data not shown).

We thus first investigated the possibility that augmentation of cytotoxicity by OK-432 was mediated by soluble factors. UFC were cultured with or without 0.2 KE OK-432/ml for 24 hours, and the culture supernatants were harvested and centrifuged to eliminate OK-432. Fresh autologous or allogeneic PBL were then incubated with medium or with these supernatants (supernatants at a final concentration of 50%) for 24 hours, and the cytotoxicity was assayed against K562 cells. As shown in table 1, cytotoxic activity of both autologous and allogeneic cells was significantly augmented by OK-432-stimulated supernatants, suggesting that some soluble factors were responsible for the augmentation of NK cell activity.

To examine whether NK cell-enhancing activity derived from NadC or AdC, we tested the effect of the supernatants from each fraction. As shown in table 2, supernatants derived from NAdL significantly enhanced NK cell activity, whereas supernatants from AdC did not.

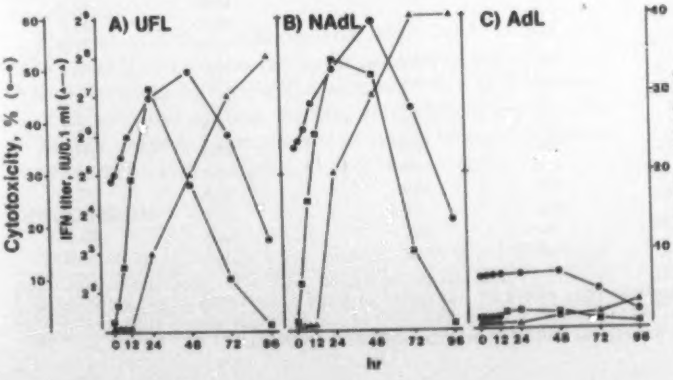
[a] Various agents were incubated with 2×10^6 mononuclear cells/ml from three donors for 24 hr. Culture supernatants were then collected, passed through a Millipore membrane, and immediately tested for their antiviral activity. Optimal incubation times, cell concentrations, and concentrations of the agents were determined in the preliminary experiments.

[b] Concentrations of the agents were 0.2 KE OK-432/ml, 10 μg SpA/ml, and 0.005% SpA-CoI.

Production of IFN and IL-2 by Stimulation With OK-432

IFN and, more recently, IL-2 are well-established molecules involved in the regulation of NK activity in both murine and human systems (*6, 10, 11*). Thus to characterize the NK-augmenting factor(s) in the supernatants of OK-432-stimulated cultures, we first examined whether OK-432 could stimulate the production of these factors, namely, IFN and IL-2, in human PBL. Normal UFL, NAdL, or AdL were cultured in the presence of OK-432. At various culture intervals, culture supernatants as well as cultured cells were harvested and assayed first for IFN and IL-2 activity and then for NK activity. The results are summarized in text-figure 1. Significant IL-2 activity was detected in the culture supernatants as early as 6 hours of culture; IL-2 activity reached the peak level at 24 hours and progressively declined thereafter (text-fig. 1A). Antiviral (IFN) activity was also detected in OK-432-stimulated culture supernatants. The kinetics of IFN production, however, were quite different from the kinetics of IL-2. Thus a progressive increase of IFN activity was observed up to 96 hours. Augmented NK



TEXT-FIGURE 1.—Kinetics of development of cytotoxic activity, induction of IFN, and IL-2 production by OK-432 in culture. Fresh UFL (2×10^6) or separated AdL were incubated for 0–96 hr with 0.2 KE OK-432/ml. At various intervals, NK cell activity of the cells (E:T=10:1) as well as IFN and IL-2 activity in the supernatants were assayed.

TABLE 4.—*IL-2 induction by various bacterial agents*[a]

Origin of supernatants	Agents[b]	IL-2 titer, U/ml		
		Expt 1[c]	Expt 2[c]	Expt 3
UFC	Control	<1	<1	<1
	OK-432	32	6	10
	SpA	50	NT	50
	SpA-CoI	4	<1	<1
	PHA	NT	NT	10

	OK-432	32	32	20
	SpA	50	NT	50
	SpA-CoI	8	8	<1
AdC	Control	<1	<1	<1
	OK-432	<1	<1	<1
	SpA	<1	NT	<1
	SpA-CoI	<1	<1	<1

[a] Various agents were incubated with 2×10^6 mononuclear cells/ml from separate donors for 24 hr. Culture supernatants were collected and passed through a Millipore membrane, and IL-2 activity in the supernatants was tested.

[b] Concentrations of the agents were 0.02 KE OK-432/ml, 10 μg SpA/ml, 0.005% SpA-CoI, and 5 μg phytohemagglutinin (PHA)/ml. PHA served as a control for the induction of IL-2 activity.

[c] NT=not tested.

activity was observed between 6 and 72 hours, the highest level being around 48 hours.

Essentially similar results were obtained for NAdL, except that both IFN and IL-2 titers as well as the degree of NK augmentation were consistently higher in NAdL cultures than in UFL cultures (text-fig. 1B). In contrast, neither IFN nor IL-2 activity was detected in the cultures of AdL throughout the culture period, nor was any significant NK augmentation noted (text-fig. 1C).

The stimulation capacity of IFN and IL-2 of OK-432 was compared with the stimulation capacity of other bacterial preparations, SpA and SpA-CoI, which were also shown to be able to augment NK activity of human PBL (*13*, *14*). These results are summarized in tables 3 and 4. SpA-CoI induced a level of IFN in UFC population comparable to the level induced by OK-432, whereas SpA did not stimulate a detectable level of IFN in 24 hours. SpA-CoI stimulated IFN production in both NAdL and AdL equally, whereas OK-432 induced IFN production only in the NAdL. In contrast, SpA was found to be a very potent IL-2 inducer, and SpA-CoI was found to be a poor inducer. IL-2 was produced by the NAdL, and no detectable IL-2 activity was found in the AdL fraction by any of the stimulants.

Thus we addressed the next question: Is the production of IFN or IL-2 by OK-432 stimulation really responsible for NK cell augmentation? First, to elucidate the role of IFN, we examined the effect of anti-IFN-α serum on the NK cell-enhancing activity of the OK-432-stimulated culture supernatants of UFC. The supernatants, which had been neutralized with anti-IFN-α antibody (antibody dilution, 1:100; incubation, 37°C for 2 hr) and/or acid treatment (at pH 2 and 4°C for 24 hr) were added to the fresh PBL cultures and then tested for their NK cell-augmenting effects. As shown in table 5, the NK cell-augmenting effect of both IFN-stimulated and SpA-CoI bacteria-stimulated supernatants was completely eliminated by treatment with a 1:100 dilution of anti-IFN-α antibody. In contrast, only partial reduction of such activity was observed in both SpA-stimulated and OK-432-stimulated supernatants. Similar results were obtained even when acid treatment was added to the anti-IFN-α antibody for the neutralization of IFN.

Second, we investigated the effect of absorption of IL-2 activity in the supernatants. The supernatants, which had been preabsorbed with CTLL-2 cells, were added to the fresh PBL cultures and tested for their NK cell-enhancing

[a] Supernatants previously IL-2 absorbed with CTLL-2 cells (4°C, 24 hr) were treated with or without the combined treatments of pH 2 glycine–HCl buffer for 24 hr at 4°C and of incubation with an equal volume of anti-IFN antibody (1:100 diluted) for 2 hr at 37°C. Supernatants were then tested for IL-2 and IFN titers. After these treatments, fresh PBL (3×10^5/30 μl) were mixed with the supernatants (300 μl, 50% of final concentration) and were incubated for 24 hr. Finally, NK cell activity was assayed. E:T=10:1. Representative data from three similar experiments are shown.

[c] NT=not tested.

effects. As shown in table 6, such treatment completely eliminated IL-2 activity in the supernatants. A significant but again partial reduction of cytotoxic activity was observed both in SpA-stimulated and OK-432-stimulated supernatants, whereas the cytotoxicity in IFN-α-stimulated and SpA-CoI-stimulated supernants remained unaffected. Finally, when both anti-IFN-α serum and acid treatment were combined with absorption by CTLL-2 cells, the cytotoxicity in OK-432-stimulated supernatants was completely eliminated.

These results thus indicate that IFN, both IFN-α and IFN-γ, *and* IL-2 are involved in the augmentation of human NK cell activity by OK-432. However, either IFN alone or IL-2 alone could explain the NK cell-augmenting activity of further degraded components of staphylococcal preparations, namely, IFN in SpA-CoI and IL-2 in SpA.

DISCUSSION

Some of us (*12*, *13*) have shown that a streptococcal immunopotentiator, OK-432, augmented natural cytotoxic activity of human PBL from healthy donors as well as from donors with cancer. In the present paper, we tried to analyze the mechanisms by which OK-432 as well as other staphylococcal preparations augment human NK activity in vitro. A number of reports indicate that OK-432 can activate the monocyte–macrophage system (*18*, *19*). The first question we thus addressed was whether monocytes–macrophages were required for augmentation of NK activity by OK-432. Our preliminary study, however, indicated that monocytes–macrophages were not required for NK augmentation by OK-432. Thus equivalent or even greater augmentation of NK activity was obtained in AdC-depleted mononuclear cells by OK-432, as compared with NK activity in UFC, and no significant NK cell augmentation was observed in AdC by OK-432.

The next question we addressed was whether OK-432 acted directly on NK effector cells to potentiate their NK activity or if OK-432 stimulated the production of some mediators, which in turn stimulated NK cells. As was clearly shown in table 1, supernatants of OK-432-stimulated cultures, which were absolutely free of OK-432 particles, strongly augmented the NK activity of fresh UFC at a comparable degree of augmentation as if OK-432 particles were present. These results clearly indicate that OK-432 can stimulate the production of secondary NK-enhancing factors, although the results do not completely eliminate the possibility that OK-432 also can directly stimulate NK effector cells.

As chemically defined molecules, IFN and most recently IL-2 are the only molecules so far known that directly stimulate NK cells (*6*, *10*, *11*), although the ways in which they act seem to vary considerably between them (*10*, *20*, *21*). Indeed, a number of agents known to augment NK activity, agents such as various mitogens, bacteria, chemicals, viruses, and allogeneic and virus-infected as well as various tumor cells are also shown to stimulate either IFN or IL-2 (*6*, *7*, *9*, *22*). Our present results indicate that, in fact, OK-432 stimulated both IFN and IL-2 simultaneously in normal human PBL.

Using a murine system, Matsubara et al. (*23*) reported that OK-432 could strongly induce IFN-γ. In the present study, we showed that IFN produced by OK-432 in human PBL was partially inactivated either by anti-IFN-α serum or by pH 2.0 treatment and was almost completely eliminated by both treatments, suggesting that both IFN-α and IFN-γ were included. Conforming to this observation, preliminary experiments showed that IFN was derived from both T-cell and non-T-cell populations of NAdC by OK-432 stimulation (data not shown). Interestingly, IFN induction by OK-432 seems to be independent of the presence of adherent accessory cells, although the possible involvement of small numbers (<2%) of contaminant accessory cells in our NAdL population could not be completely eliminated.

Other soluble IFN inducers such as polyinosinic-polycytidylic acid, phytohemagglutinin, and concanavalin A have been shown to be dependent on the presence of AdC for their action (*24*, *25*). Because OK-432 is a particulate material, the difference may well be due to the differences in the physical forms of these IFN inducers. At present, we do not know whether the same structure on OK-432 is responsible for both IFN and IL-2 production or if separate structures are involved. In this context, it is noteworthy that purified SpA, which is derived from a staphylococcal preparation, preferentially stimulated IL-2 in human PBL, whereas SpA-CoI strongly induced IFN with less IL-2 as compared to the amount of IL-2 in the SpA-stimulated preparation. Thus it seems very likely that different structures on OK-432 particles are responsible for IFN and IL-2 stimulation in human lymphocytes.

That both IFN and IL-2 are truly responsible for the OK-432-induced NK cell augmentation was undoubtedly proved by the following experiments: 1) Treatment of the OK-432-stimulated culture supernatants with anti-IFN-α serum, with pH 2.0 treatment, or with both resulted in a partial but significant reduction in the NK cell-augmenting activity; 2) absorption of the supernatants with CTLL-2 cells, which completely eliminated IL-2 activity, also resulted in a partial reduction in the NK cell-augmenting activity; and finally, 3) combined treatment of the supernatants with both procedures completely eliminated the NK cell-augmenting activity. As to how IFN and IL-2 stimulate NK activity, two basic explanations seem possible: 1) IL-2 and IFN stimulate NK activity absolutely independently of each other and 2) IL-2 stimulates IFN production, which finally stimulates NK cell activity. Study of the kinetics of these modes of production indicated that IL-2 production by OK-432 stimulation preceded the IFN production in the culture (text-fig. 1). In the murine system, it was indeed shown that partially purified IL-2 freed from IFN activity could stimulate IFN production in the normal PBL population (*26*). These observations seem to favor, but do not prove, the second possibility, that of a stepwise stimulation of NK cell activity. Recently, Farrar et al. (*27*) reported that IFN-γ produced by the stimulation with IL-2 in mixed PBL cultures was the essential signal for the generation of alloreactive, cytotoxic T-lymphocytes. The exact interrelationship between IL-2 and IFN in the NK cell system, however, remains to be further elucidated.

Carcinoembryonic Antigen: Usefulness as a Postsurgical Method in the Detection of Recurrence in Dukes Stages B_2 and C Colorectal Cancers[1,2]

Maria Koch,[3] Graeme Washer,[4] Herta Gaedke,[3] *and* Thomas A. McPherson[4,5]

ABSTRACT—Sequential carcinoembryonic antigen (CEA) plasma levels were obtained postoperatively in 181 patients with colorectal Dukes stages B_2 and C colorectal cancers to assess their usefulness as part of a follow-up program designed to detect disease progression. In all, 1,684 determinations were obtained in patients who were, at the time, free of any clinical or radiologic evidence of disease. If individual CEA determinations are considered and if 10 ng/ml is specified as the limit between normal and elevated CEA levels, both sensitivity (45.0%) and specificity (93.4%) make determination of CEA levels an acceptable screening test in this well-defined population, especially as it also fulfills the criteria of patient acceptance, potential benefit to the patient, and low cost. Preoperative CEA levels were also determined in 93 of the 181 patients, and these results confirm the prognostic value of the slope between preoperative and postoperative CEA levels.—JNCI 1982; 69:813–815.

In the fall of 1980, the Consensus Development Conference was held at the National Institutes of Health, Bethesda, Md., on the role of CEA as a marker in the management of cancer (*1*). For patients with colorectal cancer, the Conference panel recommended obtaining CEA plasma levels before surgery, 4–6 weeks after surgery, and at regular intervals thereafter. Determination of CEA plasma levels is considered to be "the best presently available noninvasive technique for postoperative surveillance" of these patients.

Low preoperative levels of CEA are correlated with better survival rates (*2*) and have been proposed as a stratifying factor in adjuvant chemotherapy protocols (*3*). Postoperative elevated CEA titers are often an indication of residual disease (*4, 5*), just as rising CEA levels in general are an indication of disease progression (*6, 7*). In some patients, CEA levels never rise above normal even in the presence of extended disease (*8*), but a normal preoperative CEA level does not preclude the possibility of rising titers if disease progression occurs (*9*).

According to Möschl et al. (*10*), patients with colorectal cancer can be divided into the following 2 groups according to the change in their CEA levels: patients whose CEA concentrations decreased postoperatively and remained normal for a year or more (recurrence rate, 9%) and patients whose postoperative CEA levels showed little or no decrease and later increased (recurrence rate, 86%).

When CEA plasma levels are utilized to monitor colorectal cancer in patients who are apparently free of disease, they must be considered as a surveillance or screening test, rather than as a diagnostic test, applied to a select population at risk and should fulfill the criteria generally accepted for screening tests (*11*): sensitivity, specificity, acceptance, low cost, and potential possible benefits to the patients. The usefulness of a screening test depends on a combination of all these factors as they relate to the population being screened.

To test the efficacy of CEA levels as a postoperative screening method, we have chosen patients with Dukes stages B_2 and C colorectal cancers, since these patients have a high probability of developing recurrent disease postoperatively (*12*).

The prognostic value of any single CEA determination in apparently disease-free patients as well as the prognostic value of the slope between presurgical and postsurgical CEA levels was analyzed.

MATERIALS AND METHODS

All CEA determinations were done by the Ziconyl-phosphate method (Z-gel) developed by Hansen et al. (*13*) as modified in our laboratory (*14*). Although for diagnostic purposes CEA plasma levels from 0 to 5.0 ng/ml are considered within normal limits and levels between 5.1 and 10.0 ng/ml are considered borderline, for screening purposes we define levels up to 10.0 ng/ml as normal. CEA slopes were obtained by the following formula: [Postoperative CEA level (ng/ml)−preoperative CEA level (ng/ml)]/interval in months. The interval ranged from 1.0 to 4.2 months. The first CEA level available 30 days or more after surgery was considered for the slope calculation.

Of the patients who presented at the Cross Cancer Institute between January 1, 1976 and December 31, 1980 with Dukes stage B_2 or C colorectal cancer as part of an adjuvant therapy program, 181 were considered in this study: All of these 181 patients had a CEA determination shortly (1–3 wk) after surgical excision of the tumor as well as one determination every 3 months. A preoperative CEA level was also available in 93 of these 181 patients.

A base-line chest X-ray and liver scan were part of the patient's postoperative clinical evaluation. On successive clinic attendances, the chest X-ray and liver scan were repeated every 6 months and a double-contrast barium enema was obtained once a year.

ABBREVIATION USED: CEA=carcinoembryonic antigen.

[5] We gratefully acknowledge Hoffmann-La Roche Inc., Nutley, N.J., for providing financial assistance needed to complete this study.

Factors known to affect CEA values such as concomitant ulcerative colitis were considered in patient management. However, all 1,684 CEA levels obtained in patients who were at the time free of clinical and/or radiologic evidence of cancer have been included in our analysis.

To calculate the sensitivity and the specificity of the test as a screening method, we used the classical definitions (*13*). Sensitivity is the probability that the test will correctly identify a diseased person: It is equal to the number of persons diseased with a positive test divided by the number of all diseased. Specificity is the probability that the test will correctly identify a nondiseased person: It is equal to the number of persons nondiseased with a negative test divided by all the nondiseased who were screened.

TABLE 1.—*CEA levels measured at different times: Correlation with eventual disease progression*

TABLE 4.—*Distribution of false-positive CEA values in patients who remained free of disease*

Parameter	No. of patients	No. of tests
Single elevated value	27	27
Chronic alcoholism	2	15
Short follow-up	4	11
Unexplained	12	132
Total	45	185

RESULTS

The 181 patients with postsurgical follow-up ranging from 6 to 64 months included 115 patients with Dukes stage B_2 colorectal cancers and 66 patients with Dukes stage C colorectal cancers. Of these, 35 patients (12 with B_2 cancers and 23 with C cancers) developed disease progression.

CEA levels obtained before surgery ($n=93$), after surgery ($n=181$), or at any time the patient was considered free of disease ($n=1{,}684$) were correlated with eventual disease progression (table 1).

According to these results, the predictive value of CEA determinations in patients apparently free of disease measured either within 3 weeks of surgery for cure or at any time during their follow-up is much more specific when the limit between normal and elevated is set at 10 ng/ml. This was the level chosen to calculate the sensitivity and specificity of the test (table 2).

The slope between preoperative and postoperative CEA levels as described by Staab et al. (*7*) was positive (rising) in 38 patients and negative (decreasing) in 54 patients (table 3).

Table 1 shows that there were 105 instances of normal CEA values in patients who eventually showed disease progression ("false-negative" values). These 105 tests belonged to 25 of the 35 patients who had disease recurrence. Of these 25 patients, CEA values remained consistently low in 7 patients and these values account for 47 negative tests. If an arbitrary time lag of 3 months is chosen as the minimum useful time by which CEA level elevations should precede the clinical and/or radiologic evidence of disease progression, another 14 tests would also qualify as false-negative. Conversely, 54 normal tests that occurred in patients who remained free of disease for at least the following 3 months should no longer be so considered. This correction improves the sensitivity of the test to 62.8 from 45.0%.

Also according to table 4, there were 185 instances of elevated CEA (>10 ng/ml) occurring in 45 patients who remained free of disease (false-positive values). Table 4 shows that in 27 cases this was an isolated CEA value in a

TABLE 3.—*Analysis of slopes between preoperative and postoperative CEA values*

Parameter	CEA levels		Slope[a]

sequence of normal ones. Two patients (accounting for 15 determinations) were suffering from hepatocellular disease due to chronic alcoholism, and in 4 cases (11 determinations) the follow-up was under 1 year (table 4).

DISCUSSION

The controversy over the potential usefulness of CEA testing has caused enough concern to assemble a panel of experts to discuss the issue (*1*), and although the panel's conclusions were favorable to the continued use of CEA plasma levels to monitor colorectal cancer patients, their recommendations are not very specific in that area.

A preoperative CEA level is most useful when assessed in conjunction with the postoperative one: High preoperative values that remain high for over 3 months after resection for cure probably indicate more advanced disease at the time of surgery and should be taken into consideration along with the preoperative value alone when one is randomizing patients to treatment protocols (*3*).

The calculation of the slope between preoperative and postoperative CEA levels showed a tendency for CEA levels to fall in those patients who remained free of disease and to rise in those patients who developed disease progression. The more abrupt rises belong to those patients whose CEA remained elevated and whose disease may have been understaged at diagnosis.

When only those patients who are seemingly free of disease are considered and 10 ng/ml is set as the limit between normal and elevated CEA levels, any particular individual test proved to be highly specific and of acceptable sensitivity. Sequential tests further increased the specificity by avoiding the error introduced by a single elevated level. Other conditions known to affect CEA levels must also be considered.

CEA testing also fulfills the other criteria for a good screening test: 1) The probability of recurrence or metastases in B_2 and C colorectal cancer patients is high, making this group a high-risk population and well worth screening. 2) In many cases the recurrences or metastases are amenable to further surgical treatment (*15, 16*). 3) CEA determination is a noninvasive test well accepted by the patients. 4) The cost of a CEA determination is only a fraction of that of liver scans and barium enemas.

In conclusion, and when the limitations of all screening tests are considered, determination of individual CEA levels in patients apparently free of disease is useful, but improvement in sensitivity can be obtained when sequential tests are considered. However, and as with many other clinical laboratory tests, CEA levels in individual patients must be given a probabilistic interpretation.

A definite assessment of CEA as a screening test in postoperative patients with colorectal cancer can be the result only of a randomized prospective trial, since the CEA values tend to affect patient management. However, it is doubtful if such a trial would now be acceptable on ethical grounds.

Interaction of Familial and Hormonal Risk Factors for Breast Cancer[1]

Louise A. Brinton,[2,3] Robert Hoover,[2] *and* Joseph F. Fraumeni, Jr.[2]

ABSTRACT—A case–control study, conducted among participants in the Breast Cancer Detection Demonstration Project, obtained detailed information on family history of breast cancer and other risk factors from 1,362 breast cancer patients and 1,250 control subjects. An affected first-degree relative was reported by 22.4% of the patients and 12.2% of the control subjects. This finding was associated with a twofold increased risk of breast cancer, although greater elevations in risk were seen in younger study subjects and in those reporting both an affected mother and a sister. Analysis of other risk factors showed that, compared to women without a family history of breast cancer, control subjects with a family history of breast cancer tended to have early or late menarche, were older at first childbirth, and were younger at oophorectomy. In addition, the effect of family history on breast cancer risk was modified by age at menarche, but not by age at first birth or type of menopause. These findings suggest that familial susceptibility to breast cancer may be mediated through hormonal factors that operate early in a woman's life. A synergistic relationship was also observed between family history of breast cancer and the occurrence of multiple biopsies for benign breast disease, although the mechanisms for this relationship remain to be elucidated.—JNCI 1982; 69:817–822.

The familial aggregation of breast cancer has been well established (*1–7*). However, apart from examining differential effects according to age at diagnosis and/or menopause status (*8–12*), few studies have assessed the interaction of familial susceptibility with other risk factors for breast cancer. Bain et al. (*13*) examined family history in relation to a variety of risk factors and found the effects most pronounced in women with younger ages at disease onset and in those who had menstruated for more than 35 years. However, this study included few older women and was not able to assess fully the effects of family history according to cessation of menstrual function. An understanding of how hormonally related factors interact with familial occurrence is of particular interest, given the strong relationship of ovarian function to breast cancer risk (*14*) and laboratory evidence suggesting that familial predisposition to breast cancer is mediated through hormonal mechanisms (*15–18*).

With the use of data collected from participants in the BCDDP, we had the opportunity to evaluate family history of breast cancer as a risk indicator in the presence and absence of a variety of hormonally related risk factors. This population was particularly amenable to the study of the effects of familial factors on breast cancer risk, since a relatively large proportion of the women who volunteered for the program had a family history of breast cancer.

METHODS

Study subjects were selected from the BCDDP, a multicenter breast cancer-screening program involving over 280,000 women at 29 widely dispersed centers. This program, jointly sponsored by the American Cancer Society and the National Cancer Institute, recruited women between 1973 and 1975 for a 5-year program of annual breast examinations by combined modalities of physical examination, mammography, and thermography. The present investigation used the case–control approach, with cases consisting of participants at 28 of the centers whose breast cancer was detected during the period July 1973 to May 1977. Control subjects were selected from participants who had not received a recommendation for biopsy or a biopsy during the course of the screening. These control subjects were chosen to be comparable to the cases on the following factors: screening center, race (white, black, oriental, other), age (same 5-yr group), time of entry (same 6-mo period), and length of continuation in the program (controls had to have had at least as many years of screening as comparable cases).

Home interviews were conducted by nurse interviewers who had been standardly trained. Completed interviews were obtained from 1,375 controls (74.2% of eligible subjects) and 1,552 cases (86.1%). The lower response rate for controls than for cases was primarily due to the fact that controls had moved and were unavailable for interviews (12.9% controls vs. 5.0% cases unavailable) and to their more frequent refusals to be interviewed (10.5% controls vs. 4.6% cases). In addition, 2.4% of the controls and 4.3% of the cases had died, and interviews were not attempted with proxy respondents. Women who were interviewed, however, did not differ significantly from those not interviewed with regard to a number of factors determined for each woman at entry to the BCDDP—including age, race, family income, and history of surgery for benign breast disease.

The cases were interviewed at various intervals after diagnosis. However, in the analyses, exposure information was truncated at the time of diagnosis for cases or the equivalent period for controls. A number of women (60 cases and 11 controls) reported a history of breast cancer prior to entering the BCDDP and were excluded from the present analysis. We also restricted this analysis to white subjects (who comprised 91% of the entire study population). The final study group consisted of 1,362 cases and 1,250 controls.

The measure of association used for the evaluation of effects of an exposure factor is the RR, as estimated by the

odds ratio. Confounding variables were evaluated by stratified techniques, with maximum likelihood estimates of combined ratios and 95% CI derived (*19*). For multiple levels of exposure, significance was assessed with the use of a one-tailed linear trend test (*20*). For assessment of the effects of interactions of variables, factors were cross-tabulated and risks computed in relation to women who did not possess either factor (i.e., the referent group). Interactive effects of factors were further assessed with the use of a disease probability (prospective) logistic model (*21*), which entered family history as an independent factor (exposure variable) and the potential interactive factor as both an independent variable and an interaction term, i.e., as both a confounding variable and an effect modifier. These interactive factors, as well as other potential confounding variables, were considered to contribute significantly to the model if the absolute value of the *T*-statistic was greater than 1.96.

RESULTS

Risks associated with having various relatives affected with breast cancer are shown in table 1. A history of breast cancer in a first-degree relative (mother, sister, or daughter) was reported by 304 patients (22.4%) as compared to 152 controls (12.2%). This resulted in an RR of 2.1 (95% CI: 1.7–2.6). Of the cases, 170 (12.5%) reported a mother and 159 (11.7%) a sister with breast cancer. The RR associated with having a mother with breast cancer was 2.1 (1.6–2.8), whereas the RR associated with having an affected sister was 2.3 (1.7–3.1). The estimate associated with having an affected sister was not confounded by women with breast cancer having more sisters than those without cancer. A small proportion of cases (2.1%) reported having both a mother and a sister affected, a condition associated with an excessively high risk (5.8; 95% CI: 2.5–13.5).

Information was also collected on history of breast cancer in paternal and maternal grandmothers. A substantial proportion of the subjects were unable to recall such information (21.2% unknown response for question regarding paternal grandmother and 13.2% for maternal grandmother). An unknown response initially appeared to be associated with significantly elevated risks; however, adjustment for history of breast cancer in a first-degree relative abolished this association. Analysis of provided information revealed nonsignificant risks associated with having affected grandmothers. The risks were similar for either ancestral line, with the RR being 1.3 (0.7–2.5) for a positive history in a paternal grandmother and 1.4 (0.9–2.4) in a maternal grandmother.

TABLE 1.—*RR associated with history of breast cancer in various first- and second-degree relatives*[a]

Unknown	10	3	3.29	0.8–15.1

[a] Unknown responses with regard to breast cancer in the mother were excluded from the analysis.

[b] RR were adjusted by age at diagnosis of study subjects.

Information on first-degree relatives was further examined according to age at diagnosis of the study subjects. The highest RR occurred among women whose breast cancer was diagnosed before the age of 40 (table 2). For these women, the RR was 5.3 (1.4–20.5). This excess derived primarily from patients having an affected mother. However, risks were also elevated for younger women who reported a sister with breast cancer.

The relationship of a maternal history of breast cancer was examined further according to age at onset of the mothers' breast cancer and to whether or not the disease was bilateral. Risks were dichotomized according to whether the mothers' disease was detected before or after age 50, an age selected because of its approximate correspondence with the onset of menopause. As seen in table 3, the RR was 1.4 for women whose mothers' disease was diagnosed prior to the age of 50 and 2.1 for women whose mothers' disease had a later onset. However, significantly more cases than controls were unable to provide information on their mothers' age at onset of breast cancer. A similar pattern of risk emerged when data on bilaterality were examined. Women whose mothers' disease was bilateral demonstrated no excess RR (0.9), whereas a significant excess RR (2.3) was associated with unilateral disease in the mother. An unknown response to whether the mother's disease was bilateral or not was also associated with a nonsignificant increase in risk (3.3). These same patterns of risk were seen in relation to characteristics of the mothers' breast cancer when analysis considered age and menopause status of the study subjects.

For assessment of possible confounding effects, correlations of familial occurrence with other breast cancer risk factors were examined among the control subjects (table 4). This analysis demonstrated that women with a family history of breast cancer in a first-degree relative had a different distribution of age at menarche than women without a family history; i.e., women with a family history tended to have either early or late menarche. In addition, those with a family history had a significantly later age at first live birth than those without affected relatives, as well as an earlier age at oophorectomy when this procedure was performed. The variable of age at oophorectomy, however, did not differ significantly between women with and without a family history of breast cancer. Other factors, including age, parity, number of miscarriages, menopause status, number of previous breast biopsies, weight, height, oral contraceptive use, menopausal estrogen use, and family income or education, did not differ between women with a family history of breast cancer and those without such a history.

	≥14	89	58	1.34	0.9–2.0

[a] Unknown responses were excluded from the analysis.

[b] RR were adjusted by age at diagnosis of study subjects. χ_1 for linear trend: without family history=−2.23 (P=0.01) and with family history=−0.92 (P=0.18).

Because of the differences observed, risk estimates associated with having various relatives affected with breast cancer were adjusted for possible confounding effects of age at menarche, age at first live birth, and age at bilateral oophorectomy. Control for these factors did not substantially alter the risk estimates associated with a family history in any first-degree relative. In addition, use of multivariate models with simultaneous control for a number of factors did not alter the previously derived crude estimates associated with a family history of breast cancer or those associated with specific attributes of family history, such as bilaterality and young age at onset of mothers' breast cancer.

Further analysis pursued the effects of a family history in relation to the presence and absence of a variety of breast cancer risk factors.

Effects of varying ages at menarche according to the presence or absence of a family history of breast cancer are shown in table 5. There was a significant decreasing trend (P=0.01) in risk with increasing age at menarche among women without a family history. Although the lowest risk occurred in the oldest age at menarche grouping among those with a family history, there was no consistent or significant trend in the RR. In fact, prior to the last grouping, the RR actually increased with increasing ages at menarche.

In contrast to age at menarche, parity and age at first live birth showed similar effects in both the presence and absence of a family history of breast cancer (table 6). In both groups, there was evidence of increasing risk with later ages at first childbirth. For women without a history of breast cancer, the RR increased significantly (P<0.01) with increasing age at first birth. Women who delayed their first childbirth until 30 years of age or later showed a 2.7-fold increased risk compared to those who had their first child before the age of 20. Nulliparous women had risks similar to those who had their first childbirth between the ages of 25 and 29. (RR compared to RR of women with a live birth prior to age 20 were 1.8 and 2.0, respectively.) Among women with a family history of breast cancer, those with a birth after the age of 30 were at highest risk, five times (95% CI: 2.8–9.1) that of the referent group (women without a family history of breast cancer and who had their first childbirth prior to the age of 20).

Table 7 shows the RR associated with family history of breast cancer and history of biopsies for benign breast disease. Among those without a family history, risk increased slightly with the number of previous biopsies for benign breast disease. Those who reported two or more biopsies had a risk 1.5 times that of women without any previous biopsies. A similar increasing trend in risk with number of benign breast disease biopsies was seen for those with a family history of breast cancer. As compared to the referent group, those with a family history and no biopsies had a risk of 2.0, those with one biopsy had a risk of 2.3, and those with two or more biopsies had a risk of 5.6.

The examination of risks according to menopause status is presented in table 8. In this analysis, it was necessary to adjust estimates among the menopausal woman by age at menopause and by hormone usage, since these variables acted as negative confounders. Women with a family history of breast cancer who had undergone a bilateral oophorectomy demonstrated an RR of 1.8 compared to nonfamilial subjects with other types of menopause (the referent group). Risks among those with a family history were similar to those among the other menopause groups, with the RR being 2.6 for premenopausal subjects and 2.2 for those who retained their ovaries during surgical menopause. Women who had a bilateral oophorectomy but no family history of breast cancer were at a slightly lower risk (0.8) than those with other types of menopause.

TABLE 6.—*Breast cancer risk by history of breast cancer in a first-degree relative and age at first live birth*[a]

Family history of breast cancer	Age at first live birth, yr	Cases	Controls	RR[b]	95% CI
No	<20	78	132	1.00	—

TABLE 8.—*Breast cancer risk by history of breast cancer in a first-degree relative and menopause status*[a]

Family history of breast cancer	Menopause status	Cases	Controls	RR[b]	95% CI
No	Ovaries retained	539	583	1.00	—
	Ovaries removed	115	152	0.81	0.6–1.1
	Premenopausal	371	338	1.30	0.9–1.7
Yes	Ovaries retained	165	84	2.15	1.6–2.8
	Ovaries removed	43	24	1.90	1.1–3.2
	Premenopausal	87	41	2.62	1.7–4.0

[a] Unknowa responses were excluded from the analysis.

[b] RR for premenopausal women were adjusted by age at diagnosis of study subjects; RR for menopausal women were adjusted by age at menopause and menopausal hormone usage.

Logistic analyses were also conducted to examine interactive effects of family history with other breast cancer risk factors. These analyses, which controlled for the influence of confounding variables on interactive effects, showed findings in close concordance with stratified analyses, i.e., no clear interaction with age at first live birth or menopause status, but an interaction of family history with multiple previous benign breast disease biopsies (RR=4.0). In addition, differential effects of age at menarche were seen according to the presence or absence of a family history of breast cancer.

DISCUSSION

In this study, we found that women who reported to have either a mother or a sister with breast cancer experienced approximately a twofold excess risk of breast cancer, an estimate that agrees with estimates given in previous reports (*2, 10–13*). Our estimates are somewhat lower than those previously derived in a study of BCDDP participants (*22*), possibly as a result of different data collection techniques (mailed questionnaire in previous study vs. home interview in this study). In the present investigation, women who reported both a mother and a sister with breast cancer had an especially high risk, and the effects of family history were greatest for women under age 40 at diagnosis. These findings are also consistent with previous observations (*9, 10, 13*). Women whose mothers had bilateral disease and/or disease at premenopausal ages were not at high risk, a finding for which we have no ready explanation. Our findings may be influenced by the higher proportion of cases than controls who were unable to provide information on the bilaterality of their mothers' breast cancer or on the age of their mothers at diagnosis.

The analysis of interactions between family history of breast cancer and other breast cancer risk factors seemed to be a useful approach toward the understanding of the mechanisms of breast carcinogenesis, since those factors that modify the effects of family history may act through common pathways. Also, since family history is likely to reflect genetic determinants, whereas other factors arise at different times in a woman's life, there was a potential for discernment of periods when familial effects tend to operate.

We observed no modification of the effects of parity, age at first live birth, or age at oophorectomy according to the presence of a family history of breast cancer. For all of these factors, effects among women with a family history were those that would have been predicted on a basis of additivity of RR; i.e., there was no evidence of any multiplicative effects or synergy. For example, additivity would have predicted that women with bilateral oophorectomy and a family history of breast cancer would exhibit a risk approximately 96% greater than that of other menopausal women without a family history; in fact, we actually observed a 90% elevation in risk. However, the effect of age at menarche seemed to be modified by a family history of breast cancer. Among women without a family history, we observed a significant linear trend of decreasing risk with increasing age at menarche, a result consistent with the pattern generally seen in studies that have examined menarche effects without reference to family history (*14*, *23*). This effect, however, was not observed in the presence of a family history. Although this difference could be due to chance, we think it may reflect some biologic interaction, since there was some evidence that risk actually rose with increasing age at menarche up to age 14.

Taken together, our findings suggest that the familial predisposition to breast cancer exerts an influence early in a woman's life. This speculation is based on the observation that familial effects were not modified by age at first live birth or oophorectomy but were modified by age at menarche. In addition, we believe that the effect is probably mediated through a hormonal mechanism, rather than a structural defect in breast tissue. This impression is supported by the observation that control subjects with a family history of breast cancer tended to have early or late menarche, a late first childbirth and a young age at oophorectomy compared to controls without such a family history.

Laboratory studies of high-risk women support the notion that familial predisposition may be mediated through hormonal mechanisms in early reproductive life. Alterations of hormonal profiles have been described among daughters (*24-26*) and among younger rather than older sisters (*27*) of women with breast cancer. This idea is also consistent with the view that breast cancer risk factors can operate at different periods in women's lives (*14*)—in this case, early in reproductive life rather than later in life.

Of special interest was the interaction observed between a history of surgery for benign breast disease and familial occurrence of breast cancer. Among women with and without a family history of breast cancer, a history of only one biopsy was a weak risk indicator; this is consistent with a previous study of BCDDP participants and may reflect the self-selection of women into this screening program (*22*). Women with two or more biopsies, however, were at excess risk: Those without a family history exhibited a 1.5-fold excess risk, whereas those with a family history had a risk of 5.6. The RR of 5.6 is greater than the product achieved by the multiplication of the RR of the individual risk factors: family history in the absence of breast surgery (2.0) and multiple biopsies in the absence of family history (1.5). This synergy seems to imply a common mechanistic pathway of carcinogenesis involved with a family history of breast cancer and with multiple surgeries for benign breast disease.

Thus we conclude that the familial excess of breast cancer is established by early adolescence and is uninfluenced by protective factors introduced later. In addition, although more speculative, the evidence also seems to imply that these familial effects are mediated through a hormonal mechanism. Although there is previous support for this hypothesis, further studies are needed that specifically address the issue. Further assessment and elucidation of mechanisms are also needed for the synergy that we observed between a family history of breast cancer and the occurrence of multiple benign breast disease biopsies.

Imaging of Human Melanoma Xenografts in Nude Mice With a Radiolabeled Monoclonal Antibody[1,2,3]

Tarun Ghose,[4] Soldano Ferrone,[5] Kohzoh Imai,[5] Stevens T. Norvell, Jr.,[6] Steven J. Luner,[4] Robert H. Martin,[7] *and* A. Huntley Blair[8,9]

ABSTRACT—External photoscanning with display of radioactivity data as a color-scaled image detected xenografts of human melanoma in male nude inbred mice of BALB/c background 48 hours after injection of ^{131}I-labeled monoclonal IgG 225.28S that is specific for human melanoma. A ^{131}I-labeled polyclonal goat IgG against human melanoma-associated antigens could also image the tumor, but with this preparation there was considerable localization of radioactivity in normal tissues, resulting in less satisfactory tumor definition. Labeled normal mouse IgG did not image the melanoma grafts. Assay of radioactivity in tissues of melanoma-grafted mice confirmed tumor-specific localization of the antimelanoma antibodies. The tumor:blood ratio of radioactivity was 6.55 with the monoclonal antimelanoma IgG and 0.45 with the polyclonal IgG.—JNCI 1981; 69:823–826.

We have successfully imaged several mouse and human tumors including human malignant melanomas and renal cell carcinomas by using ^{131}I-labeled polyclonal IgG from rabbit and goat antisera rendered specific against tumor-associated antigens by repeated absorptions with appropriate normal tissues (*1–5*). There is considerable loss of specific antibodies during absorptions, and a proportion of immunoglobulins without tumor specificity persists in absorbed antisera and even in the IgG fraction therefrom after its further purification by affinity techniques (*6–8*). Radiolabeled non-tumor-specific IgG molecules in imaging preparations contribute to high background activity that obscures small lesions and lesions with low uptake of the agent. One approach to overcoming this problem has been the application of subtraction methodology, i.e., injection of radiolabeled non-tumor-specific serum proteins (or other radiopharmaceuticals that measure blood volume) and then subtraction of the radioactivity contributed by the nonspecific agent from that of the specific antibody (*8*). However, it should be possible to substantially overcome this limitation of polyclonal antibody by use of the monoclonal antibodies against membrane-associated antigen(s), since such antibodies are homogeneous and can be obtained free from contaminating nonspecific immunoglobulin molecules (*9*). In this study we have investigated the monoclonal antibody 225.28S against human melanoma-associated antigens for imaging xenografts of human melanoma in nude mice and have compared its efficiency with that of a polyclonal antimelanoma IgG preparation derived from immune goat serum rendered specific by repeated absorptions with normal human tissues (*10, 11*).

MATERIALS AND METHODS

Tumors and cell lines.—For localization studies, the human melanoma cell line M1, obtained from Dr. P. B. Dent, McMaster University, Hamilton, Ontario, Canada, was xenografted sc (10^6 cells/mouse) into the flank of 8-week-old male nude inbred mice of BALB/c background (Harlan Sprague-Dawley, Inc., Madison, Wis.). The tumors were 1.8–2 cm in diameter at the commencement of scanning. Five other human melanoma cell lines, 4 human renal adenocarcinoma lines, HeLa cells, and human foreskin fibroblasts were maintained in RPMI-1640 supplemented with 10% fetal calf serum.

Monoclonal antibody 225.28S and goat anti-human melanoma sera.—The monoclonal antibody 225.28S, an IgG2a, is secreted by a hybridoma constructed with splenocytes from a BALB/c mouse immunized with cultured human melanoma M21 cells. Testing of this antibody with a large variety of tumor cell lines and of surgically removed normal and malignant tissues by ourselves and several other investigators (*12*) has shown that this antibody recognizes a determinant preferentially expressed on melanoma and nevi cells (*13*).

Details of production and serologic analysis of the specificity of goat anti-human melanoma IgG have been described elsewhere (*10, 11*). Viable malignant melanoma cells, 4×10^6, from fresh, surgically excised specimens, mixed with 2 ml of Freund's complete adjuvant (Difco Laboratories, Detroit, Mich.) were injected im into adult goats. Eleven subsequent injections of tumor cells were given without Freund's adjuvant. Immune sera were heat inactivated and repeatedly absorbed with group AB, Rh^+ red blood cells and homogenates of normal human liver, lung, kidney, and spleen. The absorptions were repeated until the sera would react only with the immunizing melanoma cells and not with the patient's normal skin fibroblasts, peripheral blood lymphocytes, or other normal adult human tissues. These xenogeneic antimelanoma sera have been shown to

cross-react with surface and cytoplasmic antigens of melanoma cells from several patients (*10*).

Immunofluorescence assay.—Cytoplasmic immunofluorescence was performed either on 5-μm cryostat sections of snap-frozen (−176°C) human and mouse tissues or on smears of acetone-fixed tumor cells. The sandwich method with rabbit antigoat 7S globulin or rabbit antimouse 7S globulin both labeled with fluorescein was used with appropriate controls. Membrane immunofluorescence was performed on viable cells with appropriate conjugate and normal serum controls (*10, 11*).

^{125}I-labeled protein A assay.—Aliquots of 5×10^5 melanoma cells, human neonatal fibroblasts or HeLa cells, were first incubated with 250 μg of monoclonal IgG for 30 minutes at 37°C, washed with PBS, and then incubated with ^{125}I-labeled protein A (21,000 cpm; New England Nuclear Corp., Boston, Mass.). For blocking experiments, suspensions of melanoma cells were first exposed to 250 μg, 500 μg, 1 mg, or 2 mg of goat antimelanoma IgG (which does not bind protein A) and then sequentially to 250 μg monoclonal IgG and ^{125}I-labeled protein A.

Preparation of labeled immunoglobulins, scanning, and assay of radioactivity.—We obtained NMG and goat IgG fractions by using protein A Sepharose and Sephadex G200 [Pharmacia (Canada) Ltd., Dorval, Quebec] chromatography, respectively. We labeled monoclonal IgG 225.28S, goat antimelanoma IgG, and NMG with carrier-free and reductant-free ^{131}I (New England Nuclear Corp.) by the chloramine T method (*14*) to yield approximately 1 μCi of ^{131}I bound to 3 μg of each IgG. The same method was used to bind 1 μCi ^{125}I (New England Nuclear Corp.) to 15 μg NMG.

For scanning experiments, melanoma-bearing mice in groups of 4 were each given iv injections of 150 μg (50 μCi) of ^{131}I-labeled monoclonal antimelanoma IgG, goat antimelanoma IgG, or NMG. For paired label studies, animals received injections of a mixture containing 150 μg each of ^{131}I-labeled monoclonal IgG and ^{125}I-labeled NMG. In all cases, mice were given Lugol's iodine in drinking water, starting 3 days before administration of the scanning agent. Animals under sodium pentobarbital anesthesia (35 mg/kg, ip) were scanned every 24 hours with a Nuclear Chicago Pho-Dot rectilinear scanner and a large-field-of-view scintillation camera interfaced to a PDP 11/34 computer.

For assay of radioactivity in tissues, groups of 3 melanoma-bearing mice were killed 6 days after iv injections of 150 μg of ^{131}I-labeled monoclonal antimelanoma IgG, goat antimelanoma IgG, or NMG. A 0.5-ml sample of blood was obtained by cardiac puncture from each anesthetized mouse. The axillary vessels were then severed and blood was flushed out of the organs by injection of 50 ml of warm PBS into the heart (*5*). Aliquots of tissue were washed in PBS, blotted dry, weighed, and individually digested in concentrated sulfuric acid. We determined radioactivity in duplicate aliquots by using at least 2 different dilutions of each tissue digest. In analysis of tissues from the mice given both ^{131}I- and ^{125}I-labeled IgG, appropriate windows were used for separate assays of ^{131}I and ^{125}I activities, corrections being made for the counts contributed by ^{125}I to the ^{131}I window. We assayed ^{125}I activity in these digests after allowing ^{131}I activity to decay for 50 days (≈6 half-lives).

RESULTS

Establishment of Antibody Specificity by Immunofluorescence Assay

The monoclonal IgG 225.28S and goat anti-human melanoma IgG reacted on indirect immunofluorescence with 5 human melanoma lines in long-term culture and with viable melanoma cells isolated from biopsy specimens obtained from 8 patients. Both types of antibodies were shown not to react with murine melanoma B16 cells, peripheral blood lymphocytes from melanoma patients, human neonatal foreskin fibroblasts, HeLa cells, four human renal carcinoma cell lines in long-term culture, and cryostat sections of the following adult humans tissues: skin, breast, brain, lung, liver, pancreas, large and small intestines, spleen, heart, kidney, bladder, and prostate glands.

Antibody Specificity by ^{125}I-Labeled Protein A Assay

Melanoma cells, exposed first to the monoclonal IgG and then to ^{125}I-labeled protein A, bound 30% of the protein A activity, whereas similarly exposed HeLa cells and human neonatal fibroblasts bound 10% of the protein A activity. The goat antimelanoma IgG or sera from mice bearing grafts of human melanoma did not interfere with the binding of monoclonal IgG to the M1 melanoma cells.

Scanning and Assay of Radioactivity

External scanning at 48 hours visualized the melanoma grafts in all tumor-bearing mice given either the labeled monoclonal IgG or goat antimelanoma IgG, particularly when scintigraphic data were displayed as linear color-scaled television images (fig. 1). Tumors were less distinct in the mice given ^{131}I-labeled goat antimelanoma IgG than in mice given monoclonal antimelanoma IgG, a finding consistent with the lower tumor:blood ratio of radioactivity in the former group (table 1). Tumors could not be visualized in the mice given ^{131}I-labeled NMG. Scanning at 24 hours after administration of ^{131}I-labeled 225.28S IgG showed substantial amounts of radioactivity in the thoracic cavity, liver, and spleen, resulting in variable tumor delineation from mouse to mouse at this time.

The results of assay of radioactivity in tissues of mice killed 6 days after injection of radiolabeled antibodies and NMG are presented in table 1. The mice given ^{131}I-labeled monoclonal antimelanoma IgG showed higher localization of radioactivity in the tumor than in all other tissues including blood (tumor:blood ratio=6.55). Animals given the goat polyclonal antimelanoma IgG showed higher localization in the tumor than in all other tissues except blood (tumor:blood ratio=0.45). Administration of ^{131}I-labeled NMG led to uniformly lower tumor:nontumor tissue ratios of radioactivity than those obtained with either ^{131}I-labeled monoclonal or polyclonal antimelanoma IgG. However, even NMG showed more localization in tumor than in normal tissues, with the exceptions of liver and blood.

In a separate experiment, melanoma-bearing mice were given a mixture of ^{131}I-labeled monoclonal antimelanoma IgG and ^{125}I-labeled NMG. Tumor:blood ratios of radioac-

TABLE 1.—*Melanoma:mouse tissue ratios of radioactivity in xenografted nude mice 6 days after injection of* ^{131}*I-labeled IgG*[a]

Tissue	Monoclonal IgG2a 225.28S against melanoma-associated antigen	Goat polyclonal anti-human melanoma IgG	NMG
Normal muscle adjacent to tumor	7.20	6.22	4.27
Heart muscle	13.54	9.69	3.89

[a] Human melanoma-bearing nude mice weighing 18–22 g received iv injections of 50 μCi ^{131}I bound to 150 μg monoclonal anti-human melanoma IgG, goat anti-human melanoma IgG, or NMG. Each group contained 3 mice that were killed 6 days after receiving labeled IgG. Tumor weight at killing varied from 1.2 to 1.6 g. Ratios were calculated as follows: (μCi/g tumor tissue)/(μCi/g specified tissue).

tivity (2 mice/group) at 24 hours were 0.32 for ^{131}I and 0.28 for ^{125}I; at 48 hours the respective ratios were 1.2 and 0.3. Thus at 48 hours ^{131}I accumulated to a greater extent in tumor tissue than in blood but ^{125}I failed to do so.

DISCUSSION

This study shows for the first time that radiolabeled monoclonal antibody 225.28S against a human melanoma-associated antigen can efficiently image melanoma grafts in nude mice. Although goat antimelanoma IgG also imaged these grafts as expected, the tumor:blood ratio of radioactivity was much lower with this polyclonal antibody. The failure of the goat antimelanoma IgG to block binding of the monoclonal IgG to M1 melanoma cells suggests that these two antibodies have different antigenic specificities. However, since the polyclonal preparation is likely to include multiple specificities, the presence in it of a small amount of IgG directed toward the same determinant as the monoclonal IgG cannot be ruled out.

Table 1 shows that all tumor:normal tissue ratios (radioactivity per gram of tumor tissue/radioactivity per gram of normal tissue) for both antibodies were greater than the corresponding ratios of NMG. A comparison between the groups given monoclonal and polyclonal antibodies shows that the tumor:blood ratio of ^{131}I activity achieved with the polyclonal IgG was fifteenfold lower than the corresponding ratio for monoclonal IgG even though the goat IgG as a foreign protein would be expected to have the shorter half-life in the circulation. Furthermore, the tumor:normal tissue ratios of localization of the monoclonal IgG were generally greater than those of the polyclonal IgG, the chief exception being the greater amounts of ^{131}I activity in kidneys of mice given the monoclonal IgG (table 1). These differences may reflect greater serum clearance of non-tumor-bound ^{131}I through the kidneys in mice given the labeled monoclonal IgG. It is unlikely that rapid clearance resulted from formation of immune complexes, since antigens reacting with the monoclonal antibody could not be detected in sera of human melanoma-bearing nude mice. Evidence suggests that the slow clearance of labeled polyclonal IgG rendered tumor-specific solely by absorptions with normal tissues may reflect the persistence in these preparations of contaminating antibodies that cross-react and bind to normal mouse tissues (more radioactivity being found in muscle, lungs, and bone marrow of mice given ^{131}I-labeled polyclonal goat globulin than in the same organs of mice given ^{131}I-labeled NMG). The tumor:normal tissue radioactivity ratios after injection of polyclonal antimelanoma IgG were lower than those after injection of the monoclonal IgG. Also, previous studies (*5*) have shown that further purification of normal tissue absorbed polyclonal antitumor IgG by absorption and elution with the use of glutaraldehyde-fixed tumor cells reduces localization in normal tissues and accelerates the serum clearance of these purified IgG preparations. Contaminating antibodies (against normal tissue components) in amounts not manifestly toxic can give rise to background radioactivity in nonneoplastic tissues after systemic administration of preparations that have been radiolabeled. When such antibody preparations are used as carriers of cytotoxic drugs, these amounts of antinormal tissue antibodies may contribute to the systemic toxicity of conjugates (*15*).

The tumor:normal tissue and tumor:blood ratios of radioactivity were higher for both antimelanoma IgG preparations than for NMG. Results at 48 hours of the paired labeled experiment comparing monoclonal antimelanoma IgG and NMG also demonstrated the increased tumor-localizing potential of the monoclonal antimelanoma IgG. These findings are in keeping with the observation that only labeled antibody preparations could produce sufficient contrast for successful imaging. Thus the presence of specific antimelanoma antibody was clearly essential for imaging, but imaging may well have been aided by nonspecific tumor localization of radioiodinated immunoglobulin that was not bound to target tumor antigen. Increased localization of normal serum proteins in tumor tissue has been reported before by our laboratory (*16*) and by Peterson (*17*).

The best image was provided by the monoclonal IgG at all scanning times, and this finding correlates with the observed tumor:normal tissue radioactivity ratios. The tumor:adjacent muscle ratio was somewhat higher for the monoclonal IgG than for the polyclonal IgG, but the most dramatic difference between these two was observed on comparison of tumor:blood ratios. A ratio of 6.55 was obtained for the monoclonal IgG but only 0.45 for the polyclonal IgG and 0.35 for NMG, showing the importance of elimination of irrelevant IgG molecules. Before this report, in vivo preferential localization of injected monoclonal antibodies in target antigen-bearing normal tissues or tumor tissues was reported by several groups (*9, 18–20*). High tumor:blood ratios of localization, comparable to those we observed in melanoma-grafted mice given the monoclonal IgG, were seen after injections of radioiodine-labeled monoclonal antitumor antibody in MH15 teratocarcinoma-bearing BALB/c mice (*9*) and in immunosuppressed CBA mice bearing a human teratocarcinoma (*20*). Monoclonal antibodies against tumor-associated antigens may thus provide us with specific carriers for radioimmunodetection of primary and metastatic cancers.

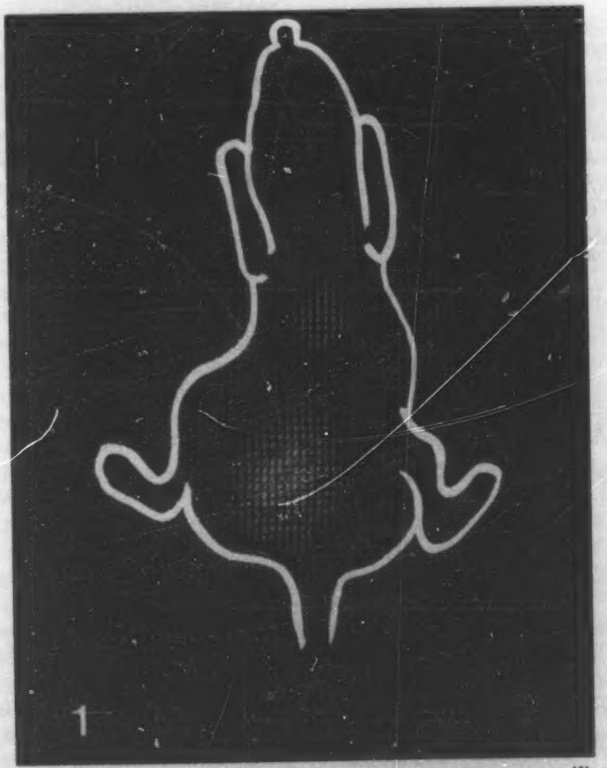

Figure 1.—Scintiscan of a human melanoma xenograft-bearing nude mouse 48 hr after iv injection of 50 μCi ^{131}I bound to 150 μg monoclonal anti-human melanoma IgG. The mouse was scanned with a large-field-of-view scintillation camera interfaced to a PDP 11/34 computer. The scan of ^{131}I distribution was obtained at 364 KeV with a 20% window, stored in the computer, and then displayed in a linear color scale from dark blue (lowest activity) to white (highest activity). Localization of radioactivity in excess of the background can be seen in the melanoma.

Functional Properties of Human Thymoma Lymphocytes: Role of Subcellular Factors in Blastic Activation[1,2]

Piero Musiani,[3] Libero Lauriola,[3] Nicola Maggiano,[3] Pietro Tonali,[4] *and* **Mauro Piantelli[3,5]**

ABSTRACT—The proliferative responses to phytohemagglutinin and the role of subcellular factors in the modulation of blastogenesis of thymoma lymphocytes from 5 thymoma patients were investigated. The addition of exogenous interleukin 1, a macrophage product, strongly augmented the blastic transformation of cultured thymocytes from both normal and neoplastic glands by influencing the production of interleukin 2 (IL-2) by a well-defined T-cell subset. The magnitudes of the blastic responses were ultimately modulated by the amount of IL-2 released in culture. The higher proliferative responses exhibited by thymocytes from thymoma were effectively sustained by a higher production of IL-2 in culture. In addition to having distinctive surface membrane receptors in common with normal thymocytes, thymoma lymphocytes were also under the influence of the same subcellular factors involved in T-cell blastic activation as thymocytes. These observations imply the presence of functionally distinct subpopulations in the thymoma lymphocyte component and add arguments in favor of their nonneoplastic nature.—JNCI 1982; 69:827–831.

Human thymomas are neoplasms composed of a mixture of thymic epithelial cells and lymphocytes, with a variation in the relative proportions from case to case and within different areas of the same tumor. The epithelial cells of thymomas display morphologic and biologic properties of neoplastic cells (*1*), whereas the morphologic and the biologic properties of thymoma lymphocytes do not suggest their neoplastic origin. The precise nature, role, and functional attributes of the lymphocytic component of thymomas remain undefined.

In previous papers we have pointed out some immunologic similarities between lymphocytes from both the neoplastic and the normal thymus (*2, 3*). In the normal human thymus, various lymphocyte subpopulations have been identified and separated on the basis of their different expression of surface membrane receptors. The majority of thymocytes from the normal thymus exhibit receptors for PNA. These PNA$^+$ cells (mainly cortical thymocytes) respond poorly to phytohemagglutinin and when tested in mixed lymphocyte culture, whereas the minor PNA$^-$ subset (mainly composed of medullary thymocytes) responds to both stimuli (*4*). Lymphocytes from thymomas with moderate or predominant lymphocytic infiltrate exhibited surface membrane receptors at numbers close to those found in the normal thymus. Furthermore, in our experiments lymphocytes from thymomas with scant lymphocyte components showed surface membrane receptors and displayed proliferative responses to phytohemagglutinin comparable to those of the more mature pool of normal medullary thymocytes (*2, 3*).

Recent studies on T-lymphocytes activation by mitogens or antigens in both experimental animals and humans have demonstrated a monocyte dependence for optimal initial mitogenesis (*5–10*). It has been postulated that monocytes exert their effect, at least in part, through the production of IL-1 (*11*) which facilitates the release of IL-2 by a T-cell subset (*12–14*). IL-2 is the obligatory modulator of T-cell blastic activation (*15*).

In the present paper we describe the study of the proliferative responses of thymoma lymphocytes to phytohemagglutinin and the role of the interleukins in the modulation of their blastogenesis. Our data indicate that thymoma lymphocytes are characterized by a distinctive surface receptor pattern similar to that of normal thymocytes. Moreover, thymoma lymphocytes are under the influence of the same subcellular factors that are involved in the blastic activation of both normal thymocytes and peripheral lymphocytes. This implies the presence of functionally distinct subpopulations in thymoma lymphocyte suspensions and argues in favor of their nonneoplastic origin.

MATERIALS AND METHODS

Thymocyte preparation.—Cell suspensions were prepared of neoplastic tissue from 5 thymoma patients with myasthenia gravis and of normal tissue from 10 children, 4 months to 7 years old, undergoing open-heart surgery. The tissues were gently teased and washed three times in Hanks' balanced salt solution. The cells were more than 95% viable as assessed by trypan blue exclusion. Monocytes within the thymic cell suspensions were assessed by nonspecific esterase staining (*16*). Tissue specimens taken for light microscopic examination were classified according to the shape of the epithelial cells, i.e., round-oval, spindle, or mixed, and the degree of lymphocytic infiltration, i.e., absent, scant, moderate, or predominant as suggested by Rosai and Levine (*1*). Tumors were also divided into two major categories, invasive and noninvasive, on the basis of the surgical and gross findings (*1*).

ABBREVIATIONS USED: E$_N$-RFC=E-neuraminidase rosette-forming cell(s); FCS=fetal calf serum; FITC=fluorescein isothiocyanate; $[^3H]$dThd=tritiated thymidine; IL-1=interleukin 1; IL-2=interleukin 2; PNA=peanut agglutinin; PNA$^-$=PNA-negative; PNA$^+$=PNA-positive; SmIg$^+$ cells=surface membrane immunoglobulin-bearing cells; T$_G$=T-cell(s) with receptors for the Fc portion of IgG; T$_M$=T-cell(s) with receptors for the Fc portion of IgM.

Separation of thymocyte subpopulations by PNA agglutination.—PNA was purified from fresh, unpeeled, shelled peanuts with the use of a sialic acid-less fetuin–Sepharose column (*17*). The thymocyte suspensions were separated in PNA$^+$ and PNA$^-$ subsets by the agglutination technique reported by Reisner et al. (*4*). The agglutinated cells were virtually all (>97%) FITC-PNA$^+$; however, the nonagglutinated fraction contained about one-third of weakly FITC–PNA$^+$ cells.

Detection of surface membrane markers.—We determined E$_N$-RFC in lymphocyte suspension as reported earlier (*2*) and scored SmIg$^+$ cells by a direct immunofluorescence test, as described by us previously (*18*). To detect the presence of T$_G$ and T$_M$, we cultured thymocytes for 24 hours in medium 199 (Gibco Bio-Cult Ltd., Paisley, Scotland) with 20% selected FCS in a humidified incubator with 5% CO_2 according to the procedure reported by Moretta et al. (*19*). We counted T$_G$ and T$_M$ after rosetting thymocytes with ox erythrocytes coated with purified rabbit IgG or IgM antibodies. Detailed descriptions of the procedures used were reported by us elsewhere (*20*). For FITC–PNA binding assay, we incubated thymocytes (0.1 ml, 3×10^6 cells) with FITC–PNA (0.1 ml, 350 μg/ml) for 20 minutes at room temperature.

Preparation of IL-1.—IL-1 was obtained following the procedure reported by Blyden and Handschumacher (*21*). IL-1-containing supernatants demonstrated an augmenting activity on lectin-stimulated thymocyte blastogenesis. In our culture conditions IL-1 dilutions capable of sustaining maximal blastogenic responses ranged between 1:5 and 1:10. Detectable activity was still found in most of these supernatants even at 1:160 dilutions. We screened all IL-1 preparations for IL-2 activity as described below and found them to be negative.

Preparation of conditioned medium containing IL-2.—We prepared IL-2-containing supernatants from peripheral blood lymphocytes from single donors or from thymocytes from both neoplastic and normal thymus tissues. We incubated peripheral blood lymphocytes or thymocytes at 37°C in RPMI-1640 medium with 3% FCS. Phytohemagglutinin was added to the culture at 0.5 μg/ml for peripheral blood lymphocyte culture and 5 μg/ml for thymocyte culture. After 48 hours, cells were removed by centrifugation at 400×*g* for 10 minutes.

Quantitative microtiter-well assay for IL-2 activity.—We assayed IL-2 activity according to the procedure described by Bonnard et al. (*22*) with minor modifications. Sensitized cells from 7-day primary one-way-mixed lymphocyte culture were resuspended at 5×10^5 cells/ml in RPMI-1640 and 10% FCS, with 10–25% of IL-2-containing conditioned medium. By day 3 or 4, the cultured T-cells reached 10^6/ml and were fed by dilution with fresh medium to 5×10^5/ml. Every 3 days thereafter, the cells were split in a similar manner. Serial 1:3 dilutions of various preparations of conditioned media were assayed for ability to stimulate proliferation of third passage (≈14-day-old) cultured T-cells (10^6) during 3 days of incubation in microtiter wells. The degree of proliferative activity was measured by incorporation of [^{3}H]dThd added during the last 4 hours of culture (sp act, 5 Ci/mmol; Amersham International Ltd., Amersham, England). As a control, 0.5 μg phytohemagglutinin/ml was also used in all experiments. Cultured T-cells were only weakly stimulated by the phytomitogen. The observed proliferative responses represent a quantitative measure of IL-2 in a given supernatant. By determination of the dilutions of supernatants needed to produce a similar stimulatory effect, it was possible to estimate graphically the relative IL-2 activities of various supernatants. An excellent correlation has been reported between the results of the assays in microtiter plates and the abilities of the various conditioned media to promote actual T-cell growth (*22*).

Thymocyte responses to mitogen.—Cell response to phytohemagglutinin was determined as previously reported (*2, 3*) with some modifications. We suspended unfractionated, PNA$^+$ and PNA$^-$ thymocytes in RPMI-1640 medium, supplemented with 10% heat-inactivated FCS. Cultures were established in flat-bottomed microtiter plates (MicroTest II, Falcon 3040; Falcon Plastics, Oxnard, Calif.) in triplicate and consisted of 0.2 ml of culture medium containing thymocytes at concentrations ranging from 5×10^5 to 2×10^6 cells/ml. Phytohemagglutinin at 5 μg/ml end concentration was added to each well. Cultures were incubated for 84 hours in a humidified environment that contained 5% CO_2; for the last 16 hours of the culture period, 0.5 μCi of [^{3}H]-dThd was added to each culture well. The cultures were then harvested for scintillation spectrometery.

RESULTS

The morphologic features of the neoplastic epithelial cells, the proportion of lymphocytes in the neoplastic tissue, and the invasiveness of each tumor are reported in table 1. The contamination of the cell suspensions with peripheral blood mononuclear cells was negligible as assessed according to Galili and Schlesinger (*23*). The percentages of E$_N$-RFC, SmIg$^+$ cells, FITC–PNA$^+$, T$_M$, and T$_G$ and the mean values plus or minus standard deviation for the control thymuses are reported in table 2.

The great majority of the lymphocytes from thymomas with abundant lymphocytic components, as well as from normal thymus, showed surface membrane receptors for PNA. Alternatively, lower numbers of PNA$^+$ cells were observed in the lymphocyte population from thymomas with a low lymphocyte-to-epithelial cell ratio.

T$_G$ were absent or very exiguous in all thymocyte suspensions. Moreover, the percentage of T$_M$ lymphocytes present in thymomas with scant lymphocytic component substantially exceeded the percentages exhibited by both the normal

TABLE 1.—*Histologic appearance and invasiveness of thymomas from 5 patients*

Patient	Age, yr	Sex	Shape of neoplastic epithelial cells	Degree of lymphocytic infiltration	Invasiveness
#1	57	♂	Round–oval	Predominant	Not invasive
#2	44	♀	Round–oval	Predominant	Invasive
#3	55	♀	Round–oval	Moderate	Not invasive
#4	59	♀	Spindle	Scant	Not invasive
#5	54	♂	Round–oval	Scant	Invasive

TABLE 2.—*Percentages of lymphocyte subpopulations in 5 thymomas and in 10 normal thymuses*[a]

Thymoma patient	E_{ox}-RFC, %	SmIg$^+$ cells, %	FITC-PNA$^+$ cells, %	T_M, %	T_G, %
#1	98	0	75	28	0
#2	96	1	63	33	0
#3	98	1	69	32	1
#4	95	1	34	49	0
#5	92	2	21	56	2
10 control patients	98.0±2.1	<1	79.1±4.9	24.8±4.2	<1

thymus and thymomas with predominant or moderate lymphocytic component. These findings are in accord with those previously reported by us (*3*).

Results concerning the proliferative responses of unfractionated, PNA$^+$, and PNA$^-$ thymocytes from both normal thymus and thymomas are shown in text-figure 1. Thymoma lymphocytes exhibit higher proliferative responses than their normal counterparts. For increasing cell concentrations up to 2×10^6/ml, [^{3}H]dThd incorporation per cell strongly increases in all preparations. The differences in mitogen responsiveness between lymphocytes from normal and neoplastic thymuses evident at low cell densities become more prominent at higher cell concentrations. At any cellular concentration the highest responses are exhibited by PNA$^-$ fractions, whereas PNA$^+$ cells are always unresponsive whether the lymphocytes are from normal or from neoplastic glands. It is significant that lymphocyte preparations from thymomas with predominant epithelial components not only show the highest percentages of PNA$^-$ cells (table 2) but also exhibit the highest proliferative response to phytohemagglutinin (text-fig. 1).

Because of the essential role of macrophages and their product IL-1 in the initiation of T-cell blastic activation, we evaluated the effect of IL-1 on the thymocyte mitogenic responses. Addition of IL-1-containing medium strongly

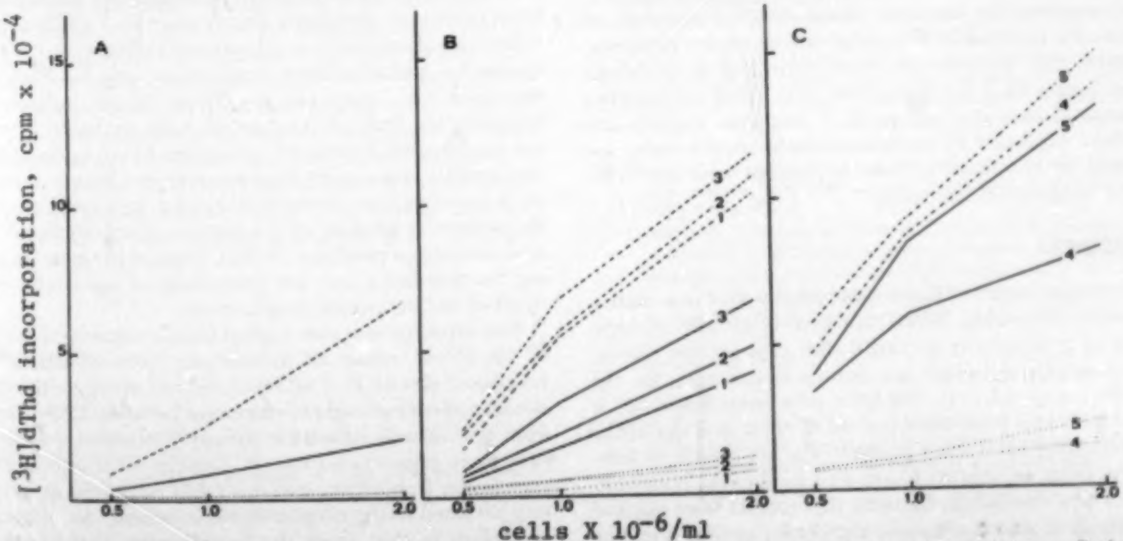
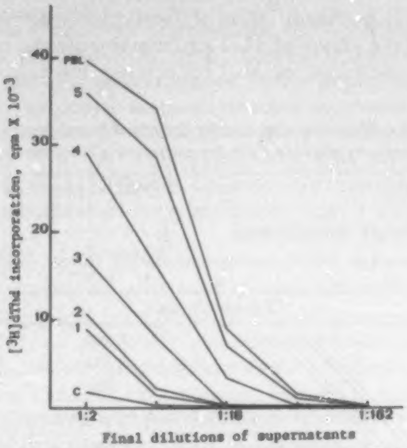
[a] 1 µg of phytohemagglutinin was added to each well containing 1.0×10^5 cells in a final volume of 200 µl.

[b] 30 µl of IL-1-containing supernatant was added to each well; preliminary data indicated that this conditioned medium concentration yielded optimum mitogenesis.



TEXT-FIGURE 1.—Proliferative responses of unfractionated (——), PNA$^-$ (-----), and PNA$^+$ (·····) lymphocytes from A) normal thymus, B) thymomas with abundant lymphocyte components, and C) thymomas with scant lymphocyte components. Lymphocytes were cultured for 84 hr at various cell:volume ratios in microtiter wells. One µg of phytohemagglutinin was added to each well containing a final volume of 200 µl.



TEXT-FIGURE 2.—Quantitative microtiter-well assay for IL-2 activity. T-cells (1.0×10^6 cells/ml) were cultured for 48 hr with the addition of various dilutions of culture supernatants from peripheral blood mononuclear cells (PBL), thymomas (1, 2, 3, 4, 5), and normal thymus lymphocytes (C).

augments the blastic transformation of lymphocytes from both normal and neoplastic glands cultured at low cell densities (table 3). The highest [^{3}H]dThd-incorporation values are exhibited by thymoma lymphocytes, particularly by those with low lymphocyte-to-epithelial cell ratios.

The magnitude of the blastic response is ultimately modulated by the amount of endogenous IL-2 produced by a T-cell subset under the influence of IL-1 (*12–15*). Therefore, we have evaluated the capacity of the lymphocytes from normal and neoplastic glands to produce IL-2. We assayed conditioned media from phytohemagglutinin-stimulated thymocytes for their ability to stimulate the proliferation of cultured T-cells from mixed lymphocyte culture. Proliferative responses of cultured T-cells to the various supernatants in the IL-2 microtiter-well assay are shown in text-figure 2. For comparison, we also determined the IL-2 activities of supernatants generated from peripheral blood lymphocytes. We found that supernatants from thymoma lymphocytes contain higher IL-2 activities than those from normal thymocytes and that the highest IL-2 amounts, slightly less than those produced by peripheral blood lymphocytes, are generated by lymphocytes from thymomas with low lymphocyte-to-epithelial cell ratios.

DISCUSSION

The precise nature of thymoma lymphocytes is a matter still open to discussion. Based on morphologic and biologic features of lymphocytes and epithelial cells present in thymomas, neoplastic nature has been assumed only for the epithelial component (*1*). We have previously found (*2, 3*) that lymphocytes from both normal thymus and thymoma bear distinctive membrane markers that are absent in lymphocytes from peripheral blood and peripheral lymphoid tissues. These similarities between thymocytes from normal and neoplastic glands are valid arguments against a theory of thymoma lymphocytes originating in the lymphoid periphery.

We have previously investigated the lectin-stimulated mitogenesis of normal unfractionated thymocytes and PNA$^+$ and PNA$^-$ subsets and showed that only PNA$^-$ thymocytes, the minor pool of more mature medullary cells, are capable of responding to the mitogen as described by Reisner et al. (*4*). To clarify the steps of mitogen-induced activation and the role of subcellular factors in the promotion and regulation of the blastogenesis of thymoma lymphocytes, we have investigated the in vitro [^{3}H]dThd incorporation of total, PNA$^+$, and PNA$^-$ lymphocytes from neoplastic thymuses in comparison with thymocytes from normal thymus under several different experimental conditions. Unfractionated thymoma lymphocytes exhibit higher mitogen-induced blastogenesis than normal thymocytes. Total lymphocyte suspensions from thymomas with low lymphocyte-to-epithelial cell ratios show the highest blastic responses upon phytohemagglutinin stimulation. As in the normal thymus, only PNA$^+$ lymphocyte preparations from thymomas are able to respond to phytohemagglutinin, whereas PNA$^+$ lymphocytes are practically unresponsive. The PNA$^-$ subset from thymomas with a low lymphocyte-to-epithelial cell ratio shows maximal blastic responses clearly higher than those exhibited by equal numbers of PNA$^-$ normal thymocytes.

At this point, it could be suspected that variable percentages of macrophages and, consequently, variable concentrations of their products could be present in the thymocyte preparations from normal thymus or thymoma, thereby influencing their response capacity. The role of accessory cells and of IL-1, a macrophage product, for the release of IL-2 by some T-lymphocyte subsets and the obligatory role of IL-2 for the blastogenesis of lectin-activated T-cells are presently widely accepted. Consequently, we added a saturating concentration of exogenous IL-1 to each thymocyte culture to overcome potential experimental artifacts and to be able to better evaluate the intrinsic blastogenic capacity of each thymocyte population. In effect, the data concerning the blastic proliferation of thymocytes from normal or neoplastic glands after IL-1 addition to the culture medium show a substantial increase in blastic response by unfractionated populations and by PNA$^-$, but not by PNA$^+$, preparations. These results indicate that lymphocytes from thymomas as well as those from the normal thymus depend on monocytes for an optimal initial mitogenesis and suggest that the inherent blastic capacities of thymocytes from both normal and neoplastic thymuses are ordinarily masked by the scarcity of macrophages and/or macrophage products. In fact, nonspecific esterase staining has revealed a very low percentage of monocytes (<1%) in all of the thymocyte preparations.

The capacity to mount a good blastic response is confined to the PNA$^-$ subset of thymocytes, both in normal and neoplastic glands. IL-1 addition did not abrogate the differences in the amplitude of responses between PNA$^-$ subsets from normal and neoplastic tissues. This effect may be due to a more pronounced blastic capacity of the total PNA$^-$ population from thymomas due to an advanced maturative step attained in the neoplastic environment. An alternative possibility is that since the lymphocytes that cannot be agglutinated by peanut lectin could represent a heterogeneous population, variable percentages of mitogen-responsive cells may be present in the PNA⁻ preparations from the various sources.

To better evaluate the subcellular factors that regulate blastic activation of thymocytes both from normal and pathologic tissues, we then investigated the effective in vitro IL-2 production by the various thymocyte preparations after phytohemagglutinin stimulation. In lymphocyte cultures from peripheral blood lymphocytes and from peripheral lymphoid tissue, both in experimental animal and human systems, a subset of T-lymphocytes produces IL-2 under the influence of IL-1. IL-2 then is taken up by antigen-or mitogen-activated T-lymphocytes and switches them to proliferative activities. In our experiments, lymphocytes from both normal and neoplastic thymuses produced IL-2 in detectable amounts. Moreover, thymoma lymphocytes produced IL-2 in significantly higher quantities than did normal thymocytes. The production of and the assumption of subcellular factors by distinct cell subpopulations are then effective in the promotion and regulation of blastic activation of lymphocytes from both thymus and thymoma, as well as from peripheral blood. The existence of such a complex system of stepwise blastogenesis control in thymoma lymphocytes implies that thymoma lymphocytes are not a homogeneous population; therefore, they are likely to be of nonneoplastic nature.

The greater than expected increase of [^{3}H]dThd incorporation in thymocytes attained by augmenting cell concentration in thymocyte cultures from normal and neoplastic glands suggests a role for subcellular factors in the regulation of blastic response in these suspensions. It is conceivable that, at the highest cell concentration per culture volume, IL-1 and the produced IL-2 are no longer diluted out in the medium and their effects can become fully manifested. However, on the basis of our experiments, the influence on mitogenesis of an increased, intimate cell-to-cell contact in culture at high cell concentration cannot be ruled out.

In conclusion, our data indicate that thymoma lymphocytes are functionally heterogeneous and functionally superior to normal thymocytes, particularly when obtained from tumors with the scantest lymphocyte component. Furthermore, the heterogeneity of thymoma lymphocytes in terms of surface marker expression and functional capacities, as well as the substantial similarities between the mechanisms that regulate mitogenesis of T-cells from normal and neoplastic glands, further suggests a nonneoplastic nature of thymoma lymphocytes.

Changes in Lung Cancer Incidence and Mortality Rates Among Americans: 1969–78[1]

John W. Horm[2, 3] *and* Ardyce J. Asire[2]

ABSTRACT—Cancer incidence data from two large cancer surveys and cancer mortality data for the entire United States were used to estimate trends in lung cancer incidence and mortality rates among whites for specific age groups during the 10 years 1969–78. Data for the Third National Cancer Survey were from 1969 to 1971; data for the Surveillance, Epidemiology, and End Results Program were from 1973 to 1978. For both incidence and mortality, the rates for women increased much more rapidly than the rates for men, except in the oldest age group (≥85). For both men and women, there was a striking similarity between the average annual percent changes for age-specific incidence rates and those for age-specific mortality rates. For the first time women and men had a similar incidence rate for the youngest (35–44) age group in 1978. If these trends continue, the data suggest that the total incidence rates for men and women will be equal by the year 2000.—JNCI 1982; 69:833–837.

Lung cancer comprises about 21% of all newly diagnosed cancer cases and 32% of all cancer deaths in white men. In white women, this cancer accounts for about 8% of all new cancers and 13% of all cancer deaths (*1*). For all patients diagnosed with lung cancer in 1970–73, the 5-year survival rate was 9% for white men and 14% for white women (*2*). Because this disease accounts for a large proportion of all cancers and results in poor survival, it is important to assess trends in the incidence of and mortality from lung cancer.

In recent years, several investigators have indicated that lung cancer incidence and mortality rates in the United States have been increasing dramatically. In particular, Cutler and Devesa (*3*) found that from 1937 to 1969 the incidence rates increased by over 400% in white men and 200% in white women. In their analysis of mortality, these authors indicated that from 1935 to 1965 lung cancer mortality rates increased by over 500% in white men and 100% in white women. Among the 11 cancer sites investigated for whites, lung cancer showed the largest increases. In a more comprehensive analysis of trends from 1935 to 1974, Devesa and Silverman (*4*) showed that lung cancer again had the largest increases in both incidence and mortality among whites. In addition, they noted that the mortality rates from lung cancer in white women had increased only since the mid-1950's, but those for white men had increased over the entire time period.

In an analysis of cancer incidence and mortality trends from 1969 to 1976, Pollack and Horm (*5*) determined that among whites lung cancer incidence increased by 1.4% per year for men and 8.6% per year for women. Mortality from lung cancer in the entire United States increased by 2.6 and 7.1% per year for white men and women, respectively. Thus, whereas the earlier studies indicated that the lung cancer incidence and mortality rates were increasing more rapidly in men than in women, the more recent Pollack and Horm study found that the rates for women were increasing more rapidly than were the rates for men.

The above-mentioned studies dealt solely with the trends in the overall age-adjusted lung cancer incidence and mortality rates. This investigation focuses on the age-specific trends in lung cancer incidence and mortality rates occurring between 1969 and 1978 in men and women in the United States.

MATERIALS AND METHODS

In recent years the National Cancer Institute has conducted two programs to assess cancer incidence in the United States: the TNCS and the SEER Program. The TNCS was conducted for the finite period of 1969–71 (*6*). The SEER Program was begun in 1973 as a continuous source of population-based cancer incidence and patient survival data in the United States. Data are now available for the years 1973–79 (*7*).

These two programs monitored approximately 10% of the U.S. population; only four registry areas, however, were common to both. In addition, the State of Connecticut has conducted a statewide cancer registry system since 1935 (*7*) and is now a participant in the SEER Program. Although the Atlanta registry was common to both programs, it did not participate in the SEER Program until 1975. Thus this analysis is restricted to the years 1969–71 and 1975–78 and to the four TNCS–SEER Program common areas plus Connecticut.

The five areas with their total populations for 1970 are the States of Connecticut (3,021,709) and Iowa (2,824,376) and the metropolitan areas of Atlanta (1,390,164), Detroit (4,199,931), and San Francisco–Oakland (3,109,519). These areas included about 7% of the 1970 U.S. population. The total black population in these areas was too small to permit an accurate evaluation of incidence trends among blacks. Therefore, the incidence rates of lung cancer discussed here have been determined for whites only from the data for these five areas.

The mortality data used in this report are from computer tapes made available to the public annually by the National Center for Health Statistics. The most recent year for which

such public-use tapes are currently available is 1978.

The populations used as denominators for computation of the incidence and mortality rates for 1969–71 are from the 1970 U.S. census. The populations for the years 1973–78 are based on projections prepared by the Bureau of the Census. For Connecticut, however, the population estimates were made by the Department of Health Services of that state.

The trends for both incidence and mortality are expressed in terms of average annual percent changes, convenient measures for trends over the 10-year period covered in this report. The measure was derived by an exponential model of the form $Y = ae^{bt}$ being fitted to the annual incidence and mortality rates by means of a regression technique. The advantage of an exponential model being used rather than a linear model is that the exponential model allows for a direct interpretation of the average annual percent change, whereas a linear model does not. The average annual percent change from the exponential model is then $(e^{b-1}) \cdot 100$.

Both the incidence and mortality rates were computed according to six 10-year age groups: 35–44, 45–54, 55–64, 65–74, 75–84, and 85 and older. An analysis was not performed for persons under age 35 because the small numbers did not permit a reasonable assessment of trends.

RESULTS

Table 1 presents the age-specific incidence rates for white men and women. The incidence rates increased with age for men, except that the rate for the oldest age group (≥85) was lower than that for the age group 65–74. A similar pattern is seen for women, but the rates for 2 age groups (75–84 and ≥85) were lower than the rate for the age group 55–64. Most noteworthy is the fact that for the first time women and men had a similar incidence rate for the youngest (35–44) age group in 1978—a direct result of the decreasing rate for men and the increasing rate for women during the 10 years covered by this study.

Age-specific mortality rates for white men and women in the entire United States are shown in table 2. The mortality patterns are seen to be generally similar to the incidence patterns. The major difference is that the mortality rate for women in the age group 35–44 did not increase as rapidly as did the incidence rate. Thus, in contrast to incidence, the

[a] Age adjusted to the 1970 U.S. population.

mortality rate for women in this youngest age group was still lower than that for men.

The age-specific mortality rates for black men and women in the United States are given in table 3. The rates for men are higher than the rates for women in each year and age group. In addition, the rates for black men are higher than the rates for white men in every age group except the 2 oldest groups (75–84 and ≥85). The rates for black women are higher than the rates for white women in the 2 youngest age groups only.

Average annual percent changes, computed for the age-specific incidence and mortality rates shown in tables 1–3, are displayed graphically in text-figure 1 (incidence) and text-figure 2 (mortality) for whites and in text-figure 3 (mortality) for blacks. These graphs show that for both incidence and mortality the rates for white women increased much more rapidly than the rates for white men except in the oldest age group (≥85). The mortality rates for black women, however, increased more rapidly than did the rates for black men in every age group except the 2 oldest groups (75–84 and ≥85). For both white men and women, there was a striking similarity between the average annual percent changes for age-specific incidence rates and those for age-specific mortality rates. This similarity reflects the poor survival experience of lung cancer patients. With a median survival time of about 6 months, these patients often died in the same year they were diagnosed. The only exception to this similarity is among women between the ages of 35 and 44; the incidence rate for these women increased at about 7% per year, whereas their mortality rate increased at about

only 2% per year. This difference could be accounted for by variability due to small numbers of cases in this age group; there were less than 100 cases/year in the five common areas. It is also possible that this difference is the result of the better survival of women in this age group. It may be that in the most recent years these young women were diagnosed with more localized disease.

DISCUSSION

This paper investigates the current trends in age-specifi lung cancer incidence and mortality among whites. Morta ity trends were derived from data for the entire Unite States; incidence trends were derived from data for fi specific areas.

Although no formal analysis of lung cancer incidence trends among blacks is shown here, the data were analyzed for changes in incidence for black men and women. The trends in the age-adjusted rates for blacks were similar to those for whites. Because of a large variation in the yearly rates, readily discernible trends were not apparent among black men for any of the 6 age groups analyzed. Among black women, the trends did seem to follow closely those for white women.

It is with concern that we view the increasing lung cancer incidence and mortality trends for women. If these trends continue, the data suggest that the total incidence rates for men and women will be equal by the year 2000. In fact, as stated above, the incidence rates for men and women are already at a similar level for the age group 35–44. Lung cancer incidence and mortality should be monitored often and completely because of the rapid changes that have occurred and are expected to occur.

Simian Virus 40 (SV40)-Specific Isoelectric Point-4.7–94,000-*M*$_r$ Membrane Glycoprotein: Major Peptide Homology Exhibited With the Nuclear and Membrane-Associated 94,000-*M*$_r$ SV40 T-Antigen in Hamsters[1,2,3]

Rupert Schmidt-Ullrich,[4] W. Scott Thompson,[4] Stuart J. Kahn,[4] Maureen T. Monroe,[4] *and* Donald F. H. Wallach[4]

ABSTRACT—Tryptic peptide maps of electrophoretically purified 94,000-molecular weight (relative) (M_r) nuclear and membrane-associated simian virus 40 (SV40) T-antigens, T_N and T_M, respectively, were compared to those of the SV40-specific isoelectric point (pI)-4.7–94,000-M_r plasma membrane component reactive with anti-T-sera from Syrian golden hamsters. Bidimensional thin-layer electrophoresis and chromatography of T_N labeled with ^{125}I revealed about 27 tryptic peptides. A similar number of peptides was identified for T_M and the pI-4.7–94,000-M_r component. A peptide homology between T_N and T_M or T_N and the pI-4.7–94,000-M_r protein exists and indicates that the previously described pI-4.7–94,000-M_r membrane component represents T_M. Only 4 of 27 peptides were labeled when T_M was subjected to lactoperoxidase-catalyzed radioiodination from the outer surface of the plasma membrane. One of these T_M peptides was metabolically labeled with [^{14}C]glucosamine. The data indicate that T_M is partially exposed on the cell surface and represents a glycosylated form of T_N. Closely associated with T_M is a pI-4.5–55,000-M_r membrane component. This component does not exhibit significant peptide homology with the 94,000-M_r SV40 protein and, therefore, appears to be coded for by the host cell genome.—JNCI 1982; 69:839–849.

Mammalian cells neoplastically transformed by SV40 express virus-specific proteins on their surface membrane. These proteins are defined as TSTA or TSSA (*1–5*). Recent evidence indicates that TSTA and TSSA may represent identical antigens that are monitored by in vivo and in vitro test systems, respectively (*6*). The two antigens also exist in a close relationship with the 94,000-M_r SV40 T-antigen. This relationship is indicated by copurification of TSTA-TSSA and T-antigen during biochemical fractionation (*4*), similar subcellular distribution of the 2 groups of antigens (*2, 7*), and their concordant expression at permissive and nonpermissive temperatures in cells transformed by nondefective tsA mutants (*8, 9*). Other data indicate that purified T-antigen can induce a TSTA response in vivo (*10*), and this finding is concordant with recent findings that a 94,000-M_r T-antigen, immunochemically indistinguishable from nuclear T-antigen, can be immunoprecipitated from membranes of SV40-transformed cells (*7, 11, 12*). That SV40 T-antigen is expressed at the plasma membrane of SV40-transformed cells is further suggested by studies in which rabbit immune serum against purified T-antigen reveals a specific indirect immunofluorescence reaction at the surface of SV40-transformed cells (*11, 13*). In previous work we have identified and partially characterized two SV40-specific proteins in membranes of SV40-transformed cells (*14–16*). Using highly purified plasma membranes of SV40-transformed GD248 hamster lymphoid cells (*14, 15*) and SV80 human fibroblasts (*15*), we presented evidence that the SV40-specific pI-4.7–94,00-M_r membrane glycoprotein of these cells represents a host-modified, glycosylated T-antigen (*15, 16*). We have now obtained tryptic peptide maps of ^{125}I-labeled SV40 proteins showing that the SV40-specific pI-4.7–94,000-M_r glycoprotein exhibits a major tryptic peptide homology with the T_N. This similar peptide homology exists when the T_M or pI-4.7–94,000-M_r protein is compared with T_N. T_M represents maximally 1% of the total cellular T-antigen. Like the 94,000-M_r intracellular T-antigen (*12, 17–19*), T_M is associated with a 55,000-M_r host cell protein. This protein does not react with anti-T serum and, on the basis of tryptic peptide analyses, does not share peptides with T_N or T_M (*20–22*).

MATERIALS AND METHODS

Chemicals, media, and materials.—Triton X-100, HEPES, DTT, BSA, and PMSF were obtained from Sigma Chemical Co. (St. Louis, Mo.); Chloramine-T was from Eastman Kodak Co. (Rochester, N.Y.); SDS and urea were from Fisher Chemical Co. (Fair Lawn, N.J.); acrylamide, *N,N'*-methylenebisacrylamide, *N,N,N',N'*-tetramethylethylenediamine, ammonium persulfate, and Coomassie brilliant blue were from Bio-Rad Laboratories (Richmond, Calif.); and ampholytes (Ampholine, pH 3.5–10.0) were from LKB In-

struments, Inc. (Uppsala, Sweden). Lactoperoxidase, from Boehringer Mannheim Biochemicals (Indianapolis, Ind.), in 3.2 *M* $(NH_4)_2SO_4$ was freed of ammonium sulfate by dialysis against the buffer used for labeling. TPCK-trypsin was from Worthington Biochemical Corp. (Freehold, N.J.). Protein A-Sepharose CL-4B beads, used as immune adsorbent, were obtained from Pharmacia Chemicals AB (Uppsala, Sweden) and hydrated in an equal volume of water (50%, vol/vol, suspension) prior to use. $Na^{125}I$ (carrier-free in 0.1 *M* NaOH, 17 Ci/mg), [^{35}S]methionine (>400 Ci/mmol), and [^{14}C]glucosamine hydrochloride (250-350 mCi/mmol) were obtained from New England Nuclear Corp. (Boston, Mass.). DMEM and EMEM were obtained from the Cancer Research Center, Tufts University School of Medicine; FCS was purchased from GIBCO (Grand Island, N.Y.) and heat inactivated prior to use. Cellulose thin-layer plates, Polygram Cell 300, were from Brinkman Instruments, Inc. (Westbury, N.Y.), and nitrocellulose sheets were from Beckman Instruments, Inc. (Palo Alto, Calif.).

Cells.—SV40-transformed human fibroblasts, SV80 cells, were grown in DMEM containing 10% FCS and were metabolically labeled during the logarithmic growth phase (*23*). Cultures of SV80 cells were grown to subconfluence in 850-cm^2 roller bottles (Corning Glass Works, Corning, N.Y.), starved in methionine-deficient EMEM containing 10% dialyzed FCS, and metabolically labeled with the use of 5 ml of the same medium containing [^{35}S]methionine (0.2 mCi/ml). The initial labeling was for 5 hours and was continued overnight after addition of 15 ml EMEM-10% FCS. Metabolic labeling with [^{14}C]glucosamine at a concentration of 0.2 mCi/ml was in EMEM-10% dialyzed FCS. After a 2-hour pulse the cultures were chased with 2 m*M* unlabeled glucosamine for 4 hours. After labeling, the cells were detached from the culture flasks with the use of phosphate-buffered saline (0.13 *M* NaCl-0.02 *M* Na phosphate; pH 7.2) containing 5×10^{-4} *M* EDTA.

SV40-transformed hamster skin fibroblasts [SK, line B (24)] were cultivated in EMEM fortified with 10% heat-inactivated FCS. At confluence, the cells were harvested by trypsinization and washed twice in EMEM free of serum. For tumor production, about 10^8 SK cells, suspended in 0.2 ml of EMEM without FCS, were injected im into the hind legs of 6- to 8-week-old outbred Syrian golden hamsters.

Membranes, nuclei.—SV80 cells were disrupted by nitrogen decompression (*25*). Nuclei were collected at 1.5×10^4 g/minute, washed twice in 0.065 *M* NaCl, 0.075 *M* KCl, 0.02 *M* HEPES, and 0.005 *M* $MgCl_2$ (pH 6.5) prior to extraction with 1% Triton X-100. Plasma membranes were isolated as small vesicles (*25, 26*).

Solubilization.—Prior to fractionation by bidimensional IEF-SDS-PAGE, purified membranes were solubilized in HEPES-Triton X-100 (0.001 *M*/1%, vol/vol), pH 8.5 (*27, 28*), and assayed for protein with the use of BSA as a standard (*29*). SV40 T-antigen was extracted from nuclei and plasma membrane purified from [^{35}S]methionine and [^{14}C]glucosamine-labeled SV80 cells. The extraction for immunoprecipitation was in 0.137 *M* NaCl, 0.02 *M* Tris-HCl, 0.001 *M* $CaCl_2$, and 0.001 *M* $MgCl_2$ (pH 9.0), 1% (vol/vol) in Triton X-100 and 10% (vol/vol) in glycerol, adjusted to 0.002 *M* PMSF (*23*). After extraction at 4°C for 1 hour, nuclear and membrane-associated debris was removed at 4×10^5 g/minute (*23*).

Antisera—Sera from SK (line B) sarcoma-bearing hamsters were obtained at the time of highest T-antigen reactivity, i.e., 5-7 weeks after im inoculation of 10^6 cells per site (*24*). At this time, the tumors were at least 0.5 cm in diameter. The T-antigen-reactive sera (anti-T-sera) were tested by indirect immunofluorescence by means of serial dilutions up to 512-fold. Sera positive at this titer were used for immunoprecipitation of membrane antigens. As controls, pooled sera from normal hamsters were used. Preabsorption of antigen was with normal sheep serum (*23*).

Isolation of SV40 transformation-associated proteins.—The 94,000-M_r SV40 T-antigen was precipitated from Triton X-100-solubilized plasma membranes and nuclei, both isolated from [^{35}S]methionine-labeled SV80 cells. For this procedure, solubilized plasma membranes and nuclei were adjusted to a protein concentration of 1 mg and 3 mg/ml, respectively, with the use of 0.137 *M* NaCl, 0.02 *M* Tris-HCl, 0.001 *M* $CaCl_2$, and 0.001 *M* $MgCl_2$ (pH 9.0), 1% (vol/vol) in Triton X-100 and 0.002 *M* in PMSF. The antigen (1 ml each) was preincubated with 0.01 ml of normal sheep serum and 0.08 ml of 50% (vol/vol) protein A-Sepharose immune adsorbent. Specific immunoprecipitation was then performed after addition of 0.01 ml of antigen-T-serum (and normal hamster serum as control) and 0.08 ml protein A-Sepharose at 4°C for 60 minutes (*23*). The protein A-Sepharose beads were washed three times in 0.5 ml of 0.1 *M* Tris-HCl, 0.5 *M* LiCl, and 0.14 *M* β-mercaptoethanol (pH 9.0) for removal of nonspecifically adsorbed protein. Specifically bound proteins were released by incubation in 0.05 ml of 0.02 *M* Tris-HCl and 0.7 *M* β-mercaptoethanol (pH 9.0), 5 and 20% (vol/vol), respectively, in SDS and glycerol at 80°C for 30 minutes.

After SDS-PAGE fractionation of immunoprecipitated SV40 T_M and T_N (*31*), the antigens were identified by ^{35}S autoradiography of dried gels. Bidimensional IEF-SDS-PAGE was as in (*15, 16*). The pI-4.7-94,000-M_r membrane component was isolated after protein staining of the slab gels with Coomassie blue (*31*). For peptide mapping the immunoprecipitated 55,000-M_r protein was used. The 94,000- and 55,000-M_r membrane proteins specifically bound to protein A-Sepharose were desorbed from the beads and separated from heavy- and light-chain immunoglobulins by means of IEF (*32*). The [^{35}S]methionine-labeled 94,000- and 55,000-M_r components focusing near pI 4.5 were isolated from the IEF gel, subfractionated by DS-PAGE, and identified by ^{35}S autoradiography. Gels run in parallel were stained with Coomassie blue to assure quantitative separation of immunoglobulin and the SV40 membrane proteins.

The reactivity of the pI-4.7-94,000-M_r and pI-4.5-55,000-M_r components with anti-T-sera was investigated by an electrophoretic blotting procedure (*33*). After IEF-DS-PAGE, plasma membrane proteins from SV80 cells, focusing between the pI-5.5 and pI-4.0 regions, were electrophoretically transferred from the slab gel onto nitrocellulose sheets. These were soaked in NaCl-BSA (0.15 *M*/3%, wt/vol) and reacted with hamster anti-T-serum (0.02 ml/ml of NaCl-BSA-0.001 *M* NaN_3) for 16 hours at 20°C. The nitrocellulose sheets were then soaked in NaCl (0.15 *M*) as in (*33*) for removal of unbound serum proteins. Specifically bound hamster immunoglobulin was identified by equilibration with ^{125}I-labeled protein A (5×10^7 cpm/mg protein) for 6 hours at 20°C followed by autoradiography.

^{125}I labeling of SV40-specific proteins.—The chloramine-T technique (*34*) was used to achieve iodination of T_N and SV40 membrane proteins to specific activities of about 10^8 cpm/mg protein. T_N, T_M, the pI-4.7–94,000-M_r protein, and the pI-4.5–55,000-M_r protein were localized by [^{35}S]methionine autoradiography and then iodinated in polyacrylamide gel pieces according to the procedure of Elder et al. (*35*). The protein-containing gel pieces were lyophilized in siliconized test tubes and rehydrated in about 0.05 ml of 0.5 *M* sodium phosphate (pH 8.5). After an additional 0.02 ml of chloramine-T (1 mg/ml in H_2O) and 0.3 mCi of Na^{125}I in 0.005 ml, iodination was allowed to proceed for 30 minutes at 20°C. The reaction was then quenched by addition of 0.02 ml sodium bisulfate (1 mg/ml in H_2O). Unreacted ^{125}I was removed by extensive dialysis against methanol (10%, vol/vol).

To identify the peptide moieties of T_M exposed at the cell surface, we ^{125}I labeled sealed plasma membrane vesicles by using lactoperoxidase-catalyzed radioiodination (*36*). In control experiments, plasma membranes were solubilized in Triton X-100 (1%, vol/vol) and subjected to the same iodination procedure. Immunoprecipitation and electrophoretic isolation of ^{125}I-labeled T_M were as for metabolically labeled proteins, except that the chloramine-T-mediated iodination prior to tryptic peptide mapping was omitted.

Trypsin treatment of SV40-specific proteins.—For cleavage with TPCK-trypsin, dried gel pieces containing ^{125}I-labeled SV40-specific proteins were hydrated with 0.02–0.05 ml of 0.05 *M* NH_4HCO_3; so TPCK-trypsin (0.5 mg/ml) was then added in the volume of 0.05 *M* NH_4HCO_3 required for complete hydration of the gel piece. Trypsinization was for 40 hours at 37°C with a second addition of 0.05 mg TPCK-trypsin after 16 hours. To assure that only peptides of the SV40 proteins were detected, we performed several control experiments under identical conditions: *a*) TPCK-trypsin was incubated alone in the presence of ^{125}I (2×10^6 cpm); *b*) [^{125}I]BSA, a protein completely unrelated to T-antigen, was subjected to cleavage by TPCK-trypsin, and *c*) a gel piece corresponding to the 94,000-M_r region, obtained from a sample precipitated with normal hamster serum, was trypsinized. The supernatant containing TPCK-trypsin and ^{125}I-labeled peptides was lyophilized, and the residue was solubilized in acetic acid–formic acid (15%/5%, vol/vol) for peptide mapping by electrophoresis and chromatography on cellulose thin-layer plates (*35*).

Peptide mapping—Bidimensional thin-layer peptide mapping was used to define the positions of peptides–glycopeptides in a two-dimensional grid (*35*). In addition, the "grouping" of peptides and the relative intensities of the peptide spots were evaluated. Finally, we investigated the identities of peptides from T_N and T_M and the pI-4.7–94,000-M_r component by mixing peptides of T_M with T_N, or the pI-4.7–94,000-M_r component, or all three proteins prior to bidimensional thin-layer electrophoresis and chromatography.

About 5×10^5 cpm ^{125}I-labeled or 10^4 cpm [^{14}C]glucosamine-labeled peptides were applied to a 10×10-cm thin-layer chromatography plate near the cathode. The plate was then moistened with acetic acid–formic acid (15%/5%, vol/vol) and a dye mixture of Orange G–acid fuchsin (2%/1%, wt/vol) spotted near the anode. Electrophoresis in the first dimension, at 1,000 V, was terminated when the dye had reached the sample spot. The plates were dried under cold air. Chromatography in butanol–pyridine–acetic acid–water (32.5/25/5/20, vol/vol) was at right angles to the first dimension. After drying, the peptide maps were obtained by autoradiography on Kodak no-screen X-ray film.

To prove the identity of peptides derived from T_N, T_M, and the pI-4.7–94,000-M_r protein, we localized individual peptides by using ^{125}I autoradiography. The peptides were scraped off the cellulose thin-layer plates and eluted by acetic acid–formic acid–water (15%/5%/80%, vol/vol). In all reelectrophoresis–rechromatography experiments, identical amounts, as determined by ^{125}I cpm, of peptides from the three SV40 proteins were rerun on thin-layer plates.

RESULTS

SV40-specific membrane proteins.—The present data were obtained with the use of SV80 cells that produce large quantities of SV40 T-antigen (*23*). As shown in figure 1A, plasma membranes of SV80 cells, purified and freed of nuclear contaminants according to the procedure described for GD248 hamster lymphoid cells and other SV40-transformed fibroblasts (*16, 25*), contain two membrane proteins characteristic for SV40-transformed cells—the pI-4.7–94,000-M_r and pI-4.5–55,000-M_r components. These proteins correspond to entities identified by us in plasma membranes of other SV40-transformed cells (*14, 16, 37*). Of SDS-denatured components, only the pI-4.7–94,000-M_r protein reacts with anti-T-serum after transfer from polyacrylamide to nitrocellulose (fig. 1B).

When Triton X-100-solubilized membrane proteins of SV80 cells are reacted with anti-T-serum, a 94,000-M_r protein and a 55,000-M_r protein are specifically precipitated (fig. 2). No proteins of this molecular mass are deposited when normal serum is used for precipitation of membrane-associated antigens (fig. 2). We have previously shown that the 94,000-M_r protein isolated by SDS-PAGE focuses between pI 5.5 and 4.5, with a major protein peak at pI 4.7 (*16*). Our data indicate that the 94,000-M_r T_M is associated with the 55,000-M_r component as has been reported for the total cellular T-antigen (*12, 17, 18, 20, 22, 38–40*). Whereas with the T_N a prominent 55,000-M_r component is deposited, this protein reproducibly precipitates to a lesser amount when plasma membranes are reacted with anti-T-serum. However, the 55,000-M_r protein per se does not react with anti-T-antibodies (*39, 41*). In agreement with others' results (*12*), the anti-T-serum does not precipitate possible 20,000-M_r T-antigen from plasma membranes.

Tryptic peptides of the SV40-specific membrane proteins.—Figures 3A–3F compare the tryptic peptide maps of T-antigen isolated by immunoprecipitation from purified plasma membranes, T_M, and from isolated nuclei, T_N, with those of the SV40-specific, pI-4.7–94,000-M_r plasma membrane protein.

The sensitivity of bidimensional thin-layer peptide mapping of ^{125}I-labeled peptides is sufficient for the resolution of at least 27 T_N peptides (figs. 3A, 3D). This peptide resolution appears to be superior to [^{35}S]methionine ion-exchange peptide mapping, which yielded maximally 19 peptides for the 94,000-M_rT-antigen (*21*). None of the ^{125}I-labeled peptides are contributed by trypsin itself, because no peptides were revealed when trypsin was incubated in the presence of free ^{125}I. Further, there was no peptide homology between ^{125}I-labeled BSA and ^{125}I-labeled T_N, both digested with identical quantities of TPCK–trypsin; no peptides could be identified when gel pieces of the 94,000-M_r and 55,000-M_r regions were processed from gels in which material, precipitated with normal hamster serum, was fractionated.

The numbering of peptides was based on the pattern obtained with SV40 T_N. Peptides with identical position and grouping in T_N, on the one hand, and T_M or the pI-4.7–94,000-M_r component, on the other hand, carry the same numbers. Peptides apparently deviating in position were assigned the numbers of the corresponding T_N peptide plus the letters *N* or *M*, depending on their characteristic appearance in the T_N or T_M peptide maps. Peptides from T_M and the pI-4.7–94,000-M_r component, not corresponding to those of T_N, were assigned letters (in alphabetical order).

Of the 27 peptides obtained by tryptic cleavage of ^{125}I-labeled T_N (figs. 3A, 3D), a significant number occur also in the maps obtained from both the 94,000-M_r T_M, isolated by immunoprecipitation from Triton X-100-solubilized membranes, and the pI-4.7–94,000-M_r protein. The two membrane proteins exhibit a major peptide homology between each other and with T_N (figs. 3B, 3C, 3E, 3F). The qualitative peptide pattern and the peptide intensity shown in figures 3A–3C are highly reproducible. On the basis of these observations, peptides 3, 7, 8, 9, and 16 exhibit different migrations and/or intensities when T_N and the SV40 membrane components are compared. Although a minor peptide of T_M is found in the area of peptide 7N, the displacement of the major peptide 7M relative to the positions of peptides 3, 8, and 9 is significant. New peptides, A and B, are found only in T_M and the pI-4.7–94,000-M_r component (figs. 3B, 3C, 3E, 3F). On the basis of the comparisons of figures 3A–3C, the distinctions between T_N and T_M appear to be confined to different migration and/or different intensities of peptides 3, 7, 8, 9, and 16 and the presence of additional peptides, A and B in T_M. Peptides 3, 7–9, and 16 are investigated in more detail by reelectrophoresis–rechromatography of groups of isolated peptides (figs. 4A–4D). Peptides 6, 14, and 16–19 obtained from T_M and the pI 4.7–94,000-M_r component comigrate (fig. 4B). Analyses of peptides 3, 7, 8, 9, and 21–23 (fig. 4C) and peptides 1, 2, 16, 18, and 19 (figs. 4D) reveal apparent identity of peptides 1, 2, 14, 17–19, and 21–23. This identity is confirmed by mixing experiments in which individual peptides from all three 94,000-M_r proteins are rerun (figs. 5A–5E). As shown in figure 5A, a mixture of peptides, three from T_M and the pI-4.7–94,000-M_r component comigrate as essentially one spot. Peptide 3 of T_N moves with a lower electrophoretic mobility (fig. 5B), which results in a lower intensity peptide from T_N and the more intense spot due to comigration of peptide 3 from T_M and the pI-4.7–94,000-M_r component. Due to some heterogeneity, peptides 7 of T_M and T_N migrate as two distinct spots. Peptide 16 (fig. 5F) migrates as three spots, indicating that this protein moiety may be different in T_N, T_M, and the pI-4.7–94,000-M_r component. Peptides 8 and 9 (figs. 5D, 5E) are identical in T_N and T_M.

Exposure of T_M at the membrane surface.—The peptide maps of the 94,000-M_r T_M, subjected to vectorial lactoperoxidase-catalyzed radioiodination (*36*), are shown in figure 6. Selective iodination of peptides 3, 7, 8, 9, and possibly 16 indicates that only these portions of T_M are exposed at the surface of the plasma membrane and accessibie to lactoperoxidase-catalyzed radioiodination. Peptides 3 and 7 are characteristic for T_M. A peptide pattern closely resembling that of T_M (fig. 3B) is obtained when T_M is isolated from plasma membranes that have been iodinated in the presence of 1% Triton X-100.

Glycosylation of T_M.—T_M isolated from SV80 cells pulse labeled with [^{14}C]glucosamine and subjected to tryptic peptide mapping reveals five peptides that selectively incorporate this sugar. The most prominent labeling occurs in peptide 7 (fig. 7). Peptides 9, 13, and 15 are weakly labeled. The different mobility of the prominent peptide 7 from T_N and T_M is at least in part due to glycosylation of this portion of T_M. These data indicate that some of the differences between T_N and T_M are due to posttranslational glycosylation of the membrane-associated SV40 T-antigen and suggest that peptide 7M represents a glycosylated polypeptide moiety. The persistence of a low-intensity peptide in the area of 7N of T_M may indicate microheterogeneity in the carbohydate residues or glycosylation of only a part of T_M.

T_M-associated 55,000-M_r membrane protein.—The peptide maps of T_N, T_M, and the pI-4.7–94,000-M_r protein reveal no apparent homology with that of the pI-4.5–55,000-M_r protein (fig. 8). Our data are in agreement with findings by others indicating that the 55,000-M_r protein represents a protein associated with T-antigen but encoded for by the host cell genome (*42, 43*).

DISCUSSION

Tryptic peptide mapping of the SV40 94,000-M_r T-antigen associated with the nucleus T_N, surface membrane T_M, and the pI 4.7–94,000-M_r membrane component, all labeled with ^{125}I, revealed at least 27 ^{125}I-labeled peptides for T_N and a similar number for the membrane protein. Significant peptide homology was observed between T_N and T_M or the pI-4.7–94,000-M_r protein and an apparently higher homology was observed between the two latter proteins. This analysis and our immunochemical analyses indicate that the pI-4.7–94,000-M_r glycoprotein (*14*) represents the membrane-associated T-antigen T_M. The glycosylation of T_M might easily be missed, unless purified plasma membranes are investigated, because T_M represents less than 1% of the total cellular T-antigen.

At least three major peptides, peptides 3, 7, and 16 (figs. 3, 4, 5), occupy different positions in peptide maps of T_N or T_M. The differences in peptides 3 and 16 could mean that the two proteins differ in their primary protein structure. Such a possibility is suggested by data of Mark and Berg (*44*) according to which a third splice site in the early messenger RNA would result in synthesis of a 94,000-M_r T-antigen with a more hydrophobic region near its carboxy terminus. Such a protein might qualify as a protein with high membrane affinity.

Posttranslational modification of T_M is indicated by our finding that T_M represents a glycosylated T_N. Data of others (*7*) and our own unpublished data indicate that T_M is also phosphorylated. It remains to be shown, however, whether the phosphate residue(s) in T_M are bound to the same residues as in T_N (*45*). A combination of translational and posttranslational modifications is conceivable.

Changes in the immunologic reactivity of the pI-4.7–94,000-M_r component after trypsin and neuraminidase treatment of intact isolated membranes from GD248 cells (*14*) and surface iodination of plasma membranes of SV80 cells indicate that portions of the T_M are exposed at the membrane surface. Serologic analyses by Soule et al. (*11*) have led to similar conclusions. Using immunofluorescence analyses and radioimmunoassays with sera against denatured isolated total cellular T-antigen, sera of tumor-bearing animals and surface-reactive anti-T-sera (all sera precipitated a 96,000-M_r T-antigen), these workers found differential reactivities of the membrane-associated T-antigen and the nuclear T-antigen. Soule et al. (*11*) concluded that membrane-bound T-antigen expresses antigenic sites absent on T_M or that, due to the conformation of T-antigen in the nucleus, certain antigenic sites are masked (*11*). The data on antigenicity and immunogenicity of T_M fit our own findings, which indicate that the heterologous guinea pig anti-GD248 membrane sera recognize neuraminidase-sensitive antigenic sites on the T_M molecule and that these sites are distinct from sites that react with anti-T-serum (*16*). Conversely, the anti-GD248 membrane serum does not react with T_N antigen (*14*).

The peptide homologies between T_N and T_M are in accord with previous data showing biochemical and immunologic similarities between T_N and the surface membrane-associated SV40 protein(s) described as TSTA–TSSA (*1–6*). However, the full relationship between TSTA and/or TSSA and T_M cannot yet be established, because there is another group of proteins that appear to be associated with SV40-induced transformation but not encoded by the SV40 genome. This group represents the 53,000- to 56,000-M_r phosphorylation proteins [e.g., (*19, 46*)] that do not react with anti-T-immunoglobulin intrinsically but can be immunogenic in some hosts bearing SV40-induced tumors (*41*). While our peptide analyses suggest, in agreement with data of others (*39, 40*), that this protein represents a host cell protein, data from other groups (*20, 22*) seem to indicate that this category of proteins exhibits partial peptide homology with SV40 T-antigen. A functional relationship between T_M and the 55,000-M_r protein is suggested because the two proteins are associated in the plasma membrane and the intracellular space (*12, 17, 18, 20–22, 38–40, 42*) and because they selectively associated in vitro (*19*).

Relationship of Lung Adenoma Prevalence and Growth Rate to Acute Urethan Dose and Target Cell Number[1,2,3,4]

Michael L. Dourson[5,6] *and* Ellen J. O'Flaherty[5,7,8]

ABSTRACT—Outbred Swiss Cox mice of both sexes were given single ip injections of 0.5–2.0 mg urethan/g body weight. Lung adenomas began to grow about 7 days after urethan administration. The relationship of plateau tumor level to dose was slightly concave upward. However, the relationship of average tumor number per 10^6 surviving target cells or alveolar type II cells to dose was markedly concave upward. Thus the definition of the urethan dose–lung adenoma prevalence curve should take into account the urethan cytotoxicity. Tumor diameters followed a log normal distribution pattern. The rate of change of geometric mean tumor diameter was independent of sex and urethan dose. In another experiment Swiss Cox mice received ip injections of 1.5 mg urethan/g body weight, and 4 weeks later chronic exposure to urethan in the drinking water was begun. The growth rate of adenomas induced by the single urethan injection was unaffected by subsequent chronic urethan administration. The results support the common assumption that tumor growth rate is independent of the rate of chronic administration of a carcinogen.—JNCI 1982; 69:851–857.

Mouse lung adenoma has been induced by all major groups of chemical carcinogens except hormones (*1*). Because of the ease of tumor induction and the rapidity of tumor appearance, this model has enjoyed wide application in carcinogenesis studies.

Urethan (ethyl carbamate) is a water-soluble carinogen with a simple chemical structure. Its administration causes adenomas of alveolar type II cell origin to appear randomly throughout the lungs of sensitive mice (*2*). Given in sufficiently large amounts, urethan is cytotoxic. Qualitative studies have demonstrated a transient drop in the number of lung cells, including alveolar type II cells, in mice given a single injection of urethan (*3, 4*). Therefore, the total number of adenomas induced by a single dose of urethan will be determined by both the carcinogenic action of urethan and its effect on the number of target cells. Although urethan dose–adenoma prevalence relationships have been investigated (*5–8*), the relative importance of the cytotoxic effects of urethan in determining the shapes of these curves is not known.

The growth rate of lung adenomas induced by single urethan injections has been studied in several mouse strains (*8–12*). Shimkin and Polissar (*10*) concluded that the initiating dose did not affect the geometric mean lung adenoma diameter. Rogers (*8*) also found that tumor size distribution was independent of the size of a single urethan dose. In addition, Rogers observed that multiple identical urethan doses did not significantly alter either the maximum tumor size or the tumor size distribution. However, neither of these studies addressed the question of the effect of chronic urethan exposure on adenoma growth rate.

The purposes of this investigation were to define the acute urethan dose–adenoma prevalence relationship to express prevalence based on the size of the viable alveolar type II cell population, to establish the growth rate of lung adenomas after single urethan injections at different doses in Swiss Cox mice, and to determine whether the growth rate of adenomas previously induced by single urethan injections could be affected by chronic urethan exposure.

MATERIALS AND METHODS

Mice.—Outbred Swiss Cox mice (Laboratory Supply Co., Indianapolis, Ind.) were used to establish a breeding colony. The animals were fed Rodent Laboratory Chow (Purina 5001; Ralston Purina Co., St. Louis, Mo.) and tap water ad libitum and were housed in standard stainless steel cages up to 5 mice per cage. All animals were maintained on a 12-hour light–12-hour dark cycle.

Acute study—adenoma prevalence and growth rate.—Mice of both sexes, 41–45 days old, were given a single ip injection of 0.5, 1.0, 1.5, or 2.0 mg urethan/g body weight in 10 µl of distilled waer. The mice were killed at various times after injection as described (*13*). Twenty controls received injections of 10 µl distilled water/g body weight. The number of exposed animals killed at each dose and time is given in table 1.

The lungs were prepared, and adenomas were counted and measured as previously described (*13*). Several lungs were chosen at random and embedded in paraffin for histologic confirmation of pulmonary adenoma.

Acute study—response of alveolar type II cells.—Mice of both sexes, 41–45 days old were treated with identical doses of urethan as before and were killed at either 6, 12, 18, or 42 hours after injection. Four animals that received identical doses were killed at each time. There were 14 controls.

At the time of killing, 2 mice of each sex at each dose level were anesthetized as before. Lungs were collapsed by opening the chest, excised, placed in cold (≈4–5°C) isotonic

[b] — = no mice killed at this dose and time.

saline, stripped of excess tissue, weighed, and expanded with cold (~10°C) double aldehyde fixative (*14*) at 20 cm of solution pressure for 2–3 minutes. Lung volume was determined by fluid displacement, and lungs were refrigerated in double aldehyde fixative for 24–48 hours.

After the refrigeration period, lung lobes were separated and 10–15 1-mm cubes were cut from the thickest portions of the three major lobes (left, apical, and posterior). Cubes were washed in Millonig's phosphate buffer (*15*) and post fixed in 2% OsO_4–Millonig's buffer solution (1:1) for 2 hours at 4°C. The cubes were dehydrated through a sequence of increasingly concentrated alcohol solutions and then by propylene oxide and embedded in Spurr plastic (*16*).

Eight different 1- to 2-μm sections of lung tissue were stained with toluidine blue for 2 minutes at 56°C. Slides were made and viewed blindly under oil immersion at 1,250×. Five fields per section were sampled at random, and dead, borderline, and live type II cells were scored based on the following criteria: Dead type II cells were identified by loss of nuclear detail, which included lack of staining of nuclear membrane and hyperchromicity of nucleus, and accumulation of large lamellar bodies in the cytoplasm (*17*); borderline cells were identified by either, but only one, of the above criteria; live type II cells had neither of these characteristics. All eight tissue sections were viewed to give 40 sampled fields. Each field enclosed an area of 15,840.0 μm^2. Approximately 80 type II cells were counted in 40 fields in control animals.

Lung parenchymal volume is 80% of the total lung lobe volume in outbred Swiss mice (*18*). Lung lobe volume in the Swiss Cox mice used in this study was 93.8% of total lung volume. Therefore, we used a factor of 0.8×93.8% or 75.0% to convert total lung volume to lung parenchymal volume.

The total number of live type II cells in the lung was calculated by multiplying the total lung parenchymal volume by the density of live type II cells in the lung parenchyma. This density was estimated by the division of the number of type II cell nuclei in 40 microscopic fields by the area of these 40 fields and then by the nuclear diameter 6 μm (*4*, *18*).

Acute-chronic study.—Mice of both sexes, 41–45 days old, were given single ip injections of 1.5 mg urethan/g body weight and returned to standard animal room conditions. Four or 6 weeks later chronic exposure was started by giving the animals distilled water ad libitum to which urethan was added to yield a 0.10 or 0.02% concentration by weight. The higher concentration has been used in studies of hyperplasia during chronic urethan exposure (*17*, *18*), but both dose schedules are able to increase the incidence of pulmonary adenoma in mice. Controls were also given injections of 1.5 mg urethan/g body weight but were given distilled water ad libitum throughout the study. The number of mice in each group is given in table 2.

All the animals were killed 4 weeks after the start of chronic urethan administration, their lungs were prepared, and adenomas were counted and measured as before. The times of killings were selected so that adenomas induced by chronic exposure to urethan should not have attained a large enough size to interfere with the count and measurement of the original adenoma population. In this way it was possible to evaluate any effect of urethan on tumor growth rate independently of its tumor-inducing action.

TABLE 2.—*Geometric mean tumor diameter with various urethan treatments in the acute–chronic study*

Acute urethan dose, mg/g body wt	Chronic urethan dose, % drinking water	No. of animals killed	No. of tumors measured	Geometric mean tumor diameter, 10^{-4} m	Logarithm of tumor diameter, mean±SD

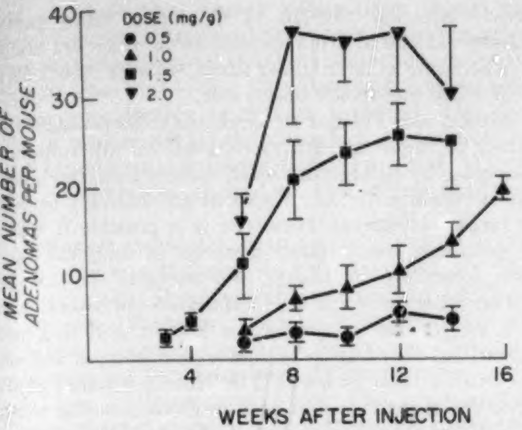
[a] — = no animals killed at this time.

[b] Data from tables 1 and 3, all doses (0.5, 1.0, 1.5, and 2.0 mg/g body wt) were combined, as well as data for male and female mice.

RESULTS

Adenoma Prevalence

Average tumor number was dependent on both time and dose (text-fig. 1). These averages were about half of those



TEXT-FIGURE 1.—Mean tumor No. per animal at different times after different single urethan doses. *Bars* indicate ±SEM. Data of animals that had a number of tumors in excess of 2 SD were disregarded.

expected for A mice, the common strain used in such studies (*1*). In agreement with other reports for small groups of animals (*1*, *2*), there were no consistent sex-related differences in average tumor numbers. As a result, data from both sexes were combined as shown.

Average tumor numbers appear to reach a plateau between 10 and 14 weeks at three of the four doses (0.5, 1.5, and 2.0 mg/kg). These findings are consistent with previous observations in other mouse strains. Shimkin and Stoner (*1*), in a summary of several studies, stated that average tumor numbers reach a plateau by 7 weeks if histologic methods are used to identify the adenomas, or by 16 weeks if only the surface tumors are counted. The present method of adenoma identification is apparently intermediate in its sensitivity. The anomalous behavior of the 1.0-mg/g dose group at 16 weeks is perhaps due to sampling variability, because in other measured variables (e.g., tumor growth rate and lung weights) this group was consistent with other doses. Plateau values were estimated at each dose in this study as the mean of the three highest adenoma averages. The relationship between plateau tumor level and dose was slightly concave upward (text-fig. 2).

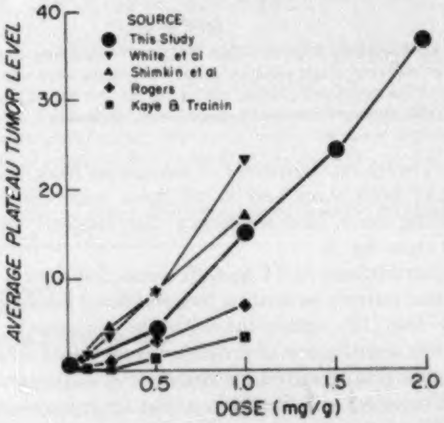
Average Number of Live Type II Cells

There were no differences between sexes in the average number of live type II cells per lung; therefore, data from both sexes were combined. The average number of live alveolar type II cells showed a transient decrease that was dose and time related. The largest decreases were seen at the highest doses and shortest times (text-fig. 3). Increases in dead and borderline type II cells, in general, reflected the decreases in live type II cells. When 6-, 12-, and 18-hour data for each dose were averaged, the percent decrease in live type II cells was linear with respect to dose.

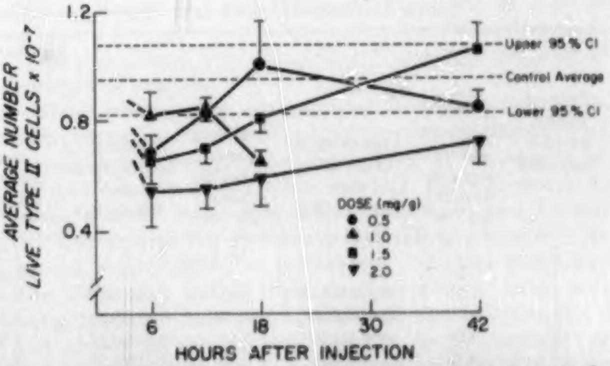
From the estimated plateau tumor level and the 6- to 18-hour averaged number of live type II cells (text-fig. 3), the mean tumor number per 10^6 surviving alveolar type II cells at each dose was calculated. The relationship between this measure of prevalence and dose is shown in text-figure 4.

Adenoma Growth—Acute Study

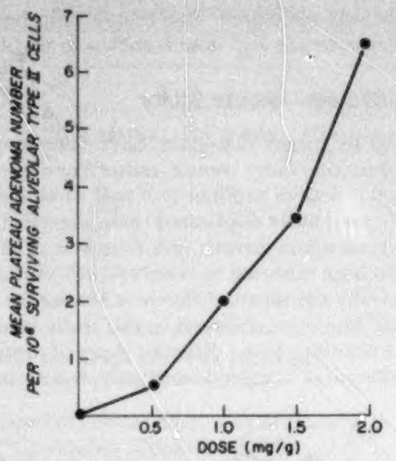
Variations in tumor diameters have been shown to be greater within the same mouse rather than among mice given an acute dose of urethan (*10*) and to be independent of sex (*11*). Our results duplicated these observations. Independence of adenoma growth rate from size of the urethan dose has also been reported by others (*8*, *10*). Although there were statistically significant differences among the geometric mean tumor diameters observed in this study in mice killed at the same time but given different doses of urethan (table 3), such differences occurred randomly and were not dose



TEXT-FIGURE 2.—Mean plateau tumor No. per animal at various single doses of urethan. Plateau tumor levels have been estimated by averaging the 3 highest averages of adenoma No. at each dose. The estimated plateau tumor levels in this study were: 0.0 mg/g, 0.2; 0.5 mg/g, 4.3; 1.0 mg/g, 15; 1.5 mg/g, 25; and 2.0 mg/g, 37. Experimental prevalence taken from the literature has been adjusted for control prevalence wherever possible. Data from White et al. (*6*) on animals given injections on the 1st and last days of the study were combined and averaged.



TEXT-FIGURE 3.—Average No. of live alveolar type II cells per lung ($\times 10^{-7}$) at different times after various single doses of urethan; *each point* represents 4 animals. *Bars* indicate ±SEM. Control level of live type II cells was 0.96×10^7 cells/lung based on 12 animals; the 95% confidence interval on the control mean is indicated in the figure. The No. of live cells is assumed to be normally distributed among animals. Mice given 1.0 mg urethan/g body wt were not examined at 42 hr.



TEXT-FIGURE 4.—Mean plateau tumor No. per 10^6 surviving alveolar type II cells at different single urethan doses. The means were calculated by division of the estimated plateau tumor No. by the No. of live alveolar type II cells, averaged over 6, 12, and 18 hr at each dose.

related. Therefore, diameters of adenomas from individual animals of both sexes and at all doses were combined at each killing time, and frequency distributions were constructed (text-fig. 5).

The distributions at 14 and 16 weeks followed a normal logarithmic pattern according to a modified Kolmogorov—Smirnov test (*19*), consistent with the apparently normal logarithmic distribution of tumor cross-sectional area (*9–11*) and volume (*12*) reported previously. An important aspect of these frequency distributions is that large fractions of the induced tumors are unobservable 3 and 4 weeks after urethan injection. The fraction of total tumors that is unobservable decreases steadily with increasing time before killing so that by 10–12 weeks virtually all tumors are observable. This phenomenon is consistent with the time needed to reach a plateau, between 10 and 14 weeks, when average tumor numbers were plotted as a function of time after urethan injection (text-fig. 1). Geometric mean tumor diameters calculated from experimental data are therefore more accurate at later killing times, because relatively more of the small tumors are observable.

Shimkin and Polissar (*9*) dealt with the problem of estimation of tumor growth rates when not all tumors were observable by eliminating small tumors from consideration and calculating the mean area of an arbitrary number of the largest adenomas. However, it is possible to calculate the geometric mean tumor diameter at early killing times more accurately by taking into account the number of unobservable tumors, if the total number of tumors induced by a single dose of urethan is known and if a normal logarithmic distribution of tumor diameters is assumed at times earlier than 14 weeks. The plateau number of adenomas induced per mouse at each urethan dose was estimated by averaging the three largest mean numbers of adenomas per mouse counted at that dose (text-fig. 2). Since construction of the frequency distributions was done without regard to dose, the total number of tumors expected in the mice sampled for tumor size at each killing time was calculated by multiplying the number of mice on each dose by the plateau number of adenomas per mouse induced by that dose and summing the products. The number of tumors observed at each killing time was then divided by this expected number of tumors to give the fraction of tumors observable at that time; that is, the probability that any given tumor would have a diameter equal to or greater than 0.1 mm—the lower limit of visible tumor diameters. The value of the expression $Z=(x-d)/\sigma$ corresponding to each observed probability was obtained directly from a standard normal distribution table. In this expression d is the mean log tumor diameter in millimeters, σ is the standard deviation of the log tumor diameter, and x in this case equals log 0.1.

The standard deviation of the log tumor diameter was estimated by averaging all experimental standard deviations. These should represent accurately the true standard deviation σ only at late killing times when virtually all

TABLE 3.—*Geometric mean tumor diameter as a function of urethan dose and killing time in the acute study*[a]

[a] Logarithms of tumor diameters were normally distributed according to the Kolmogorov-Smirnov test. Data of male and female mice have been combined.

[b] — = no mice killed at this dose and time.

[c,d,e,f] Means with identical superscripts at the same killing time are significantly different at $P=0.05$ (95% confidence interval exclusion).

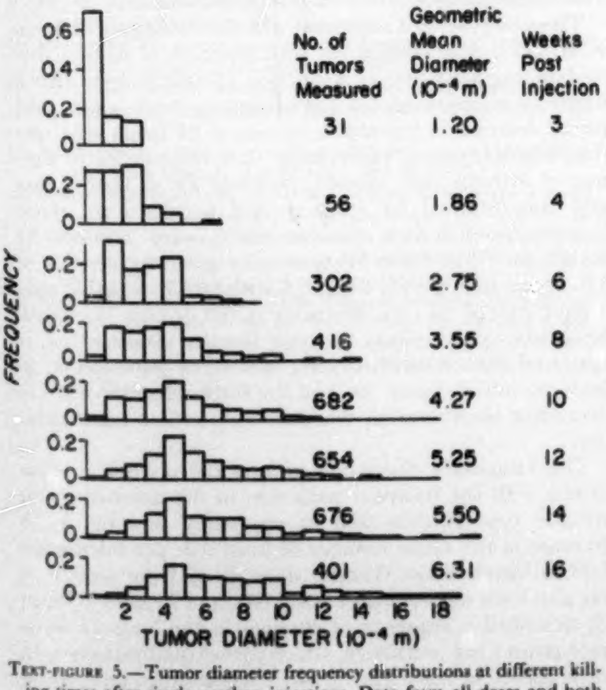
tumors are observable. Earlier killing times should yield smaller experimental standard deviations. However, table 3 suggests that experimental standard deviations varied randomly with dose and killing time except at 3 weeks where they were considerably smaller as expected. This small number of tumors (n=31) did not affect the estimate of σ when all experimental standard deviations, weighted by the number of tumors at each dose and killing time, were averaged.

The adjusted geometric mean tumor diameter at each killing time was calculated by the equation: μ=antilog d=antilog ($x-\sigma Z$). There are other methods by which true geometric mean diameter could be estimated. This technique, which utilizes not only the tumor size distribution measurements but also the estimated plateau tumor number at each dose, is simple and direct. The adjusted mean diameter calculated in this way should provide a reasonable estimate of the true geometric mean.

When these adjusted mean diameters were plotted as a function of time after injection in a double logarithmic coordinate system, the transformation gave the straight line in text-figure 6.

Adenoma Growth—Acute-Chronic Study

Geometric mean tumor diameters (not adjusted for unobservable tumors at early times) for the acute-chronic experimental groups are shown in table 2, where they are compared with the corresponding unadjusted means from table 3 for groups given only single urethan injections. These data indicate that chronic urethan administration to mice at drinking water concentrations up to 0.1% did not affect the growth rate of lung adenomas previously established by single urethan injections.



No. of Tumors Measured	Geometric Mean Diameter (10^{-4}m)	Weeks Post Injection
31	1.20	3
56	1.86	4
302	2.75	6
416	3.55	8
682	4.27	10
654	5.25	12
676	5.50	14
401	6.31	16

DISCUSSION

Adenoma Prevalence

The relationship between acute urethan dose and lung adenoma prevalence has been investigated previously. Kaye and Trainin (*7*) observed no tumors in groups of mice 12 weeks after ip injection of 0.1 or 0.25 mg urethan/g body weight. Above this experimental threshold, prevalence appeared to increase linearly with doses of 0.5 and 1.0 mg urethan/g. Shimkin et al. (*5*) also observed what appeared to be a linear response, but without threshold, in mice 18.7–22 weeks after ip injection of 0.25, 0.5, or 1.0 mg urethan/g body weight. Alternatively, within the same dose range the data of Rogers (*8*) and White et al. (*6*) can be used to construct dose-prevalence curves that are concave upward. These prevalences were observed at 9 and 24 weeks after ip injection of urethan.

These relationships are included in text-figure 2. The adenoma prevalences recorded in this study are intermediate between the higher prevalences observed by Shimkin et al. (*5*) and White et al. (*6*) in mice of the highly susceptible A-strain, and the lower ones observed by Kaye and Trainin (*7*) and Rogers (*8*) in Swiss mice lacking selectively enhanced susceptibility to pulmonary adenoma induction. The differences among these dose-prevalence curves presumably are due both to strain differences and the sensitivity and timing of the methods used to detect tumors. For example, tumors in Rogers' mice were counted at an early time and with the use of a technique that detected only surface tumors, which suggests that not all tumors may have been counted.

Urethan cytotoxicity was not considered in these studies. When cytotoxicity is taken into account, as in text-figure 4, the relationship between dose and adenoma prevalence is more nearly quadratic than linear. Since most mechanistic models of tumorigenesis suggest that prevalence should be related to the *m*th power of the dose, where *m* is the number of mechanistic stages affected by the tumorigen (*20*), the relationship shown in text-figure 4 could imply that urethan induces adenomas by a two-stage mechanism. However, independent evidence suggests that urethan acts only at one stage in the induction of mouse lung adenomas. To begin with, one dose is sufficient for the induction of tumors. Since urethan and its metabolites persist in the mouse for only slightly longer than 24 hours at these doses (*21*), to be affected by urethan, a second stage would have to occur almost immediately after the first stage. The results of divided-dose studies (*5*, *6*, *22*) are equivocal and would be consistent with a multistage mechanism of urethan tumorigenesis if cells in stages intermediate between normal cell and tumor cell were to replicate at a rate different from that of their normal neighbors. The results of chronic exposure studies, (*23*) however, provide direct support for the concept that urethan affects only one stage in murine adenogenesis.

Factors other than the mechanism of action may also contribute to nonlinearity in the dose-prevalence relationship. Stochastic models of tumorigenesis generally do not take into account interindividual variability in susceptibility to a carcinogen. Heston and Schneiderman (*24*) pointed out that variation in individual "thresholds" should confer concave upward curvature on dose-prevalence curves in low dose ranges. Regardless of the mechanism of action, therefore, some degree of upward curvature in the dose-prevalence relationship is to be expected for all carcinogens in low dose ranges. This curvilinearity should be less pronounced for dose-prevalence curves obtained with the use of highly inbred test strains and more pronounced when the test population is genetically heterogeneous. Some of the differences among dose-prevalence curves in text-figure 2 may therefore be attributable to the greater genetic heterogeneity of the Swiss mouse test groups than of the inbred A-strain test groups. Furthermore, the urethan dose range where this curvilinearity occurs is a range associated with only mild and transient urethan cytotoxicity (text-fig. 3). Therefore, it is reasonable to speculate that part of the curvilinearity in the urethan dose-lung adenoma-prevalence relationship results from variability in individual thresholds for carcinogen action.

Another explanation must be sought, however, for the curvilinearity in the dose-prevalence relationship in text-figure 4 at urethan doses greater than 0.5 mg/g, because all mice given 0.5 mg urethan or more per gram body weight developed adenomas. White (*21*) has shown that the rate of urethan metabolism in female A-strain mice is not directly proportional to dose. At doses as low as 0.25 mg urethan/g, metabolism shows signs of approaching saturation indicated by increasing persistence of radiolabel with increasing dose and by a curvilinear relationship between integrated internal dose of radiolabel and injected dose of urethan. Since only the radiolabel was monitored, it was not possible in this study to relate adenoma prevalence to persistence of either individual metabolic products or parent urethan. However, prevalence was found to be more linearly related to integrated internal exposure to radiolabel than to administered dose, at least at tumor prevalences of less than about 35 adenomas per mouse which were associated with exposures up to 1.0 mg/g in this sensitive strain.

White's data for internal dose as a function of administered dose cannot be used to transform our administered dose to internal dose because they do not extend beyond an administered dose of 1.0 mg/g and because different strains of mice were used in the two studies. Nevertheless, comparison of White's data with the data in text-figure 4 shows that the dependence of tumor prevalence on administered dose is similar in the dose range of coincidence. Thus curvilinearity in the dose-prevalence relationship at doses greater than about 0.5 mg/g may be attributable partly to nonlinearities of urethan metabolism.

Adenoma Growth Rate

Based on the fit by linear regression of the data points in text-figure 6, μ (the adjusted mean diameter) is 1.0×10^{-4} m, the size of the smallest visible tumor, at 33 days post injection. This time agrees closely with that found by Shimkin and Polissar (*9*, *10*), who observed histologically a geometric mean tumor diameter of 1.0×10^{-4} m in strain A mice and (by extrapolation) in C3H mice at about 28 days after acute urethan injection.

Extrapolation from text-figure 6 indicates that μ is 0.1×10^{-4} m, the diameter of one tumor cell (*10*), at about 7 days after urethan injection. If the extrapolated portion of the line is a good approximation to the true growth curve in the range of unobservable tumor sizes, then tumors induced by single urethan injections do not enter a phase of significant growth until several days after induction.

This observation is consistent with the findings of Shimkin et al. (*25*), who studied the incorporation of labeled thymidine into lung cells as a function of time in mice after a single ip injection of 1.0 mg urethan/g body weight. An initial decrease in thymidine uptake at 24 hours after urethan administration, expressed as thymidine index, or fraction of alveolar cells labeled, persisted for at least 3 days and was followed by recovery and a subsequent sharp increase by 5-7 days. Similar results were obtained by Kauffman (*4*) in Swiss Webster mice given ip injection of 1.0 mg urethan/g body weight. Kauffman showed that only a small part of the total alteration in cell division rate could be attributed to effects on type II cells. Nevertheless, it appeared that individual lung cell types participated in both the initial depression and the subsequent elevation of thymidine incorporation that followed urethan administration.

This temporary depression of lung cell division rate coincides with the transient reduction in the number of live alveolar type II cells seen in our study (text-fig. 3). A decrease in the mean number of lung cells per microscope field in female Swiss Webster mice given 1 mg urethan/g has also been reported previously (*4*), and Brachetto-Brian (*3*) described a sequence of changes in the lungs of Swiss mice given 1 mg urethan/g, which agrees qualitatively with the sequence in text-figure 3. Since we observed an increase in the number of dead alveolar type II cells at the same time that live type II cells were reduced in number, the reduction in live type II cells must be attributable partly to urethan cytotoxicity. However, the persistence of live type II cell reduction for several days may be related to inability of the lung to respond to the deficit with an increase in the rate of cell division during this period. Thus it is reasonable to speculate that, although single adenoma cells appear shortly after urethan injection in mice, their period of rapid replication with consequent measurable adenoma growth does not begin, on the average, until several days later. This lag time is associated with inhibition of cell division, a cytotoxic effect of urethan probably not directly related to its tumorigenic action (*25*).

Rogers (*8*) gave multiple urethan doses to Swiss mice 7 weeks apart to avoid any possible extension of influence of the first urethan dose to the time of the second, but he did not sample the lungs until 8 weeks after the last injection. His conclusion that multiple injections did not result in adenomas of generally larger size was based on the largest observed tumor size coupled with a crude tumor diameter breakdown. Other investigators (*5, 6*) have also given multiple injections of urethan to mice. In none of these studies has the effect of total urethan dose, as related to the total number of adenomas and the timing of their appearance, been distinguishable from an effect of urethan on adenoma growth rate. The experimental design utilized in our study allows such a distinction to be made and indicates that adenoma growth rate in mice is independent of chronic urethan exposures of up to 0.1% in the drinking water.

Relationship Between Urethan Dose Rate and Adenoma Latency: Relevance of Tumor Growth Rate and Target Cell Number[1,2,3,4]

Ellen J. O'Flaherty[5] *and* Michael L. Dourson[5,6]

ABSTRACT—Outbred Swiss Cox mice of both sexes were chronically exposed to urethan added to their drinking water at levels of 0.02–0.10% by weight. The number and sizes of lung adenomas that developed as a result were monitored as functions of time and dose rate (DR). The relationship between dose per unit time, or DR, and time (t_1) needed for the development of a mean of one observable tumor per mouse was: $DR \times t_1^n = K$, where K and n are constants. The value of n was 2.75. This value could be largely accounted for by the DR-independent tumor growth time, although an increase in the number of target cells at higher urethan dose rates may also be a factor in the relationship between DR and t_1. Examination of the relationships between cumulative incidence and DR and between cumulative incidence and adenoma induction time suggests that urethan acts at one stage of a two-stage mechanism in the induction of mouse lung adenomas.—JNCI 1982; 69:859–865.

It has been firmly established that for chronic exposure to chemical carcinogens in general, the effects of DR and time are not equivalent; that is, cumulative tumor incidence associated with a given total carcinogen exposure is not constant but is dependent on whether exposure was low and continued over a long period of time, or was high and took place over a short period. The relationship was expressed by Druckrey (*1*) as: $DR \times T_{50}^n = K$, where DR is dose rate, T_{50} is the time to reach 50% tumor prevalence in the study population, K is a constant, and n is a constant but not necessarily an integer. The value of n varies among carcinogens. If n were equal to 1, prevalence would be directly proportional to total dose. For chemical carcinogens, $n>1$; that is, the effect of time dominates the effect of dose (*1, 2*).

With the exclusion of any contributions by nonlinearities of metabolism or by age-related changes in the host, the Druckrey effect might be the result of either alteration in size of the target cell population at higher dose rates as a result of cytotoxicity, or of dose-independent tumor growth rate. The second hypothesis is particularly interesting since it deals with tumor latency, a feature of carcinogenesis whose incorporation into regulatory decision-making processes is still a subject of controversy.

Latent period is the time from initial administration of the carcinogen to initial observation of the neoplasm. It consists of the induction time, or time needed to transform a normal cell into a tumor cell, and the growth time, the time until the tumor reaches minimum detectable size. Direct proportionality between cumulative incidence, expressed as mean number of tumors per mouse, and total dose would require both induction time and growth time to be inversely proportional to DR. This is, however, not likely to be the case. In particular, most investigators assume that mean tumor growth rate is independent of DR (*3*). The specific test system of interest to us is the urethan-induced mouse lung adenoma. For this test system there is experimental support for the independence of tumor growth rate from DR. The growth rate of adenomas induced by urethan exposure is independent of either acute dose (*4, 5*) or chronic DR (*5*).

The specific aims of this study were to determine whether in the urethan-induced mouse lung adenoma test system the Druckrey effect can be accounted for on the basis of DR independence of tumor growth rate and/or an alteration in size of the target cell population at higher DR of urethan. Some of the data accumulated in the course of this work also have direct bearing on the kinetics of the mechanism of urethan adenogenesis.

MATERIALS AND METHODS

Mice.—Outbred Swiss Cox mice (Laboratory Supply Co., Indianapolis, Ind.) were used to establish a breeding colony. The animals were fed Rodent Laboratory Chow (Purina 5001; Ralston Purina Co., St. Louis, Mo.) and tap water ad libitum and were housed in standard stainless steel cages, up to 5 mice per cage. The animals were maintained on a 12 hour light–12 hour dark cycle.

Chronic study—rate of appearance and growth of lung adenomas.—Mice of both sexes, 41–45 days old, were given distilled water ad libitum to which different amounts of urethan were added to yield several concentrations by weight (0.02, 0.05, or 0.10%). Five males and 5 females from each dose rate group were killed at 4, 6, 8, 10, 12, or 14 weeks after the start of treatment. The 31 controls were given distilled water ad libitum, and the intake was monitored regularly. Immediately after the mice were killed, their lungs were excised

---

ABBREVIATIONS USED: DR=dose rate(s) [dose(s) per unit time]; t_1=time(s) of appearance of a mean of 1 observable adenoma per mouse; t_g=growth time from one adenoma cell to a mean of 1 observable adenoma per mouse; t_i=time(s) required for induction of a mean of one adenoma cell per mouse; T_{50}=time to reach 50% tumor prevalence in a study population; TD_1=total dose(s) at t_1; TD_i=total dose(s) at t_i.

and expanded with Tellyesniczky's fixative. The expanded lobes were later separated and cleaned and viewed on a lightbox for counting and sizing of adenomas according to the procedure described previously (*6*).

Chronic study—lung type II cell population size response.—Mice of both sexes, 41–45 days old, were given distilled water ad libitum to which different amounts of urethan were added to yield 0.02, 0.05, or 0.10% concentrations by weight. Three to 6 mice from each DR group were killed at 2, 6, 8, 10, 11, or 12 weeks after initiation of treatment. There were 8 control mice.

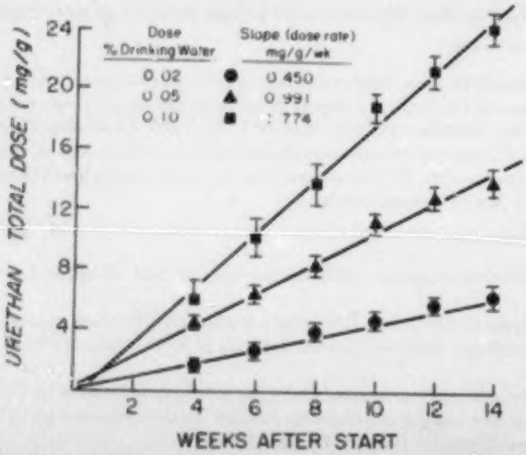
For the purpose of this study, the lungs were expanded with cold double aldehyde fixative before being embedded in plastic and sectioned at 1–2 µm to observe the number of live, borderline, or dead type II cells after the various treatments. The techniques have been given previously (*5*).

RESULTS

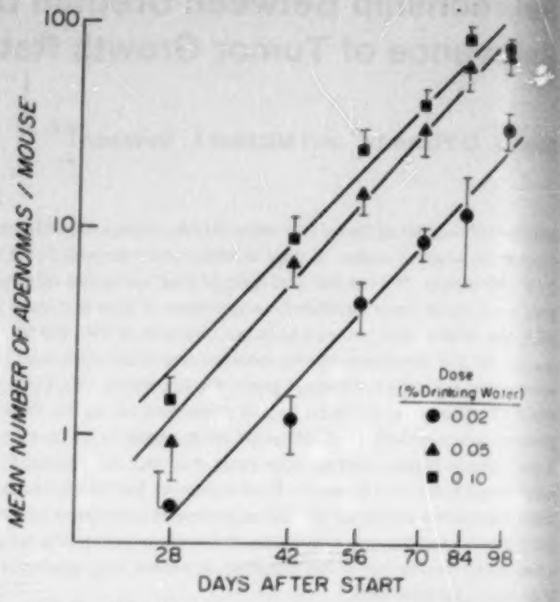
Dose rates.—The total amount of urethan ingested per gram of body weight increased linearly with the length of time of continuous urethan administration in the drinking water (text-fig. 1). The slopes of the lines are expressed in milligrams of urethan per gram body weight per week; that is, they are the DR. These DR are not directly proportional to concentration in these drinking water because the mice drank less water when the urethan concentration was high.

Mean tumor number.—The tumor number per animal had a normal distribution among experimental animals. Accordingly, we used arithmetic means in all calculations that involved tumor number. Mean tumor numbers were related to both dose and time during chronic urethan administration. An average of 0.03 adenomas/mouse was observed for control mice at all killing times. This value was so low that mean tumor numbers at other dose rates were not corrected for control prevalence. Text-figure 2 shows that the relationship between mean tumor number per animal and time was linear in a log–log coordinate system and that the lines for the three DR appeared to be parallel.

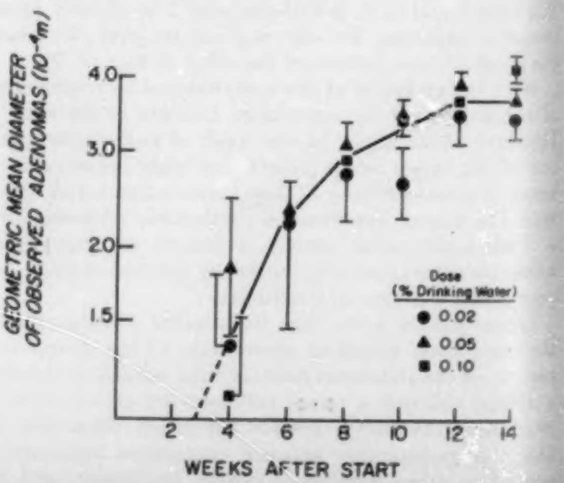
Mean tumor growth rate.—Comparison of the geometric mean diameters of observed adenomas at different single killing times showed that there was no significant systematic



TEXT-FIGURE 1.—Total urethan dose as a function of time after the start of chronic administration to mice. Total doses were calculated from water consumption rates of individual mice. *Each point* represents data from 10 animals. *Bars* indicate the 95% confidence interval. Lines are fit by linear regression. Slopes of these lines represent the urethan dose rates in mg/g body wt/wk.



TEXT-FIGURE 2.—Mean No. of lung adenomas/mouse at different times during chronic exposure to urethan. Data are plotted in a log–log coordinate system. *Each point* represents data from 10 animals. *Bars* indicate ±SEM. Lines are fit by linear regression. From these lines, extrapolated in the case of the highest DR, the times to the appearance of a mean of 1 adenoma/mouse are estimated.

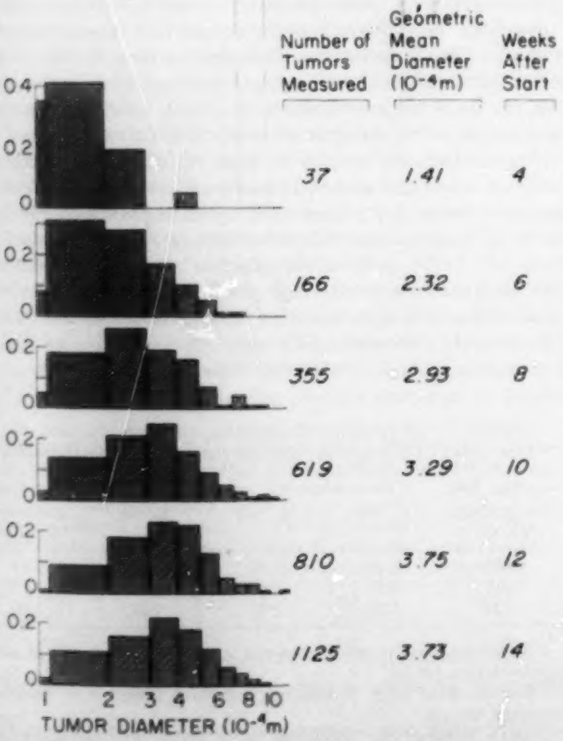


TEXT-FIGURE 3.—Geometric mean diameters of observed lung adenomas at different times during chronic exposure of mice to urethan are plotted in a log linear coordinate system. The 95% confidence intervals for the points are shown where possible. *Solid line* connects geometric means calculated over all doses. *Dashed line* shows the extrapolation to a geometric mean diameter of 0.1 mm, the size of the smallest observable adenoma.

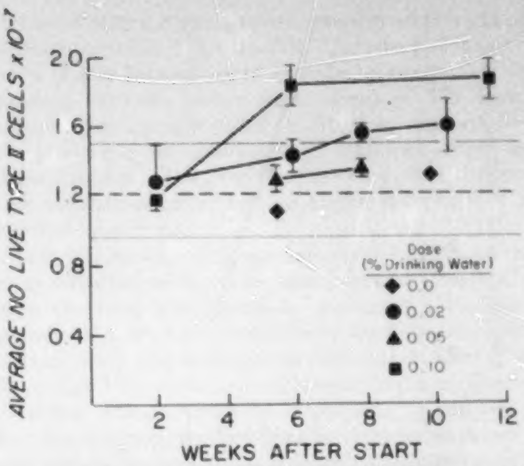
dependence of geometric mean tumor diameter on DR (text-fig. 3). Accordingly, we combined tumor diameter data for all DR at each killing time. Tumor diameters appeared to have a normal logarithmic distribution at intermediate killing times (text-fig. 4) (*5*). At earlier or later killing times, these distributions were skewed to the left, presumably due either to the large fraction of unobservable (<0.1 mm in diameter) tumors (at early times) or to the continual influx of smaller tumors (at later killing times).

Number of live type II cells.—The number of live alveolar type II cells per lung increased by 50% between 2 and 6 weeks after the initiation of chronic urethan administration at 0.1% in the drinking water. After this time the number of live type II cells per lung reached a plateau at 1.83×10^7 (text-fig. 5). In mice given 0.02% urethan in the drinking water, the number of live alveolar type II cells per lung also showed a time-related increase (text-fig. 5), reaching 1.57×10^7, 28% above control values, at 10 weeks after the start of urethan administration. The number of live alveolar type II cells per lung in mice given 0.05% urethan, however, remained within the control range instead of reaching an intermediate level between the numbers associated with the other two DR.

The number of dead and borderline type II cells also increased relative to control values during chronic administration of urethan.



TEXT-FIGURE 4.—Lung adenoma diameter frequency distributions at various killing times after the start of chronic urethan treatment. Data from all dose groups were combined for the purpose of calculation. Killing time, in wk after start of treatment, is given with each distribution.



TEXT-FIGURE 5.—Average No. of live alveolar type II cells/lung at different times during chronic exposure to urethan. *Each point* represents data from an average of 4–5 mice. *Bars* indicate ±SEM. *Dashed line* represents the control mean of 1.23×10^7 cells; *horizontal, solid lines* indicate the 95% confidence interval around the control value. No. of live cells is assumed to be normally distributed among animals.

DISCUSSION

The data for mouse lung adenoma induction by urethan exemplify the Druckrey effect. When total dose is calculated by multiplying the observed time to a mean of 1 adenoma, t_1 (text-fig. 2), by the DR (text-fig. 1), it is found not to be constant for the selected prevalence of 1 observable adenoma per mouse (table 1). Therefore, prevalence is not directly proportional to total dose, and n is not equal to 1.

One can find the value of n for this test system by taking advantage of the Druckrey equation $\log \text{DR} = \log K - n \log t_1$ and by plotting log DR against log t_1 as shown in text-figure 6. Note that time to a mean of 1 tumor, from text-figure 2, is used here as the equivalent of T_{50}, the time to occurrence of 1 tumor in 50% of the study population. As long as tumor numbers are normally distributed, this alternative is justified. Furthermore, since the lines in text-figure 2 are roughly parallel, and since total urethan dose is linearly related to time (text-fig. 1), values of n calculated from times to different mean numbers of tumors should be about the same. If the lines in text-figure 2 were parallel, the choice of the number of tumors would not affect the value of n at all. The value of n (text-fig. 6) is 2.75. This value is consistent

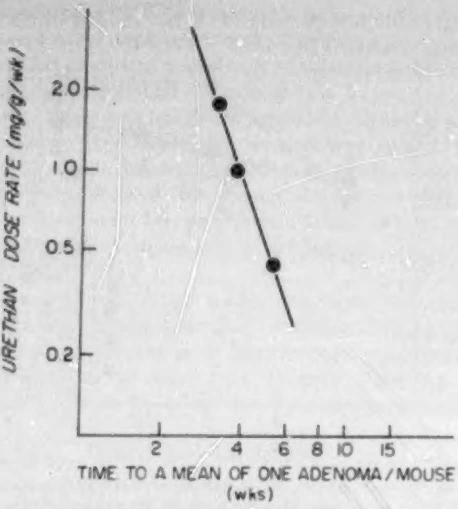
[a] Time required for appearance of a mean of 1 observable adenoma/mouse=latent period.

[b] Total exposure at the time of appearance of a mean of 1 observable adenoma/animal; DR×t_1.



TEXT-FIGURE 6.—Relationship of urethan dose rate to the latent period, or time to a mean of 1 observable adenoma/mouse. The line was fit by linear regression; absolute value of its slope, 2.75, equals the value of *n*.

with those calculated for other chemical carcinogens, most of which fall in the range 2–4 (*2*).

Text-figure 3 shows that adenoma growth rate is independent of urethan DR in these mice rather than being inversely proportional to DR as would be required if *n* in the Druckrey equation were equal to 1. Therefore, it is of interest to determine whether adenoma prevalence is proportional to total dose calculated to the time of appearance of a mean of one adenoma cell per mouse, rather than to the time of appearance of a mean of 1 observable adenoma per mouse. One can estimate the time of appearance of a mean of one adenoma cell per mouse by subtracting from the total latent periods (table 1) the mean growth time from 1 adenoma cell to 1 observable adenoma per mouse, which can be approximated from the adenoma growth rate data (text-fig. 3).

As noted, tumor diameter distributions reflecting adenoma growth rates were generally not of a normal logarithmic nature but were skewed to the left, particularly at earlier and later killing times, as a result of both the left truncated nature of these distributions and the continual influx of small tumors. There is some question regarding the most appropriate measurement of the central tendency of these skewed distributions, and as to whether these measurements should be adjusted either because the distributions are skewed or because of the presence of unobservable (<0.1 mm) tumors, as was done previously (*5*). The geometric mean appears to be a reasonable measure. In this case, however, we did not make adjustments to the geometric means for unobservable tumors because we could not determine the total number of tumors induced by urethan in this experimental design, and, therefore, the ratios of unobservable tumors to total tumors at different killing times were unknown. The means also were not adjusted for the continued influx of induced tumors either. This influx affected the geometric means of tumors principally at later killing times. As described below, we used adenoma size data only of groups that were killed early in the approximation of the mean adenoma growth rate from 1 adenoma cell to 1 observable adenoma per mouse.

Originally, it was thought that the adenoma growth curve from the acute study (*5*), which was adjusted for the fraction of unobservable tumors, could be used to approximate the adenoma growth rate from 1 adenoma cell to 1 observable adenoma per mouse. This seemed quite reasonable in light of the fact that adenoma growth rate is independent of both acute and chronic urethan dose (*5*). This approximation, however, failed to take into account that the total latent periods observed in this study were almost certainly determined by a subpopulation of fast-growing tumors. Therefore, the average adenoma growth rate obtained in the acute study, which adequately described the data for all tumors (whether observable or not), should not be expected to be applicable in this situation. Additional work is being done to characterize the growth rates of adenomas during chronic urethan exposure.

The chronic adenoma growth curve (text-fig. 3) is not linear in any of the common coordinate systems. Since there is no theoretical reason to give preference to any of these transformations, a growth time of 18.6 days or 2.65 weeks from one cell to a mean of 1 observable tumor was approximated by extrapolation of the line determined by the geometric mean values at 4 and 6 weeks in text-figure 3. As a practical matter, it is not particularly important whether this extrapolation is done in a log linear (as done here), in a log–log, or in a linear coordinate system. Extrapolation of a log–log plot yields a growth time of 17.5 days; extrapolation of a linear (arithmetic) plot yields a growth time of 19.3 days. Although the magnitude of these differences does alter the results of the calculations in the following paragraphs, it does not affect the general conclusions of this study.

Subtraction of the growth time of 2.65 weeks from one cell to a mean of 1 observable tumor from the latent periods given in table 1 results in the times to development of a mean of 1 adenoma cell per mouse, or induction times, at each DR (table 2). When the appropriate DR and induction times are multiplied with each other, the resulting calculated total doses (TD_i) associated with one transformed type II cell actually decrease, although very slightly, as DR is increased. Table 2 summarizes these calculations.

TABLE 2.—*Dependence of adenoma induction time and the associated TD_i on urethan DR during chronic administration*

Urethan DR, mg/g body wt/wk	t_l,[a] wk	t_g,[b] wk	t_i,[c] wk	TD_i,[d] mg urethan/g body wt
0.450	5.28	2.65	2.63	1.18
0.991	3.79	2.65	1.14	1.13
1.774	3.25	2.65	0.60	1.06

[a] Time required for appearance of a mean of 1 observable adenoma/mouse=latent period.

[b] Growth time from 1 adenoma cell to a mean of 1 observable adenoma/mouse.

[c] Time required for induction of a mean of 1 adenoma cell/mouse=induction time.

[d] Total exposure at the time of appearance of a mean of 1 adenoma cell/mouse; DR×t_i. The relationship among the three time periods is $t_l=t_g+t_i$.

However, the effect of urethan on the number of type II lung cells should also be taken into account in this calculation. If it is assumed that the probability of tumor induction by a given amount of carcinogen is directly proportional to the number of susceptible cells, then, when more cells are present, a relatively smaller total amount of carcinogen should be required on the average to induce the same number of tumors. Therefore, as target cells increase in number at higher dose rates, the TD_i would be expected to decrease. This is, in fact, the direction of the trend in the calculated TD_i values in table 2. Any adjustment to TD_i made on the basis of the plateau number of type II cells in the lung cannot be better than an approximation, since plateau levels of type II cells were not reached before the 6th or 8th week of chronic urethan administration (text-fig. 5), although many of the adenomas registered had been induced well before this time. Nevertheless, it is worthwhile to determine whether an adjustment with the use of plateau numbers of target cells would be of the right order of magnitude to account for the rather slight trend in TD_i in table 2.

Adjustment for the plateau number of target cells presents the problem that the intermediate urethan dose, 0.991 mg/g body weight/week, showed anomalous behavior with respect to type II cell induction; that is, it did not appear to increase the number of type II cells at all. This behavior is inconsistent with the effect of this DR on the more general index of increased cellularity, percent increase in lung weight, which was intermediate between the effects of the other two doses. The degree of type II cell induction by the highest DR of urethan appears to be a reliable figure since it is very close to the value reported by Kauffman (*7*), who observed a 60% increase in the number of live type II cells per lung between 3 and 8 weeks after the start of chronic urethan administration at 0.1% in the drinking water of Swiss Webster mice. The number of cells reached a plateau at about 1.8×10^7 per lung. Therefore, a fractional increase in the number of type II cells was interpolated for the intermediate dose rate as indicated in table 3.

The fractional increases in target cell numbers at different DR of urethan can be used to adjust calculated TD_i to a control number of target cells. These calculations are summarized for all urethan DR in table 3. They demonstrate that adjustment of TD_i to the plateau numbers of target cells causes only a slight alteration in the magnitude of any systematic trend in TD_i with DR. The effect of the number of type II cells is therefore of an order of magnitude that is consistent with the rather slight trend in TD_i with DR observed in this study (table 2). Thus it appears that the value of *n* in this test system can be explained largely by the independence of DR of tumor growth time, with the increase in the number of target cells at higher urethan DR being much less important.

TABLE 3.—*Dependence of TD_i adjusted for the urethan dose-related increase in steady state type II cell population, on urethan DR during chronic administration*

Urethan DR, mg/g body wt/wk	TD_i,[a] mg urethan/g body wt	Plateau level of type II cells relative to control	TD_{ic},[b] mg urethan/g body wt
0.450	1.18	1.285	1.52
0.991	1.13	1.407[c]	1.59
1.774	1.06	1.496	1.59

[a] Required to induce a mean of 1 adenoma cell/mouse (from table 2).

[b] Needed if type II cells had not increased with higher DR (i.e., adjusted to control level of type II cells).

[c] This value is not an experimental value. It was interpolated from an analysis of lung weights at all DR and plateau levels of type II cells at the other two values.

Other factors, such as dose-dependent kinetics of carcinogen metabolism or excretion, alterations in host sensitivity during the long latent periods associated with very low exposure rates, or severe cytotoxicity leading to uncompensated cell death and reduction in the total number of target cells at high DR, could also contribute to the production of a Druckrey effect. Aging, as it pertains to the Druckrey effect, has not been studied directly. Studies of tumor incidence and tumor growth in animals of different ages have produced ambiguous and sometimes conflicting results (*6, 8, 9*).

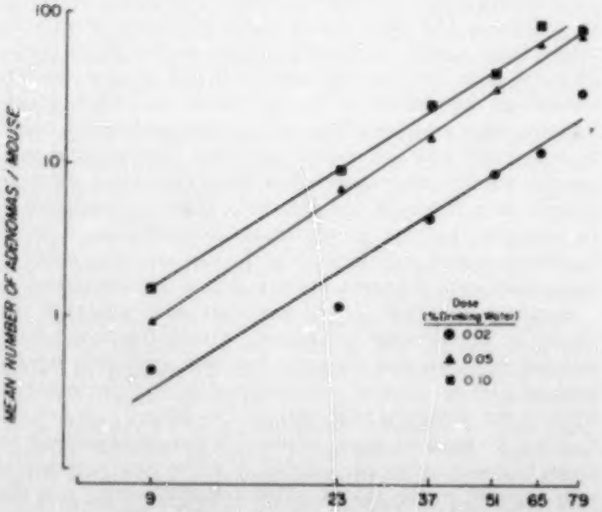
Some of these factors could operate to reduce, rather than increase, the value of *n*. For example, an increase in the number of target cells with increasing DR, as shown in this experiment, would produce a value of $n<1$ in the absence of any other contributory factors. Similarly, *n* should be less than 1 if metabolism of the active carcinogen to inactive forms approached saturation at higher chronic exposure rates. The observation that generally $n\geq1$ with chemical carcinogens may provide some insight into the relative importance of factors that would tend to decrease the value of *n*.

Selective growth of transformed but precancerous cells is an additional factor that has received much attention. Selective growth advantage is a mechanistic equivalent of the "reinforcing action" to which Druckrey attributed the effect he observed. The idea that a clone of precancerous cells might enjoy a selective growth advantage was given mathematical form by Armitage and Doll (10) so that the observed age dependence of human cancer incidence, which in many cases suggests a five- or six-stage mechanism, could be reconciled with the absence of direct experimental support for mechanisms of more than two stages. Since selective growth as a factor in the Druckrey effect is restricted to carcinogens that act in multistage mechanisms, it is of interest to examine the kinetics of the mechanism of urethan tumorigenesis as expressed in the results of the present study.

Armitage and Doll (*11*) showed that development of the model for a multistage mechanism of tumorigenesis, with *r* number of stages and constant (but not necessarily equal) probabilities $p_1 \ldots p_r$ of occurrence of each of the *r* stages, leads to the predicted relationship: $I = Np_1p_2 \ldots p_r\, t_i^r/r! = k\, t_i^r$ or $\log I = \log k + r \log t_i$, where *I* is tumor prevalence or mean tumor number per animal, *N* is the total number of cells exposed to the risk of a first transformation, t_i is the induction time, and *k* is a constant, at fixed DR, characteristic of a particular value of *r* with its associated product of probabilities. The *r* can be equated with the number of stages in the tumorigenesis mechanism only if there is no Druckrey effect (i.e., if $n=1$).

A linear relationship between log *I* and log *t* has been demonstrated in many other studies of the occurrence of cancer in human (*11*) and experimental animal (*2*) populations, although generally in these analyses tumor growth time has been assumed to be negligible, and t_i has been taken to be equivalent to the time t at which the tumors induced by time t_i were actually observed. Induction times can be estimated for the cumulative tumor incidence measurements of the present study, however, by subtraction from each killing time of the growth time from 1 adenoma cell to a mean of 1 observable adenoma per mouse, 2.65 weeks (table 2). When this is done, the log t_i–log I relationships take the form shown in text-figure 7. Since this transformation of the data effectively eliminates the Druckrey effect in this test system, the slopes of these lines should represent the value of r, the number of stages in the tumorigenesis mechanism. The mean slope of the three lines in text-figure 7 is 1.97. Thus the value of r is consistent with the premise that there are two stages in the mouse lung adenogenesis mechanism.

Urethan, however, need not act at both of these stages. Whatever the total number of stages in a multistage mechanism, the number m induced by the carcinogen should be given by the slope of a graph of log cumulative incidence against log DR at a fixed time: log I=log k_t+m log DR, where k_t is a constant, as shown by Whittemore (*3*). The value of m can therefore be determined directly from plots of log I, log DR at a fixed time. When the three data points for the three DR at each of the six killing times of the present study are fit by linear regression and the slopes are calculated and averaged, the value of the mean slope is found to be 1.1. Thus these data suggest that urethan acts at only one stage of the adenogenesis mechanism. The kinetic data are therefore in agreement with independent evidence that has led to the consensus that urethan acts at only one stage in the induction of mouse lung adenomas. This evidence, principally from acute studies, includes both the observation that urethan and its metabolites persist in the body only for a short period of time and the nature of the relationship between cumulative adenoma incidence and total acute dose. Deviations from linearity in the acute dose, cumulative incidence relationships reported by us (*5*) and by others may be explained by variations in susceptibility to the tumorigenic action of urethan and by dose-dependent urethan elimination kinetics. The mouse lung adenoma may be considered a special case with regard to the order of the tumor induction mechanism since mice display a high spontaneous incidence, which suggests that the transformation effected by urethan may occur in conjunction with a spontaneously occurring transformation.



TEXT-FIGURE 7.—Mean No. of lung adenomas/mouse plotted in a log–log coordinate system as a function of the mean induction time, or the time at which that No. of tumors had been induced as single adenoma cells. *Each point* represents data from 10 mice. Lines are fit by linear regression; mean value of their slopes is 1.97.

The urethan-induced mouse lung adenoma lends itself to this type of investigation because, first, urethan affects only one stage of the adenogenesis mechanism; and second, a large fraction of the latent period can be assigned to tumor growth. It would be of interest to extend this type of analysis to a tumor test system for which induction, not growth, represents the greater part of the latent period. Rat liver carcinogenesis by diethylnitrosamine is one example. This test system is apparently analogous to the lung adenoma test system in that development of identifiable hyperplastic foci of altered cells precedes the appearance of liver carcinoma. For induction of these hyperplastic foci, m is apparently equal to 1 (*12*).

Additional possibilities present themselves with test systems whose mechanisms involve more than one carcinogen-related stage. The diethylnitrosamine-induced liver carcinoma and urethan-induced lung adenocarcinoma are interesting in this context, since induction of rat hepatic carcinoma requires continuing exposure to diethylnitrosamine while mouse lung adenocarcinomas appear after a long latent period following a single exposure to urethan.

Tumor Cell-Triggered Macrophage-Mediated Suppression of the T-Cell Cytotoxic Response to Tumor-Associated Antigens.

I. Characterization of the Cell Components for Induction of Suppression[1,2]

Chou-Chik Ting[3,4] *and* **Dennis Rodrigues**[3,5]

ABSTRACT—A tumor cell-triggered macrophage-mediated suppressor mechanism was demonstrated. It suppressed the induction of specific tumor immunity in the syngeneic, primary mixed lymphocyte tumor cell culture reactions. Preexposure of splenic adherent cells (SAC) to syngeneic FBL-3 tumor cells induced complete suppression of the generation of cytotoxic T-cells. The SAC responsible for inducing suppression were consistent with being macrophages. They were resistant to the treatment of anti-Thy-1.2 antibody plus complement and were relatively radioresistant (at least ≤750 R X-radiation). Adherent cells obtained from lymph nodes or thymuses acted in the same way as SAC. However, preexposure of peritoneal adherent cells to tumor cells failed to induce suppression. In contrast, the simultaneous presence of peritoneal adherent cells with SAC upon exposure to tumor cells prevented the induction of suppression. These peritoneal cells were also consistent with being macrophages. These results confirmed our previous observations obtained with experiments performed in the allogeneic system. An immunoregulatory circuit existed between two subsets of macrophages that were derived from the population of cells in the peritoneal cavity and from spleen, lymph nodes, or thymus. In the presence of tumor cells, these macrophages produced both positive regulation and negative regulation of the T-cell-mediated cytotoxic response against syngeneic tumor cells. The tumor cells may have utilized the host's own immune network to activate the suppressor mechanisms, thus successfully evading the host's immune surveillance.—JNCI 1982; 69:867–872.

It has been demonstrated in various systems that tumor cells or their products can be immunosuppressive (*1*). The mechanisms for the induction of suppression by tumor cells are still not well understood. In our recent studies we have demonstrated that there may be a unique suppressor mechanism that is mediated by tumor cells via macrophages (*2*, *3*). When a population of macrophages of splenic origin is preexposed to a nonsuppressive dose of tumor cells, generation of CTL in the allogeneic MLC reactions is completely suppressed by further addition of another population of macrophages derived from the peritoneal cavity. There is a strict requirement for the preexposure of splenic macrophages to tumor cells for the induction of suppression. Not only does preexposure of PM to tumor cells fail to induce suppression but also the simultaneous presence of PM with SAC will preclude the induction of suppression by tumor cells (*3*).

To further determine whether this tumor cell-triggered macrophage-mediated suppressor mechanism may operate in the induction of specific tumor immunity, we extended the study to the syngeneic system. We have examined the interactions between two subsets of macrophages (splenic and peritoneal) and tumor cells and their effect on the generation of a T-cell-mediated cytotoxic response in the primary syngeneic MLTC reactions.

MATERIALS AND METHODS

Mice.—Female C57BL/6 (B6) mice 2–5 months of age were obtained from the Small Animal Section, Veterinary Resources Branch, Division of Research Services, National Institutes of Health.

Tumor cells.—Four cultured tumor lines were used: a Friend virus-induced leukemia FBL-3 (*4*) and a benzo[*a*]pyrene-induced leukosis EL-4 (*5*), both of $H\text{-}2^b$ haplotype, and a Friend virus-induced leukemia HFL/d (*6*) and a 3-methylcholanthrene-induced sarcoma Meth A (*7*), both of $H\text{-}2^d$ haplotype. All tumor lines were adapted to grow in suspension tissue culture and were maintained in RPMI-1640 medium containing 5% FBS (Grand Island Biological Co., Grand Island, N.Y.).

MLTC reactions.—MLTC reactions were performed by a technique similar to that developed by Nabholz et al. (*8*). The culture medium was RPMI-1640 containing 5% FBS, 5×10^{-5} *M* 2-mercaptoethanol (Sigma Chemical Co., St. Louis, Mo.), and 2×10^{-2} *M* HEPES[6] buffer solution (Media Unit, National Institutes of Health). The responding cells (responders) were spleen cells obtained from normal B6 mice. The stimulators were 10,000-R X-irradiated B6 FBL-3 tumor cells. The spleen cells were pressed gently in HBSS containing 5% FBS and passed through two layers of cotton gauze for preparation of single cell suspensions. They were

treated with ammonium chloride–potassium lysing buffer (NH_4Cl, 0.155 M; Na_2EDTA, 0.1 m*M*; $KHCO_3$, 0.01 *M*) for 2 minutes at 4°C for removal of erythrocytes. The responders were always suspended in culture medium at a final concentration of 1.5×10^6/ml. They were incubated either alone (control culture) or with stimulators at an R:S of 150:1. Each flask usually contained 10 ml of cultured cells. All cultures were established in 30-ml tissue culture flasks (Falcon Plastics, Oxnard, Calif.) and incubated in an upright position at 37°C in a humidified atmosphere containing 5% CO_2. After 6 days of being cultured, the cells were counted, washed once, and resuspended in RPMI-1640–10% FBS at the appropriate concentrations to be tested in the $[^{125}I]$IdUrd release assay for cell-mediated cytotoxicity.

Preparation of adherent cells from spleen, lymph nodes, or thymus.—The adherent cells were obtained by the method described by Cowing et al. (*9*) with some modification. Spleen cells, pooled lymph node cells (cervical, axillary, and inguinal), or thymocytes at 1×10^7/ml in RPMI-1640 medium–5% FBS were incubated in T30 flasks in an upright position at 37°C for 2 hours in a 5% CO_2 atmosphere. The nonadherent cells were removed by three washings with HBSS containing 5% FBS.

Preparation of PC.—The PC were obtained by irrigation of the peritoneal cavity with HBSS containing 5% FBS.

Removal of phagocytes by the carbonyl iron and magnet technique.—PC (1–3×10^7) were preincubated with carbonyl iron particles (Technicon Instruments Corp., Tarrytown, N.Y.) for 1 hour at 37°C; the phagocytes were then removed with a magnet. This treatment could remove over 99% of the phagocytes as shown by the latex bead ingestion assay.

Treatment with anti-Thy-1.2 antibody.—Monoclonal anti-Thy 1.2 antibody was purchased from New England Nuclear Corp. (Boston, Mass.) and was designated as "NE001." Usually, each 1×10^7 spleen cell was incubated with 0.1 ml of the anti-Thy 1.2 antibody at a 1:100 dilution for 30 minutes at room temperature. The spleen cells were washed and then incubated a second time with 0.1 ml of a nontoxic rabbit serum at a 1:5 to 1:10 dilution as the source of complement. They were then washed, counted, and resuspended to the appropriate concentration. This treatment eliminates all the proliferative response to the T-cell mitogens concanavalin A and phytohemagglutinin, with increases of twofold to threefold of proliferative response to the B-cell mitogen lipopolysaccharide.

Cell-mediated cytotoxicity assay.—The $[^{125}I]$IdUrd release assay was used to measure cell-mediated cytotoxicity. The details of the technique have been described elsewhere (*10*). $[^{125}I]$IdUrd-labeled FBL-3 target cells (0.05 ml) at 1×10^5/ml and effector cells (0.15 ml) at an appropriate concentration were added to the wells of MicroTest II plates. All effector cells were adjusted to contain the same number of viable cells for each E:T. Incubation was done at 37°C in a 5% CO_2 atmosphere for 18–24 hours. Then the cells and supernatants were harvested by MASH II (M.A. Bioproducts, Walkersville, Md.). The supernatants and cell pellets were collected separately, and their radioactivity was determined in a well-type gamma scintillation counter. The results were expressed as total percentage of lysis and net percentage of lysis according to the following formulas: Total percent lysis=[cpm in supernatant/ (cpm in supernatant + cpm in cells)] × 100, and net percent lysis=total percent lysis obtained with responders incubated with stimulators − total percent lysis obtained with responders incubated alone. The standard errors obtained with total percent lysis were usually between 0.5 and 3%.

RESULTS

Restoration by PC of the T-cell-mediated cytotoxic response in primary, syngeneic MLTC reactions.—It has been demonstrated that FBL-3 cells have persistently failed to induce primary cytotoxic response both in the allogeneic and syngeneic MLTC reactions. However, the immunogenicity of FBL-3 cells could be restored by the addition of small amounts of PC syngeneic to the responders (*11–13*). When studying the time course relationship between the addition of PC and the restoration of cytotoxic response, we have found that if PC were added at 4 hours or later after starting the MLTC, the cytotoxic response could no longer be restored. Two representative experiments are shown in table 1. This finding is consistent with our results obtained in the allogeneic MLC experiments. In the presence of a nonsuppressive dose of tumor cells, addition of PC at a later time (1 day after MLC was started) induced suppression (*2*). Therefore, we performed further experiments to determine whether the same mechanism also operates in the syngeneic system, i.e., cytotoxic response against tumor-associated antigens.

Suppression of T-cell-mediated cytotoxic response by preexposure of SAC to FBL-3 tumor cells.—Experiments performed in the allogeneic MLC have shown that the macrophage-mediated suppression requires the collaboration of two subsets of macrophages (splenic and peritoneal) and the preexposure of splenic macrophages to tumor cells (*2, 3*). Similar experiments were performed to determine whether this was also true in the syngeneic MLTC. Results obtained from four representative experiments are shown in table 2. With addition of 10% syngeneic PC, primary MLTC could generate 20–50% of cytotoxicity against syngeneic FBL-3 tumor cells (group 2). However, if SAC were first prepared and preexposed to FBL-3 cells prior to the MLTC reactions (group

[a] At 0 hr SAC were prepared by incubation of 1×10^7 normal B6 spleen cells in T30 flasks in an upright position.

[b] After 2 hr the nonadherent cells were removed by three washings with HBSS containing 5% FBS. In group 3, 2 ml lymphocyte culture medium was added to the T30 flask containing SAC. In group 4, 10,000-R X-irradiated FBL-3 tumor cells (XFBL-3) were added at 1.0×10^5/2 ml (equivalent to an R:S of 150:1, *see* footnote c).

[c] Primary syngeneic MLTC was performed by addition of 1.5×10^7 normal B6 spleen cells (NS) and 1.0×10^5 10,000-R X-irradiated FBL-3 cells (XFBL-3) (group 1); 10% syngeneic PC obtained from normal B6 mice were also added in groups 2 and 3; only NS and PC were added in groups 4 and 5. The final volume in each T30 flask was 10 ml.

[d] After 6 days of MLTC reactions, the effectors were washed, counted, and tested in the [^{125}I]IdUrd release assay at an E:T of 100:1. The target cells were FBL-3.

TABLE 3.—*Characterization of SAC involved in suppression*[a]

Treatment of SAC[b]	Time of addition of stimulators, hr[c]	PC[d]	Net % lysis
—	0	−	−4
—	0	+	24
SAC	0	+	20
SAC	−4	+	−4
SAC+anti-Thy 1.2+C	0	+	23
SAC+anti-Thy 1.2+C	−4	+	−6
SAC+X-radiation	0	+	22
SAC+X-radiation	−4	+	−5
—	—	+	4

[a] All responders were normal B6 spleen cells.

[b] Spleen cells, untreated (—) or treated with anti-Thy 1.2 antibody plus complement (C) or with 750 R X-radiation, were incubated at 1×10^7 cells in 2 ml in a T30 tissue culture flask in an upright position, at 37°C in a 5% CO_2 atmosphere. After 2 hr they were washed and the nonadherent cells were removed. These SAC were then incubated alone in medium or were incubated with 10,000-R X-irradiated FBL-3 tumor cells at a dose that was equivalent to an R:S of 150:1. After 4 hr of further incubation, MLTC were set up in these flasks.

[c] It is relevant to the time when MLTC was set up. X-irradiated FBL-3 cells were added at an R:S of 150:1; — = no addition of stimulators.

[d] 10% syngeneic PC were added at the onset (0 hr) of the MLTC; — = not added; + = added.

4), the cytotoxic response was completely suppressed, whereas the presence of extra amounts of SAC without preexposure to FBL-3 cells (group 3) gave the same degree of cytotoxic response as the control group (group 2). The amount of X-irradiated FBL-3 cells added in each group was exactly the same (1×10^5). In group 4, the FBL-3 cells were added in the presence of SAC at 4 hours prior to MLTC. In some experiments, addition of PC to responders (group 5) could generate 15–30% cytotoxicity above that of responders cultured alone. These experiments were excluded because the results were difficult to interpret.

Characterization of SAC responsible for inducing suppression.—To determine the nature of SAC responsible for inducing suppression, we pretreated the spleen cells with excess amounts of anti-Thy-1.2 antibody plus complement to remove T-cells, or we gave 750 R X-radiation to remove radiosensitive lymphocytes. These treated spleen cells were then incubated in T30 flasks to prepare adherent cells. The SAC obtained after such treatments were fully capable of inducing suppression (table 3). Thus they were consistent with being macrophages.

Characterization of PC responsible for inducing suppression.—The PC were subjected to the same treatments as the SAC in the preceding experiment. Their effects on the induction of suppression were tested. The results are summarized in table 4. These cells were also consistent with being macrophages: They were adherent to plastics, relatively radioresistant, and resistant to anti-Thy-1.2 antibody lysis.

Induction of suppression by tumor cells of various origins.—Two chemically induced tumors (EL-4 and Meth A) and two Friend virus-induced tumors (FBL-3 and HFL/d) were used in these experiments. EL-4 and FBL-3 are of syngeneic origin and are of the *H-2*^{b} haplotype. Meth A and HFL/d are of allogeneic origin and are of the *H-2*^{d} haplotype.

PAC	XFBL-3	NS+PC	31
		NS+PC	3

[a] 1×10^7 normal SAC, pooled lymph node cells (LAC) or thymocytes (TAC), or 1.5×10^6 normal PC (PAC) were incubated in T30 flasks for 2 hr. The nonadherent cells were removed by three washings with HBSS containing 5% FBS. Each flask contained ≈$5–10\times10^5$ adherent cells.

[b] 1×10^5 of 10,000-R X-irradiated FBL-3 cells (XFBL-3).

[c] Primary syngeneic MLTC was performed by addition of 1.5×10^7 normal B6 spleen cells (NS) and 1.0×10^5 10,000-R X-irradiated FBL-3 cells (XFBL-3) with or without PC. The final volume in each T30 flask was 10 ml.

[d] Target cells were FBL-3; E:T=100:1.

If SAC were preexposed to these tumor cells, significant suppression was induced (table 5, groups 4–7). In contrast, preexposure of SAC to X-irradiated normal spleen cells gave no suppression. Among these four tumor lines, only EL-4 cells were suppressive without being preexposed to SAC (group 9), but the degree of suppression was much lower than that of the group (group 5) that was preexposed to SAC.

Induction of suppression by adherent cells from lymph nodes and thymus.—To determine whether the macrophage-mediated suppression is unique to the SAC, we performed experiments using adherent cells obtained from other origins: pooled lymph nodes (cervical, axillary, and inguinal), thymus, and peritoneal cavity. We found that adherent cells obtained

TABLE 7.—*Preclusion of suppression by simultaneous presence of PM*

8	SAC	PC-CIM+XFBL-3	NS+uPC	0	

[a] PM and SAC mixture (group 5) was prepared by incubation of 1.5×10^6 PC with 1×10^7 spleen cells for 2 hr in T30 flasks. The nonadherent cells were removed by three washings with HBSS containing 5% FBS.

[b] At 1×10^5 of 10,000-R X-irradiated FBL-3 cells (XFBL-3). uPC = untreated PC, PC-NT=PC treated with anti-Thy 1.2 antibody plus complement and then with 750 R X-radiation, and PC-CIM=PC treated with carbonyl iron and magnet. All PC were added at 1.5×10^6 cells/flask.

[c] Primary syngeneic MLTC was performed by addition of 1.5×10^7 normal B6 spleen cells (NS) and 1.0×10^5 10,000-R X-irradiated FBL-3 cells (XFBL-3) (group 1); 10% syngeneic uPC (untreated PC) obtained from normal B6 mice were also added in groups 2 and 3; only NS and uPc were added in groups 4–6 in expt 1 or groups 4–8 in expt 2. The final volume in each T30 flask was 10 ml.

[d] Target cells were FBL-3.

from lymph nodes or thymus induce the same degree of suppression as the SAC (table 6). In contrast, preexposure of peritoneal adherent cells to tumor cells does not induce suppression. This result is consistent with our results obtained in the allogeneic MLC reactions (*2, 3*).

Preclusion of suppression by PM.—In the allogeneic MLC experiments, not only did preexposure of PM to tumor cells fail to induce suppression but also their simultaneous presence could preclude the induction of suppression by preexposure of SAC to tumor cells (*3*). We performed similar experiments to determine whether this was also true in syngeneic MLTC. The results are summarized in table 7. We found that the simultaneous presence of PM indeed precluded the suppression (group 5, expt 1). In this experiment, PM and SAC were prepared by incubation of PC and spleen cells together. To rule out the possibility that the adherence of SAC might be inhibited by the presence of PC, we performed additional experiments to obtain SAC and then we added PC 2 hours later (expt 2). When X-irradiated FBL-3 cells were added to trigger the suppression, suppression was precluded (group 6, expt 2), indicating that the preclusion was not due to the inhibition by PC of the SAC adherence. Furthermore, removal of T-cells from the PC populations did not affect its ability to prevent the suppression (group 7, expt 2). However, if phagocytes were removed from the PC, they were no longer able to prevent the suppression (group 8, expt 2).

DISCUSSION

Macrophages are heterogeneous in nature and so are their functions (*14-16*). Being the antigen-presenting cells or producers of various humoral mediators (e.g., macrokines), they are essential for the initiation of many immune responses to antigenic or mitogenic stimulation. Contrarily, macrophages exert suppressive effects on many immune functions, including antibody production (*17*), lymphoproliferative response (*18-20*), generation of cytotoxic T-cells (*19, 21, 22*), and T-cell-mediated hypersensitivity reaction (*23*). In tumor-bearing hosts, macrophages have been demonstrated to be one of the major components for inducing immunosuppression (*17, 18, 20*). In the present study, we have described a unique suppressor mechanism which was triggered by tumor cells and was mediated through the collaboration of two populations of macrophages. This suppressor mechanism restrained the generation of CTL in syngeneic MLTC reactions.

Our previous study demonstrated that the syngeneic MLTC reactions induced by FBL-3 cells are antigenically specific and are T-cell-dependent (*24*). The cytotoxic responses generated in the in vitro MLTC reactions are generally much weaker than those generated in vivo. This is especially true for the primary MLTC (*25*). The major reason for the weak in vitro response was found to be due to the tumor cell-induced immunosuppression, which can be overcome by the addition of exogenous PM [(*12, 26*), table 1]. In previous reports (*11, 13, 24*) we have shown that T-cells were the effectors for mediating the cytotoxic reactions generated in the syngeneic, primary MLTC reactions. The cytotoxic reactions was also specific for the Friend–Moloney–Rauscher tumor-associated antigens (*11, 13, 24*). This was true for the weak primary MLTC without addition of PC (*24*) and for the augmented primary MLTC with addition of PC (*11, 13*). We have also shown that in the PC-augmented MLTC, the cytotoxic reactions were mediated by T-cells and PM did not participate in the cytotoxic phase of the reactions (*13*).

In this study, there are several unique features in the tumor cell-triggered macrophage-mediated suppression. Three major cellular components are involved and they have to be interacted in a specific manner. These cellular components are: tumor cells, SAC, and PC. One critical requirement for induction of suppression is the preexposure of SAC to tumor cells (table 2). If peritoneal adherent cells are preexposed to tumor cells, there is no suppression (table 6), whereas adherent cells from lymph nodes or thymuses act in the same manner as SAC (table 6). Furthermore, the simultaneous presence of PC and SAC prevents the induction of suppression (table 7). These findings indicate that there are at least two populations of macrophages involved here, one from the peritoneal cavity and the other from spleen, lymph nodes, or thymuses. At present, there are no cell surface markers to distinguish these two populations. Both appeared to be macrophages (tables 3, 4, 7) and lacked the Ia antigen (not shown). In the SAC population, especially that prepared from T-cell-depleted spleen cells (table 3), almost all of the cells were macrophages as shown by their morphology and their phagocytic activity. In the PC population (table 4), the T-cell-depleted preparation also contained more than 90% macrophages.

Tumor cells are also a critical component for triggering of the suppressor mechanism. The origin of tumor cells is not critical. They can be from tumors induced by a different etiologic agent or from tumors of different *H-2* haplotype (table 5). In contrast, normal spleen cells treated in the same manner fail to induce suppression (table 5). Since the suppression could be induced by tumor cells of different etiologic origins, it was evident that the suppression of T-cell response was not antigen-specific; i.e., the effect of the mechanism is a general suppression of CTL induction. In previous reports (*2, 3*) we have demonstrated that this mechanism suppressed the induction of CTL against alloantigen. In the present study, we have shown that similar mechanisms suppressed the induction of CTL against the tumor-associated antigen(s).

Therefore, the macrophage-mediated suppressor mechanism described here is quite different from the mechanisms reported by other investigators (*17-23, 27, 28*). In other systems, either there was no need for the presence of tumor cells, or one source of macrophages (splenic or peritoneal) was sufficient. In our experiments, the exact reason for the need for two populations of macrophages is still not clear. Experiments performed in the allogeneic systems had clearly shown that both populations were needed for triggering of suppression. In regard to the preclusion of suppression by PC (table 7), it is possible that PM do not prevent suppression but provide help. This help overcomes the suppression induced by SAC and thus shifts the balance from suppression to assistance.

In this study, all experiments were performed strictly in the syngeneic system. We have found that tumor cells can indeed activate a suppressor mechanism via macrophages. This suppression may be mediated through three pathways: 1) generation of suppressor cells (suppressor macrophages or suppressor T-cells), 2) inactivation of helper T-cells, or 3) production of suppressive factors. Because suppressor cells and suppressive factors have been demonstrated in various tumor models (*27–31*), it is very likely that tumor cells can utilize different mechanisms to evade host immune surveillance. These issues will be examined in the accompanying paper (*32*).

Tumor Cell-Triggered Macrophage-Mediated Suppression of the T-Cell Cytotoxic Response to Tumor-Associated Antigens.
II. Mechanisms for Induction of Suppression[1,2]

Chou-Chik Ting[3,4] *and* **Myrthel E. Hargrove**[3,5]

ABSTRACT—The mechanisms were investigated for the tumor cell-triggered macrophage-induced suppression of T-cell-mediated tumor immunity. Interaction between tumor cells and macrophages triggered the production of prostaglandin(s) (PG) that initiated the suppressor events. In our experiments, PGE_1 or PGE_2 suppressed the generation of cytotoxic T-lymphocytes in the syngeneic mixed lymphocyte tumor cell cultures. Indomethacin, a PG synthetase inhibitor, blocked the induction of the macrophage-mediated suppression, which suggested that suppression was caused by endogenous PG. This suppression might be further mediated by the generation of suppressor T-cells. Significant reduction in the levels of macrophage-induced suppression was seen in hosts receiving cyclophosphamide treatment, which could eliminate the precursors of suppressor T-cells. These findings indicated that tumor cells may trigger a chain of reactions, through the generation of suppressor factors or suppressor cells, to subvert the host's immune surveillance.—JNCI 1982; 69:873–878.

We have demonstrated a unique mechanism for tumor cell-induced suppression. This mechanism was mediated through the participation of two populations of macrophages. It was first demonstrated in the allogeneic system—suppression of the generation of CTL against alloantigen (*1*, *2*). This observation was extended to the syngeneic system—suppression of CTL against tumor-associated antigen (*3*). In this study, we have further examined the mechanisms involved in this tumor cell-triggered macrophage-mediated suppression.

It has been reported that macrophage-mediated suppression could be attributed to the production of PG (*4–8*). In some systems, PG further triggered the generation of suppressor T-cells (*6*) or inactivation of TCGF (*7*). The net result was the suppression of immune response. We have performed experiments to determine whether these mechanisms were involved in the generation of a specific T-cell-mediated tumor immunity.

MATERIALS AND METHODS

Mice.—Female C57BL/6 (B6) mice 2–5 months of age were obtained from the Small Animal Section, Veterinary Resources Branch, Division of Research Services, National Institutes of Health.

Tumor cells.—FBL-3, a Friend virus-induced leukemia in B6 mice (*9*) was adapted to grow in suspension tissue culture and was maintained in RPMI-1640 medium containing 5% FBS (Grand Island Biological Co., Grand Island, N.Y.).

MLTC reactions.—MLTC reactions were performed by a technique similar to that developed by Nabholz et al. (*10*). The culture medium was RPMI-1640 containing 5% FBS, 5×10^{-5} *M* 2-mercaptoethanol (Sigma Chemical Co., St. Louis, Mo.), and 2×10^{-2} *M* HEPES[6] buffer solution (Media Unit, National Institutes of Health). The responding cells (responders) were spleen cells obtained from normal B6 mice. The stimulators were 10,000-R X-irradiated B6 FBL-3 tumor cells. The spleen cells were pressed gently in HBSS containing 5% FBS and passed through two layers of cotton gauze for preparation of single cell suspensions. They were treated with ammonium chloride–potassium lysing buffer (NH_4Cl, 0.155 *M*; Na_2EDTA, 0.1 m*M*; $KHCO_3$, 0.01 *M*) for 2 minutes at 4°C for removal of erythrocytes. The responders were always suspended in culture medium at a final concentration of 1.5×10^6/ml. They were incubated either alone (control culture) or with stimulators at an R:S of 150:1. Each flask usually contained 10 ml of cultured cells. All cultures were established in 30-ml tissue culture flasks (Falcon Plastics, Oxnard, Calif.) and incubated in an upright position at 37°C in a humidified atmosphere containing 5% CO_2. After 6 days of being cultured, the cells were counted, washed once, and resuspended in RPMI-1640–10% FBS at the appropriate concentration.

Preparation of SAC.—The SAC were obtained by the method described by Cowing et al. (*11*) with some modification. Spleen cells at 1×10^7/ml in RPMI-1640 medium containing 5% FBS were incubated in T30 flasks in an upright position at 37°C for 2 hours in a 5% CO_2 atmosphere. The nonadherent cells were removed by three washings with HBSS containing 5% FBS.

Preparation of PC.—The PC were obtained from normal mice by irrigation of the peritoneal cavity with HBSS containing 5% FBS.

Cell-mediated cytotoxicity assay.—The [^{125}I]IdUrd release as-

[6] 4-(2-Hydroxyethyl)-1-piperazine ethanesulfonic acid.

say was used to measure cell-mediated cytotoxicity. The details of the technique have been described elsewhere (*12*). [^{125}I]IdUrd-labeled FBL-3 target cells (0.05 ml) at 1×10^5/ml and effector cells (0.15 ml) at an appropriate concentration were added to the wells of MicroTest II plates. All effector cells were adjusted to contain the same number of viable cells for each E:T. Incubation was done at 37°C in a 5% CO_2 atmosphere for 18–24 hours. Then the cells and supernatants were harvested by MASH II (M.A. Bioproducts, Walkersville, Md.). The supernatants and cell pellets were collected separately, and their radioactivity was determined in a well-type gamma scintillation counter. The results were expressed as total percentage of lysis and net percentage of lysis according to the following formulas: Total percent lysis=[cpm in supernatant/(cpm in supernatant+cpm in cells)]×100, and net percent lysis=(total percent lysis obtained with responders incubated with stimulators−total percent lysis obtained with responders incubated alone).

The standard errors obtained with total percent lysis were usually between 0.5 and 3%.

PG and PG synthetase inhibitors.—PGE_1, PGE_2, and $PGF_{1\alpha}$ (Sigma Chemical Co.) were dissolved in 95% ethanol alcohol at 5×10^2 *M* and stored at −20°C. The PG synthetase inhibitor indomethacin (Sigma Chemical Co.) was stored in dry form at 4°C. Immediately before use, indomethacin was dissolved in 95% ethanol alcohol at a 1×10^{-2} *M* concentration and was then diluted in RPMI-1640–5% FBS at an appropriate concentration.

Cyclophosphamide.—Cyclophosphamide was purchased from ICN Pharmaceuticals, Inc. (Plainview, N.Y.). It was dissolved in phosphate-buffered saline before use.

TCGF.—Two preparations of TCGF were used. One preparation (TCGF-R) was made according to the method of Gills et al. (*13*) by coculturing of inbred W/Fu rat spleen cells with the T-cell mitogen concanavalin A (Calbiochem-Behring, San Diego, Calif.). Rat spleen cells at 5×10^6/ml were cultured with concanavalin A at 5 µg/ml for 2 days. The supernatants were harvested, passed through 0.20-µm Millipore filters (Nalge Co., Rochester, N.Y.), and stored at −70°C. The optimal concentration of TCGF-R for supporting the T-cell growth was at 7.5–10%. Another preparation (TCGF-M or IL2) was obtained from a TCGF-producing EL-4 clones (*14*). This preparation was free of lectin or FBS.

RESULTS

Effect of PG on generation of T-cell-mediated cytotoxic response in syngeneic MLTC.—PG have been shown to suppress cell-mediated cytotoxic reactions (*5*, *16*). We performed experiments to determine the direct suppressive effect of PG in the generation of cytotoxic T-cells against tumor-associated antigens. The results are summarized in table 1. We found that 5×10^{-6} *M* of PGE_2 completely suppressed the MLTC cytotoxic response (expt 1); this suppressive effect was also seen at 5×10^{-7} *M* of PGE_2 (expt 2). In other experiments, 1-5×10^{-7} *M* of PGE_2 gave complete suppression (not shown). Indomethacin, PG synthetase inhibitor, did not alter the direct suppressive effect of PG. PGE_1, which had a chemical structure similar to that of PGE_2, also gave strong suppression. $PGF_{1\alpha}$ had no suppressive effect. If PGE_2 was added at the effector phase of the cytotoxic reaction (on days 5, 6), no suppression was seen (not shown). These results indicated that PGE can suppress the induction of a T-cell-mediated cytotoxic response. Addition of PGE_2 or PGE_1 into MLTC cultures was not always associated with reduction of cell viability, yet strong suppression of cytotoxic response was always seen. Furthermore, during the cytotoxicity test, all the effector preparations have been adjusted to contain the same number of viable cells (*see* "Materials and Methods"). Thus the PG-induced suppression could not be attributed to its cellular toxicity.

[f] [(Net % lysis obtained with group 2−net % lysis obtained with other group)/net % lysis obtained with group 2] ×100.

[g] Statistics were evaluated by the Welch distribution *t*-test by comparison with group 2.

Reversal by indomethacin of the macrophage-mediated suppression.—Experiments were performed to further determine whether endogenous PG was produced in our experiments, i.e., the macrophage-mediated suppression of specific T-cell-mediated tumor immunity (*3*). It has been shown in several experimental systems that macrophage-mediated suppression was attributed to the production of PG (*6*, *7*). This PG-induced suppression was blocked by a PG synthetase inhibitor, e.g., indomethacin (*6*, *7*, *16*). This was found to be the case in our experiments (table 2). As noted before (*3*), preexposure of FBL-3 cells to SAC induced suppression of the MLTC cytotoxic response (group 4). Addition of 1×10^{-5} *M* of indomethacin completely blocked the macro-

[a] At 0 hr SAC were prepared by incubation of 1×10^7 normal B6 spleen cells in T30 flasks in an upright position.

[b] After 2 hr the nonadherent cells were removed by three washings with HBSS containing 5% FBS. In group 3, lymphocyte culture medium was added to the T30 flasks containing SAC. In groups 4–7, 10,000-R X-irradiated FBL-3 tumor cells (XFBL-3) were added at 1.0×10^5/2 ml (equivalent to an R:S of 150:1; *see* footnote *c*).

[c] Primary syngeneic MLTC was performed by addition of 1.5×10^7 normal B6 spleen cells (NS) and 1.0×10^5 10,000-R X-irradiated FBL-3 cells (XFBL-3) (group 1); 10% syngeneic PC obtained from normal B6 mice were also added in groups 2 and 3; only NS and PC were added in groups 4–7. Final vol in each T30 flask was 10 ml.

[d] Final concentration of indomethacin added.

[e] After 6 days the effectors were washed, counted, and tested in the [^{125}I]IdUrd release assay at an E:T of 100:1. Target cells were FBL-3.

phage-induced suppression, and the effect could be seen with a concentration of 1×10^{-7} *M* indomethacin (groups 5–7). These findings strongly suggest that endogenous PG is being produced and that endogenous PG accounted for the suppression of T-cell immunity.

Effect of indomethacin added at different times after MLTC reactions.—To determine how early indomethacin was needed to block the suppression, we performed a kinetic study. The results are summarized in table 3. We found that if indomethacin was added within the first 48 hours of the MLTC reaction, the macrophage-induced suppression was completely blocked. If it was added after that time, indomethacin was no longer able to block the suppression. This finding further confirmed that sufficient amounts of endogenous PG were produced in the first 48 hours to suppress the induction of cytotoxic T-cells, and indomethacin had no effect on the preformed PG.

TABLE 3.—*Effect of indomethacin added at different times of MLTC*

[a] At 0 hr SAC were prepared by incubation of 1×10^7 normal B6 spleen cells in T30 flasks in an upright position.

[b] After 2 hr the nonadherent cells were removed by three washings with HBSS containing 5% FBS. In group 3, lymphocyte culture medium was added to the T30 flasks containing SAC. In groups 4–8, 10,000-R X-irradiated FBL-3 tumor cells (XFBL-3) were added at 1.0×10^5/2 ml (equivalent to an R:S of 150:1; *see* footnote *c*).

[c] Primary syngeneic MLTC was performed by addition of 1.5×10^7 normal B6 spleen cells (NS) and 1.0×10^5 10,000-R X-irradiated FBL-3 cells (XFBL-3) (group 1); 10% syngenic PC obtained from normal B6 mice were also added in groups 2, 3; only NS and PC were added in groups 4–8. Final vol in each T30 flask was 10 ml.

[d] Indomethacin was added at a final concentration of 1×10^{-5} *M*, at indicated time of MLTC.

[e] Target cells were FBL-3; E:T = 100:1.

Effect of cyclophosphamide treatment on the macrophage-mediated suppression.—In some systems it has been reported that the suppressive effect produced by PG was attributed to the generation of suppressor T-cells (*5, 6*). It has also been demonstrated that the precursors of the suppressor T-cells could be effectively removed by pretreatment of the hosts with cyclophosphamide (*17*). We had taken this approach to determine whether the mechanism for macrophage-mediated suppression was due to the induction of suppressor T-cells. In these experiments, some mice were given 100 mg cyclophosphamide/kg body weight 2 days before the experiments, and then their spleens and PC were removed. The effect of cyclophosphamide treatment on the macrophage-mediated suppression was then tested. The yield of spleen cells in cyclophosphamide-treated mice was usually between 20 and 30% of that in the untreated mice. There was a slight reduction (10–20%) in the yield of PC. The results are summarized in table 4. The PC from both the cyclophosphamide-treated hosts and the normal hosts could restore the same levels of cytotoxic response in the syngeneic MLTC (group 6 vs. group 2). Addition of extra amounts of SAC into the MLTC did not alter these responses (groups 3, 7). However, if SAC were preexposed to tumor cells before the MLTC were started, significant suppression was induced in the untreated host (group 4) but not in the cyclophosphamide-treated host (group 8), in which only a marginal suppression occurred in one experiment (expt 2).

Effect of TCGF and indomethacin on MLTC and macrophage-mediated suppression.—It has been shown that PG could inhibit the production or reduce the activity of TCGF (*18*). To determine this possibility, we supplemented exogenous TCGF in the cultures to determine its effect on MLTC or macrophage-mediated suppression. The results are summarized in table 5. Two different preparations of TCGF were used. Rat TCGF (TCGF-R) was used in experiment 1; it contained lectin (concanavalin A). TCGF-M or IL-2 (*13*) was used in experiment 2; it was obtained from a TCGF-producing EL-4 cell line and was lectin-free. Without the

[f] Target cells were FBL-3; E:T=100:1.

addition of exogenous PC, neither preparation restored the cytotoxic response of the syngeneic MLTC (groups 2, 3). Addition of indomethacin alone also failed to restore the cytotoxic response (groups 4, 5). In the macrophage-mediated suppression (group 8), addition of TCGF failed to inhibit the suppressive effect (groups 9, 10), whereas indomethacin could effectively block the suppression (groups 11, 12).

DISCUSSION

Macrophages can induce suppression in a variety of immune responses. In most cases, the suppressive effect appears to be more pronounced at the induction phase of the immune response. Generally, the effector phase is not affected. This has been noted, for example, in the generation of cytotoxic responses (*19–21*), lymphoproliferative responses (*19, 22, 23*), and production of lymphokines (*24*).

In this study, the tumor cell-triggered macrophage-mediated suppression is initiated in the first 4–6 hours of the immune response [(*3*), table 2]. Three critical components are involved: tumor cells, SAC, and peritoneal macrophages. The unique feature of this suppressor mechanism is the requirement of preexposure of the SAC to tumor cells [(*3*), table 2], indicating that preexposure is the first key element in the initiation of the suppressor events.

In several macrophage-mediated suppression systems, PG have been identified as the humoral mediators for induction of suppression (*4–9*). PG have also been proposed to modulate the extent or severity of numerous immune responses (*25, 26*). The E-type PG (E_1 or E_2) have been shown to suppress a variety of immune functions, such as T-cell-mediated cytotoxicity (*16*), lymphoproliferative responses (*5, 27*), lymphokine production (*24, 28*), and antibody response (*29*). The PG-induced suppression generally follows the same spectrum as that of the macrophage-mediated suppression.

Our experiments clearly demonstrated that PGE_1 and PGE_2 but not $PGF_{1\alpha}$ suppress the generation of cytotoxic T-cells against tumor-associated antigens (table 1). The macrophage-mediated suppression is blocked by indomethacin, a PG synthetase inhibitor (table 2). However, indomethacin has no effect on the preformed PG (tables 1, 3). Taken together, these findings strongly suggest that the macrophage-induced suppression is mediated by the endogenous production of PG, which act on the induction phase of the cytotoxic responses.

The exact immunoregulatory role of the PG remains to be determined. It has been shown that at least in some systems PG-induced suppression can be attributed to the generation of suppressor T-cells (*5, 6*).

Approaches were taken to eliminate the precursors of suppressor T-cells by treatment of the host with cyclophosphamide (*17*). Then the host's ability to induce macrophage-mediated suppression was examined (table 4). It was shown that cyclophosphamide treatment significantly reduced the host's ability to induce the macrophage-mediated suppression, which suggests that this suppressor mechanism was mediated by the generation of suppressor T-cells

TCGF does not seem to play a role here. It fails to restore the cytotoxic response to tumor-associated antigen (groups 2, 3; table 5), and it cannot block the suppressive effect of macrophage-induced suppression (groups 9, 10; table 5). However, these experiments cannot rule out the possibility that PG may interfere with the activity of TCGF rather than with its production.

In the present study, we have demonstrated that the tumor cell-triggered macrophage-mediated suppression is very likely caused by the increased production of E-type PG. The PG may further trigger the generation of suppressor T-cells that suppress the generation of cytotoxic T-cells. This mechanism may be normally operative in the hosts for the regulation of immune response. However, tumor cells may trigger the early production of PG and thus cause premature termination of the T-cell response. It has been shown that subversion of the in vivo immune response by tumor cells may also be attributed to the PG (*30*). Therefore, understanding these underlying mechanisms may help to design an effective strategy to prevent the tumor cells from evading the host's immune surveillance.

Inducible Macrophage Cytotoxins. I. Biokinetics of Activation and Release In Vitro[1,2]

Thomas H. Reidarson,[3] Walter E. Levy III,[3] Jim Klostergaard,[3,4,5] *and* **Gale A. Granger**[3,6]

ABSTRACT—Peritoneal exudate macrophage monolayers (PEMM) from C57BL/6 and DBA/2 mice inoculated ip with tumor allografts were induced to release in vitro labile cell toxin(s), herein called "macrophage cytotoxin(s)" (MCT). Macrophages released MCT spontaneously for a short interval when initially established as monolayers, and they were reinduced to secrete MCT by exposure to allogeneic and syngeneic tumor cells (but not to normal cells) and by exposure to polyinosinic-polycytidylic acid (poly I·poly C) and lipopolysaccharide (LPS). PEMM from normal mice treated ip 3 days previously with thioglycollate were also induced to release toxins in vitro. These cells did not release MCT spontaneously before or after treatment with neoplastic cells but were induced to release MCT by exposure to poly I·poly C or LPS. Resident peritoneal macrophages did not release MCT either spontaneously or after treatment with tumor cells, poly I·poly C, or LPS. MCT released from alloimmune mice stimulated with syngeneic or allogeneic tumor cells were resolved by molecular sieving into a major peak at 140,000–160,000 daltons, called "α-MCT," and into a minor peak at 60,000 daltons, called "β-MCT." However, supernatants from thioglycollate-induced PEMM, stimulated with poly I·poly C or LPS, appeared to be composed entirely of the α-class. α-MCT from poly I·poly C-stimulated PEMM caused 31–56% lysis of syngeneic EL-4 and allogeneic L-929, NS-1, and YAC-1 tumor cells in vitro but was not cytotoxic for normal cells. Secretion of the MCT by PEMM derived from thioglycollate-treated animals stimulated with poly I·poly C was inhibited by colchicine, emetine, iodoacetic acid, trypan blue, and cytochalasin B.—JNCI 1982; 69:879–887.

The activated state of a murine PEM is characterized by increases in size, in motility, in phagocytic capacity, and in production of lysosome enzymes; by greater adherence to glass; and by an increased ability to nonspecifically destroy allogeneic and syngeneic neoplastic cells over normal cells in vitro (*1–8*). The mechanism by which the activated murine PEM destroy tumors is not known. However, in vitro evidence suggests that this mechanism requires contact between effector and target cells, occurs in 24–72 hours, and does not involve phagocytosis (*9–12*).

In a recent review, Hibbs Jr. et al. (*13*) described various treatments that induce the activation of murine PEM to tumoricidal activity in vitro. The first treatment induces the macrophage to a "stimulated" but nontumoricidal stage. This inducement can be brought about by ip injection of thioglycollate before harvest of the PEM or by maintenance of the macrophage in vitro. Secondary stimulation in vitro is initiated by addition of LPS, macrophage activating factor, or various "serum factors," which raise the PEM to the final tumoricidal stage. Most investigators believe that activated macrophages selectively destroy neoplastic over normal cells (*1, 5–7, 11–13*); however, evidence indicates that such macrophages may also destroy normal cells (*14*).

The destruction of neoplastic cells by activated macrophages normally requires contact between effector and target cells. Several investigators (*15*) have suggested that tumor cell lysis subsequent to contact with the effector is mediated by materials derived from the activated macrophage lysosome system. It has been demonstrated that PEM from BCG-immune mice, obtained with or without purified protein derivative challenge, or that PEM from normal mice stimulated with LPS and poly I·poly C release cell toxins in vitro (*16–19*). These toxins have not been well characterized; however, their involvement in the lytic event has been suggested.

The present study describes an inducible system of cell lytic molecule(s) called "MCT" that are released by activated murine PEM in response to different in vitro stimuli.

MATERIALS AND METHODS

Culture media and cell lines.—Culture media used in these studies consisted of RPMI-1640 supplemented with 3 or 10% heat-inactivated (56°C, 60 min) FCS (GIBCO, Grand Island, N.Y.) or NBCS (GIBCO), 100 μg streptomycin/ml, and 100 U penicillin/ml. Murine α-L-929 (C3H-H-2^k) transformed fibroblasts, which had previously been selected in our laboratory from a number of L-cell strains for extreme sensitivity to lysis by human lymphotoxins, were grown in 32-oz prescription bottles in RPMI-1640 with 3% NBCS at 37°C in a 95% air–5% CO_2 atmosphere and passed twice a week, indefinitely. Murine C57BL/6 EL 4 (H-2^b) lymphoma, Balb/c NS-1 (H-2^d) myeloma, P815 DBA/2 (H-2^d) mastocytoma, A/Sn YAC-1 (H-2^a) lymphoma, and human K562 erythroid leukemia cell lines were grown in RPMI-

1640 supplemented with 10% FCS. Naive BALB/c (H-2^d) spleens were asceptically removed and prepared on the day of the experiment. Spleens were minced, and a single cell suspension was formed and then transferred to a T-25 culture flask (Corning Glass Works, Corning, N.Y.) at 4×10^6 cells/ml in RPMI-1640 supplemented with 10% FCS. The cells were allowed to incubate for 1 hour at 37°C for removal of adherent cells. Viability was 93–98% as determined by eosin Y dye exclusion. Blasts were induced by Con A (1 μg/ml) treatment of normal nonadherent splenocytes for 4 hours at 37°C.

Induction of PEC.—PEC were obtained by three methods: *a*) P815 mastocytoma cells (10^7) suspended in RPMI-1640 or PBS were injected ip into C57BL/6 mice; 10–14 days later the PEC were harvested as previously described (*20*). PEC induction was similarly performed by ip injection of EL 4 lymphoma cells into DBA/2 mice. Thioglycollate (3 ml) (BBL, Cockeysville, Md.) was prepared and injected ip into C57BL/6 mice. Approximately 15–20×10^6 PEC/mouse was harvested 3 days later. *c*) Resident PEC (2–4×10^6/mouse) from nonmanipulated C57BL/6 or DBA/2 mice were harvested by peritoneal lavage 24 hours before in vitro stimulation.

Preparation of PEMM.—PEMM were obtained from C56BL/6 (Kingston Colony, Charles River Breeding Laboratories, Wilmington, Mass.) and DBA/2 (ARS, San Diego, Calif.) mice 6–8 weeks old. Mice were killed by cervical dislocation, and each peritoneal cavity was irrigated aseptically with 7–8 ml cold PBS (pH 6.9). The exudate was pooled and centrifuged for 5 minutes at 1,500×*g* at 4°C. The cell pellet was resuspended in 5–10 ml of either cold-modified EMEM in HBSS or RPMI-1640 (GIBCO) supplemented with 10% FCS or NBCS, 100 U penicillin/ml, and 100 μg streptomycin/ml. The PEC were then suspended in either EMEM in HBSS or RPMI-1640 and placed in T-culture flasks at $1\times10^6/5$ cm^2/ml. The flasks were incubated at 37°C in 95% air–5% CO$_2$ for 2 hours and then washed four times with serum-free RPMI-1640 or sterile PBS to remove nonadherent cells. Monolayers were maintained in RPMI-1640 at 37°C. The composition of the adherent cells was determined by examination of tetrachrome-, eosin Y-, and neutral red-stained cover slip PEMM. The monolayers were 99% or more macrophages and 100% viable.

Assay for direct macrophage-mediated cytolysis.—PEC obtained as described above were pelleted by centrifugation, resuspended in RPMI-1640 supplemented with 10% heat-inactivated NBCS, and plated in 16-mm diameter Costar plates (Costar, Cambridge, Mass.) at a density of 0.5×10^6 cells/well. After 2 hours, the monolayers were washed and allowed to incubate for an additional 24 hours in RPMI-1640 supplemented with 10% FCS before use.

The PEMM were then treated with 40 μg poly I·poly C/ml (P-L Biochemicals, Inc., Milwaukee, Wis.) in RPMI-1640 containing 10% NBCS, incubated for 1 hour, and washed four times with serum-free media. Various tumor target cells were added at a 10:1 effector-to-target cell ratio (total vol, 0.5 ml). After 12 and 36 hours of incubation at 37°C, we removed the remaining target cells from the monolayers by aspirating five to seven times, followed by a short trypsinization. Upon visual inspection, less than 5% of the tumor cells remained associated with the monolayers after this treatment. The washes and trypsin supernatant were then pooled and centrifuged. The pelleted tumor cells were resuspended in 0.1% eosin Y in PBS solution, and viable cells were enumerated in a hemacytometer. All targets were nonadherent cells.

Production of MCT.—Alloinduced PEMM were incubated in RPMI-1640 containing either 10% FCS, 10% NBCS, or 0.01% LAH (GIBCO) for various lengths of time. Supernatants were then collected, rendered cell-free by centrifugation, and assayed for MCT activity. We attempted restimulation of alloinduced macrophages by adding 2.5×10^6 EL 4 or P815 tumor cells, poly I·poly C (P-L Biochemicals, Inc.), LPS (Sigma Chemical Co., St. Louis, Mo.), Con A (Sigma), or PHA-P (Difco Laboratories, Detroit, Mich.) to PEMM in serum-free RPMI-1640. After incubation for 1–2 hours, the PEMM were washed thoroughly with serum-free medium and then the medium was replaced; the supernatant was assayed for MCT activity as described later.

Thioglycollate-elicited or resident macrophages were treated in a similar fashion with either EL 4 or NS-1 tumor cells, poly I·poly C, LPS, Con A, or PHA-P for 1–2 hours; cultured; and assayed for MCT activity. Media were either assayed for MCT immediately or frozen at −20°C and analyzed within 48 hours.

Assay for MCT and determination of the number of units of activity in a supernatant.—Methods are detailed in (*20*). Serial dilutions of MCT-containing or control supernatants in RPMI-1640 were added to duplicate 1-ml slant-tube cultures, which were seeded with 10^5 mitomycin C-treated α-L-929 cell targets. These nondividing targets were used for evaluation of cytolysis only and not cytostasis. After 14–24 hours at 37°C, the remaining viable adherent cell number was then enumerated on a model F Coulter counter. Nonattached cells were determined to be greater than 95% nonviable by eosin Y staining. One unit of MCT activity is defined as that amount of material that destroys 50% of the target L-cells (50,000). The reciprocal of the highest dilution that destroys 50% of the target L-cells denotes the number of MCT unit per milliliter in a given supernatant.

Generation of activated macrophage supernatants, molecular sieving fractions containing α-MCT, and assay for MCT-induced tumor cell cytolysis.—The 10×10^6 thioglycollate-elicited PEC were established as monolayers in T-75 culture flasks as described above. The PEMM were washed and stimulated with 40 μg poly I·poly C/ml. Following the last wash, 10 ml RPMI-1640 supplemented with 0.01% LAH was added, and the monolayers were incubated for 2 hours at 37°C. The supernatant was collected and either: *a*) immediately assayed for units of lytic activity on L-929 cells or *b*) concentrated 20 times by ultrafiltration on an Amicon PM10 membrane and passed through an Ultrogel AcA 44 column. We applied 2 ml of twentyfold to thirtyfold concentrates of MCT supernatants to an Ultrogel AcA 44 column (2.5×60 cm) equilibrated in 10 m*M* potassium phosphate (pH 7.2) and 10^{-4} *M* EDTA. Fractions of 4 ml were collected at a flow rate of 40 ml/hour. The peak of cytolytic activity detectable on murine L-929 cells at 140,000–160,000 daltons, called "α-MCT," was pooled and concentrated as described above. The α-MCT was filtered through a cellulose nitrate membrane with a 0.2-μm pore (Sartorious membrane filter; Science Essentials, Fullerton, Calif.) and then added to the various tumor targets. Following 12 and 36 hours of incubation at 37°C, the remaining cells were removed and viable cells enumerated as described previously.

Determination of macrophage viability.—We added 25 μCi $Na_2{}^{51}CrO_4$/ml RPMI-1640 to 0.5×10^6 macrophages seeded in 16-mm Costar plates (Costar) and incubated them for the release period (4–6 hr) at 37°C. PEMM were then washed thoroughly for removal of the nonincorporated counts, solubilized with 0.5 ml 10% SDS in PBS, and enumerated in a Beckman biogamma counter.

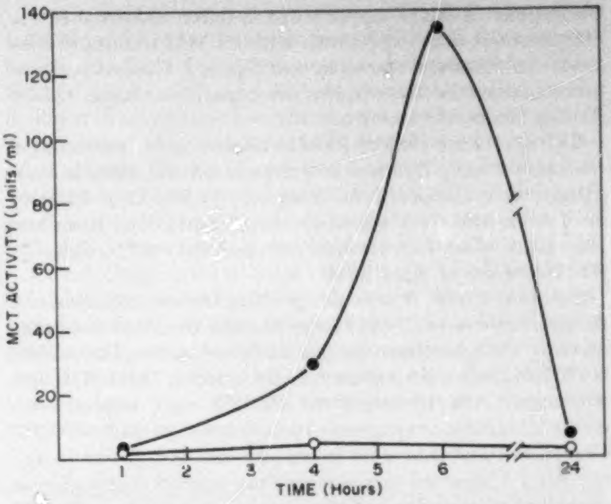
Inhibitors.—The inhibitors colchicine, emetine, iodoacetic acid, SBTI, and trypan blue were dissolved directly in RPMI-1640. Trypan blue was dialyzed against 500 vol PBS before use. Inhibitor cytochalasin B was first dissolved in dimethyl sulfoxide and then diluted with RPMI-1640. All inhibitors here came from Sigma.

Use of trypan blue.—Thioglycollate-elicited macrophage monolayers were established as described previously. Trypan blue was added to monolayers at various concentrations as described by Hibbs Jr. (*15*). After 24 hours, the monolayers were washed four times; then they were incubated for 2 hours in 0.01% LAH, after 1 hour of poly I·poly C stimulation. The supernatant was removed and assayed for lytic activity. To evaluate the amount of trypan blue incorporated by the macrophages, we solubilized the monolayer with 10% SDS in PBS and determined the light absorption at 600 nm with a Beckman model 25 spectrophotometer.

RESULTS

Spontaneous MCT release in vitro from PEMM obtained from C57BL/6 allografted mice.—PEMM, from C57BL/6 mice that had received an ip injection of P815 tumor, were established as described in "Materials and Methods." Samples of medium were removed at various intervals and tested for MCT activity on L-929 cells. As seen in text-figure 1, low levels of MCT activity were detected in the initial 1- to 4-hour culture; then between 4 and 6 hours, activity climbed to a peak, followed by a decline to less than 6 U MCT by 24 hours. While the data are not shown, additional experiments revealed that release of MCT rapidly ceased after 6–8 hours in these cultures. Resident macrophages released less than 6 U MCT/ml during the same culture period.

Restimulation of MCT release in vitro from C57BL/6 and DBA/2 alloimmune PEMM after a short exposure to P815 or EL 4 tumors.—PEMM from alloimmune C57BL/6 or DBA/2 mice were cultured in vitro for 6–8 hours, as described in "Materials and Methods." The monolayers were then washed thoroughly and reexposed to allogeneic or syngeneic tumor cells for 1 hour. The data shown in table 1 reveal that alloimmune macrophages released from 75–110 U MCT/ml in 4–6 hours when reexposed to EL 4 or P815 tumors for 1 hour. Resident or naive macrophages, however, did not release detectable levels of activity under the same conditions. Moreover, when exposed to allogeneic or syngeneic normal lymphocytes, these alloimmune macrophages did not release detectable levels of activity (data not shown). Exposure of alloimmune macrophages to Con A lymphoblasts caused the release of low levels (10–15 U/ml; data not shown) of a toxin into the supernatant. However, the nature of this toxin is currently unclear (*see* "Discussion").



TEXT-FIGURE 1.—Spontaneous release of MCT from alloimmune and resident PEMM. Alloimmune (●——●) and resident (○——○) C57BL/6 PEM were collected, cultured as monolayers, and then allowed to release MCT up to 24 hr. Supernatants were collected at various intervals of time and assayed for lytic activity as described in "Materials and Methods."

Next, experiments were designed to determine if MCT could be induced from alloimmune and thioglycollate-elicited PEMM maintained in culture for various periods of time without stimulation. In numerous experiments, we were able to restimulate alloimmune cells up to 12 days in culture by reexposure to tumor cells for 1 hour. Moreover,

TABLE 1.—*Release of MCT by PEMM[a] obtained from alloimmune and normal C57BL/6 and DBA/2 mice following a 1-hour exposure to allogeneic and syngeneic tumor cells*

PEMM	Treatment	MCT U/ml
Alloimmune		
C57BL/6 immunized with P815	EL 4	110±60[b]
	P815	90±30[b]
	None	12±3[b]

	P815	75±25[b]
	None	8±4[b]
Resident[c]		
C57BL/6	EL 4	<6
	P815	<6
	None	<6
DBA/2	EL 4	<6
	P815	<6
	None	<6

[a] PEMM were obtained from C57BL/6 and DBA/2 mice 10–15 days after intraperitoneal allografts of P815 and EL 4 tumors, respectively. PEMM were treated as described in "Materials and Methods" and supernatants were collected 6 hr after exposure to tumor cells and tested for MCT activity.

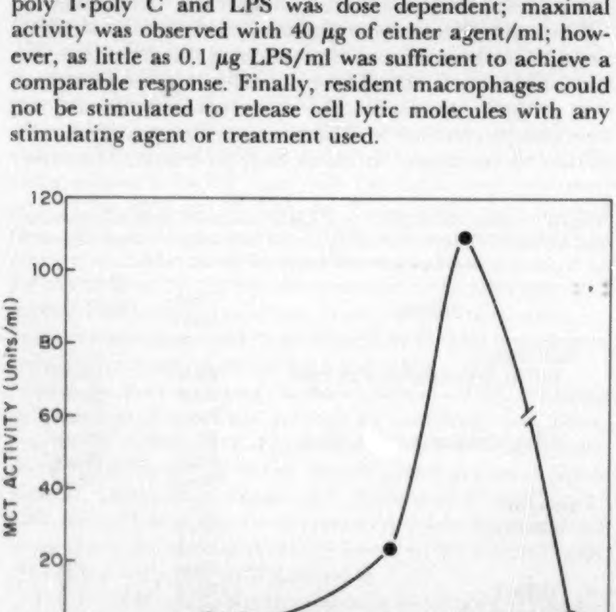
[b] Values are means ± range.

[c] Resident PEMM were obtained from nonimmunized mice and treated as stated in *footnote a*.

the release of MCT approached original maximal levels. One restimulation experiment with PEMM maintained for 5 days in culture is shown in text-figure 2. Control resident macrophages did not acquire the capacity to release MCT during this period in vitro.

Thioglycollate-elicited PEMM could also be restimulated with poly I·poly C. After 3–4 days in culture, these macrophages were reexposed to 40 μg poly I·poly C or LPS/ml for 1 hour and then allowed to release MCT as described previously (data not shown). We observed MCT release to 90–95% of the original level.

Induction of MCT secretion by PEMM from alloimmune or thioglycollate-treated C57BL/6 mice treated with various stimulating agents.—Thioglycollate- or tumor-elicited macrophages from C57BL/6 mice were cultured as described in "Materials and Methods." After 8 hours, the PEMM were treated with either allogeneic or syngeneic tumors or poly I·poly C, LPS, Con A, or PHA that were tested at levels from 0.1 to 75 μg/ml. After 1 hour the monolayers were washed thoroughly as described previously, and then supernatants were collected after 4 hours and assayed for lytic activity. As seen in table 2, syngeneic or allogeneic tumor cells stimulated release from PEMM from allografted animals but not thioglycollate-elicited PEMM. However, poly I·poly C and LPS were capable of inducing the release of cell-lytic material from thioglycollate-elicited and alloinduced macrophages. In contrast, the lectins Con A and PHA did not induce MCT release in any of these cultures. While not shown, release by poly I·poly C and LPS was dose dependent; maximal activity was observed with 40 μg of either agent/ml; however, as little as 0.1 μg LPS/ml was sufficient to achieve a comparable response. Finally, resident macrophages could not be stimulated to release cell lytic molecules with any stimulating agent or treatment used.



TEXT-FIGURE 2.—Restimulation of C57BL/6 alloimmune PEMM by short exposure to allogeneic tumor cells. Alloimmune (●——●) and resident (○——○) C57BL/6 macrophages were cultured for 5 days, exposed to P815 allogeneic tumors for 1 hr, washed free of tumors, and then allowed to release material for 24 hr. Supernatants were collected at various times and assayed for MCT activity as described in "Materials and Methods."

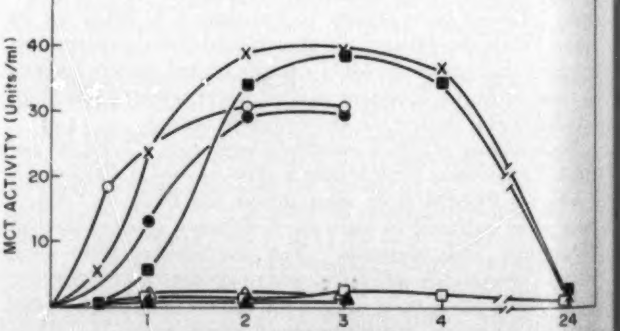
[a] PEMM were established and 8 hr later were treated with various stimulating agents as described in "Materials and Methods." Each culture was then thoroughly rinsed and fresh RPMI-1640 containing 10% FCS added. After 2–4 hr, supernatants were removed and assayed for MCT activity.

[b] Poly I·poly C, LPS, PHA, and Con A were used at 40 μg/ml.

[c] Values are means ± range.

Kinetics of MCT release from thioglycollate-elicited C57BL/6 PEMM in vitro under various stimulation and culture conditions.—Thioglycollate-elicited PEMM were treated with poly I·poly C or LPS for 1 hour and placed in fresh medium, and MCT release was measured at various time intervals as described in "Materials and Methods." As seen in text-figure 3, there was a lag period of 30–60 minutes following poly I·



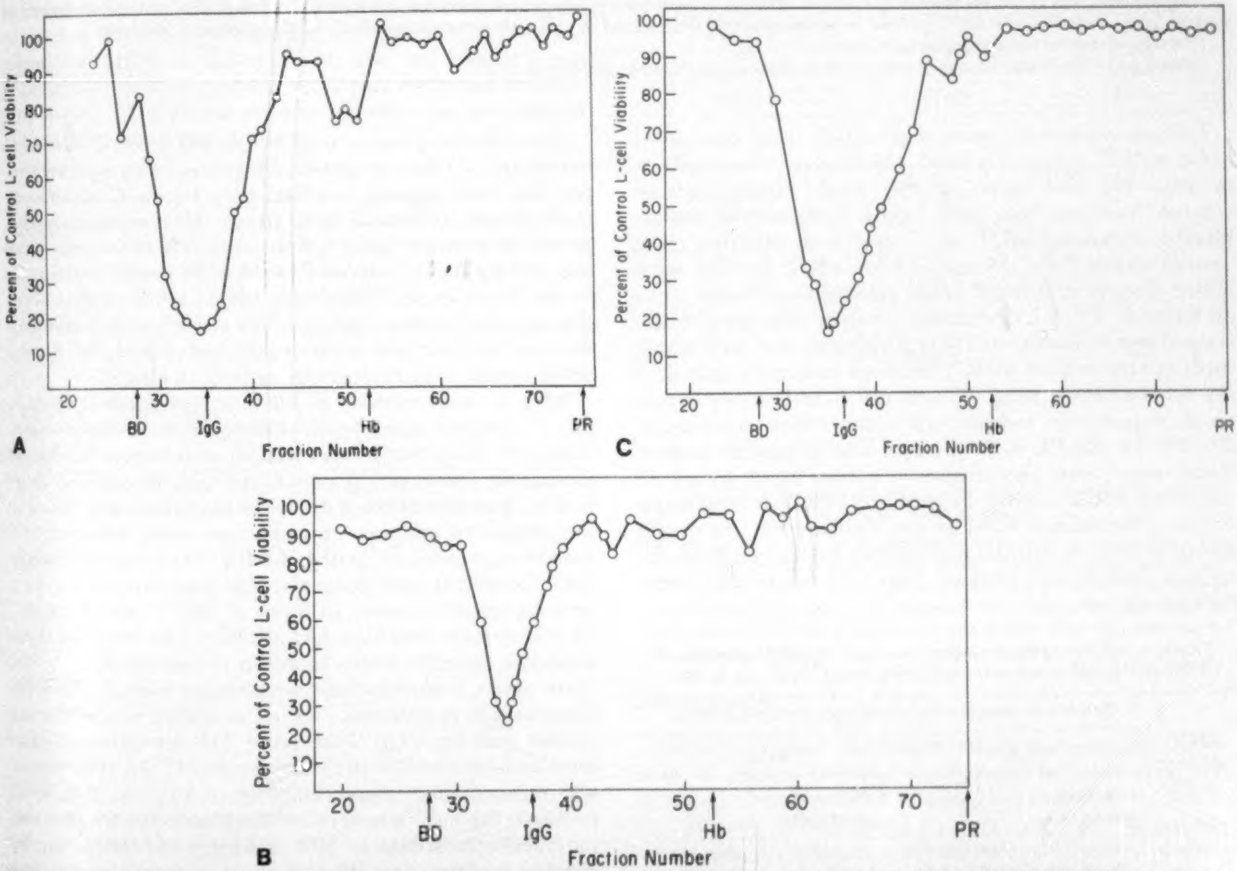
TEXT-FIGURE 3.—Kinetics of MCT release from C57BL/6 poly I·poly C-stimulated PEMM in vitro. Thioglycollate-elicited C57BL/6 PEMM were stimulated with 40 μg poly I·poly C/ml for various lengths of time (■——■, 30 min; ×——×, 60 min; ●——●, 90 min; ○——○, 120 min; ▲——▲, 180 min; △——△, 240 min) and then allowed to release MCT over 24 hr. Resident PEMM (□——□) was treated similarly. Supernatants were collected at various time intervals and assayed for lytic activity as described in "Materials and Methods."

poly C stimulation, and maximal levels of MCT were detected after 2 hours of culture. When macrophages were exposed to poly I·poly C for either 90 or 120 minutes, the lag period disappeared; if exposed for greater than 180 or 240 minutes, no release was observed.

Production of MCT from thioglycollate-elicited C57BL/6 PEMM under various culture conditions.—To generate quantities of MCT for biochemical characterization, we explored the capacity of thioglycollate-elicited PEMM monolayers to release MCT under various in vitro conditions. When poly I·poly C-stimulated macrophages were allowed to release MCT in medium containing 10% FCS, 10% NBCS, 0.01% LAH, 200 μg serum albumin/ml, or 200 μg ovalbumin/ml, levels of lytic activity were comparable, averaging between 21 and 48 U MCT/ml (data not shown). Only under protein-free conditions were both MCT activity levels and macrophage viability lowered.

Definition of the molecular classes of murine MCT.—Supernatants from PEMM obtained from C57BL/6 mice immunized with EL 4 lymphoma were concentrated and chromatographed on Ultrogel AcA 44. A typical elution profile is shown in text-figure 4A. Also shown are elution profiles of supernatants obtained from LPS or poly I·poly C-stimulated thioglycollate-induced macrophages as described in "Materials and Methods" (text-figs. 4B, 4C). The elution profiles of the various molecular weight markers blue dextran, IgG, α-hemoglobin, and phenol red are also indicated.

Clearly, supernatant MCT stimulated by all induction methods can be resolved into one major class of approximately 140,000–160,000 daltons known as α-MCT and a smaller class of activity of approximately 60,000 daltons called "β-MCT." The β-MCT class was only observed when supernatants from PEMM from alloimmune mice were stimulated by tumor cells.



TEXT-FIGURE 4.—Ultrogel AcA 44 chromatography of MCT-containing supernatants obtained from C57BL/6 PEMM stimulated in various ways. Molecular mass markers: Blue dextran (BD), $>2\times10^6$ daltons; IgG, 140,000–160,000 daltons; hemoglobin (Hb), 64,000 daltons; and phenol red (PR), 354 daltons. Columns were equilibrated and eluted with 10 m*M* phosphate (pH 7.2) containing 10^{-4} EDTA. A) Alloinduced: A 1-ml sample of a twentyfold-concentrated supernatant generated by incubation of PEMM from P815 alloimmune C57BL/6 mice stimulated with P815 cells was chromatographed over a 60-cm gel bed on Ultrogel AcA 44 in a 2.5×75-cm column. Four-ml fractions were collected at 40 ml/hr, and 200-μl samples were tested from every other fraction for MCT activity. For details, see "Materials and Methods." Toxic activity of each sample is expressed as percent viability. B) LPS induced: A 1-ml sample of a twentyfold-concentrated supernatant generated by LPS stimulation of PEMM from thioglycollate-induced C57BL/6 mice was chromatographed as above. Samples were collected and tested, and results were expressed in a manner identical to those in text-fig. 4A. C) Poly I·poly C induced: A 1-ml sample of a thirty-fold-concentrated supernatant generated by poly I·poly C stimulation of PEMM from thioglycollate-induced C57BL/6 mice was chromatographed and tested for MCT activity as described in text-fig. 4A.

[a] Target cells, 0.5×10^6, were added to supernatants containing various MCT lytic activities (total vol, 0.5 ml). After 12 and 36 hr, the remaining cells were removed and enumerated on a hemacytometer, as described in "Materials and Methods." These data are representative of two expts. Values are means ± range. *Values in parentheses* represent viabilities of the remaining tumor targets ± range.

[b] Supernatant was generated from poly I·poly C-stimulated peritoneal macrophages, rendered cell-free by centrifugation, and added directly to various target cells. Units of MCT in these supernatants were determined by an L-cell assay as described in "Materials and Methods."

[c] Percent of control number, untreated targets.

[d] Prepared by molecular sieving of supernatants obtained as stated in *footnote b*.

Cytolysis–cytostasis of various target cells by whole supernatants and by α-MCT elaborated by poly I·poly C-stimulated macrophages in vitro.—We next tested whether whole supernatants or column fractions from poly I·poly C-stimulated macrophages containing MCT were capable of affecting these various tumor cells. Materials with MCT activity were added directly to 0.5×10^6 target cells and incubated up to 36 hours at 37°C. The remaining tumor cells were vitally stained and enumerated. Table 3 indicates that both whole supernatants and the α-MCT fractions from molecular sieving columns containing 175 and 150 U of L-cell-lytic material, respectively, reduced cell number from controls by 20–52% for the EL 4, NS-1, and YAC-1 murine targets. These targets were also affected to a lesser extent by a 1:10 dilution of MCT activity. Interestingly, MCT at these levels did not affect human K562 targets. Furthermore, the results shown in table 4 indicate that murine spleen lymphocytes, normal counterparts of these lymphoid tumor cells, were resistant to lysis.

[c] Values are means ± range of viable treated cells as compared to values for untreated controls. *Values in parentheses* represent mean viabilities ± range of treated cells as compared to viabilities of untreated controls.

Direct cytolysis of various target cells by poly I·poly C-stimulated macrophages.—When syngeneic, allogeneic, or xenogeneic target cells were exposed to intact poly I·poly C-stimulated macrophages, reduction in all tumor cell numbers was observed. As shown in table 5, from 23 to 70% of the cells were removed by the stimulated PEMM at 36 hours. In contrast to the above experiments with MCT, K562 targets were destroyed by the macrophages. The reduction in tumor cell numbers in these and the previous studies could be due to either cytostasis or cytotoxicity or to both effects.

Effect of various inhibitors on MCT secretion in vitro by poly I·poly C-stimulated macrophages.—PEMM from thioglycollate-induced C57BL/6 mice were treated with various inhibitors during the 1-hour poly I·poly C stimulation, washed thoroughly, and then allowed to release materials for 2 hours in the absence of inhibitors. Supernatants were collected and tested for cytotoxicity, as described in "Materials and Methods." Colchicine and iodoacetic acid inhibited release, in a dose-dependent manner, at levels of 5×10^{-5} and 1.2×10^{-4} M, respectively (text-figs. 5A, 5B, 5C). The effect of these inhibitors on cell viability is shown in text-figure 5. At the above levels, these inhibitors were not toxic to the PEMM. Cytochalasin B, however, was not as effective in inhibiting release (text-fig. 5C). Text-figure 5D demonstrates that emetine inhibited 75% of the release at 10^{-5} M. However, it also reduced macrophage viability to 83%. At this level, protein synthesis (^{75}selenium–methionine incorporation) was inhibited approximately 30%. Further, the inhibition by emetine was not dose dependent; at a concentration two orders of magnitude higher, 10^{-3} M, MCT release was inhibited only 80%, whereas viability was reduced to 57%. An inhibitor of trypsin-like proteases, SBTI, was also tested. Neither viability nor release was significantly affected at a concentration of 10^{-4} M (data not shown).

Finally, trypan blue, a vital stain reported to be an inhibitor of lysosomal hydrolysis (*15*), was tested. Macrophages were pretreated with various concentrations of try-

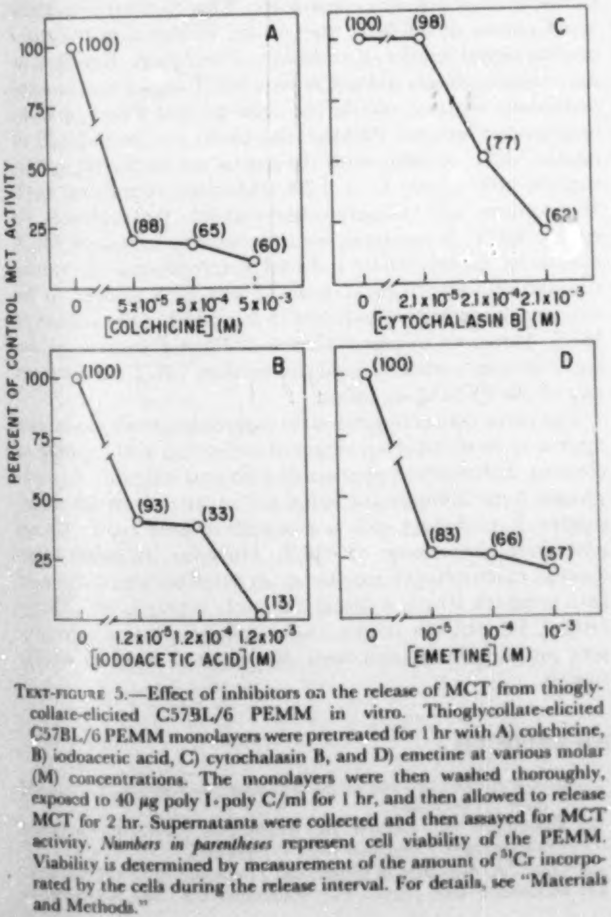
[a] Target cells, 0.5×10^6, were added to 5×10^5 poly I·poly C-stimulated C57BL/6 PEMM (10:1 effector-to-target cell ratio). After 12 and 36 hr, the remaining tumor cells were removed, and total viable cells were enumerated on a hemacytometer, as described in "Materials and Methods." Values are means ± range.

pan blue. After 24 hours, the residual vital stain was washed from the macrophages, poly I·poly C was added, and release was allowed to proceed, as described in "Materials and Methods." The incorporation of trypan blue by the macrophages, as determined by OD_{600}, is shown in table 6. Clearly, incorporation was inhanced with increasing concentrations of the dye. Trypan blue inhibited approximately 50% of the release of MCT at 2.2×10^{-3} *M*, and cell viability was approximately 70% (text-fig. 6). Upon restimulation with poly I·poly C, a similar pattern of inhibition and effector cell viability was observed.



Text-figure 5.—Effect of inhibitors on the release of MCT from thioglycollate-elicited C57BL/6 PEMM in vitro. Thioglycollate-elicited C57BL/6 PEMM monolayers were pretreated for 1 hr with A) colchicine, B) iodoacetic acid, C) cytochalasin B, and D) emetine at various molar (M) concentrations. The monolayers were then washed thoroughly, exposed to 40 μg poly I·poly C/ml for 1 hr, and then allowed to release MCT for 2 hr. Supernatants were collected and then assayed for MCT activity. *Numbers in parentheses* represent cell viability of the PEMM. Viability is determined by measurement of the amount of ^{51}Cr incorporated by the cells during the release interval. For details, see "Materials and Methods."

Text-figure 6.—Effect of incorporated trypan blue on the primary and secondary stimulation and release of MCT from thioglycollate-elicited C56BL/6 PEMM in vitro. Following solubilization of the monolayer as described in "Materials and Methods," the PEMM were examined for cell viability by ^{51}Cr incorporation and trypan blue incorporation by absorbance at 600 nm.

DISCUSSION

PEMM obtained from alloimmune mice can be stimulated to release cell-lytic molecule(s) in vitro. The cell toxin(s) are herein termed "macrophage cytotoxin(s)" MCT. Furthermore, PEMM from animals that had rejected the tumor allograft spontaneously released MCT when initially established as monolayers, whereas PEMM from an occasional animal that did not reject the tumor did not release detectable levels of MCT. Release in vitro from PEMM begins 4 hours after a 1-hour contact with tumor cells. Release ceases at 4–6 hours; in cultures left at 37°C, activity declines by 12–24 hours. After 6–8 hours, or even 4–5 days in culture, release can be reinitiated by a 1-hour exposure to fresh allogeneic or syngeneic tumor cells but *not* by exposure to normal allogeneic or syngeneic lymphocytes. Moreover, the second round of release follows similar patterns of kinetics. Treatment of the alloimmune macrophages with Con A lymphoblasts caused release of low levels of a cytotoxin. However, the treated PEMM were associated with bound lymphoblasts (presumably binding via free valences of lectin) during the release period, and in this case the toxin may in fact be lymphocyte derived. This is clearly an inducible system of cell-lytic molecules. No MCT is detectable in these cultures if the tumor cells are not removed, which will be discussed later. In contrast to the response of alloimmune macrophages, resident macrophages release negligible MCT under all conditions.

Although we were able to generate significant levels of lytic activity from alloimmune macrophages, other methods were examined for induction of these molecules for further study. We found that thioglycollate-elicited PEMM treated with 40 μg poly I·poly C/ml responded quite uniformly and released high levels of MCT. Following the removal of poly I·poly C, there was a 30- to 60-minute lag period, after which the levels climbed to a peak by 2 hours and then declined to very low levels by 24 hours. The loss of MCT activity in the supernatant is clearly due to two effects: *a*) cessation of biosynthesis and secretion and *b*) degradation of already secreted forms.

Upon chromatography of supernatants from stimulated C57BL/6 macrophages on Ultrogel AcA 44, MCT can be resolved into two molecular species: α- and β-classes—140,000–160,000 and approximately 60,000 daltons, respectively (text-fig. 4A–C). The α-class is observed in supernatants from alloimmune PEMM and in poly I·poly C-stimulated and LPS-stimulated thioglycollate-induced PEMM. However, the β-class is observed rather infrequently and *only* in supernatants from alloimmune macrophages (text-fig. 4A). Although not examined, this smaller β-form may be a subunit or degradation product of the larger α-class.

When supernatants from poly I·poly C-stimulated PEMM and α-MCT obtained from these supernatants are added to murine EL 4, NS-1, and YAC-1 tumor targets, a 30–55% reduction in cell number is observed. However, there was little or no effect either on the human K562 tumor or on normal BALB/c spleen cells. When the above transformed cells are added to poly I·poly C-stimulated thioglycollate-elicited PEMM at a 10:1 ratio, 24–70% of the targets are removed. Whether cytolysis or cytostasis is occurring is difficult to prove unequivocally. As observed in table 3, the reduction in cell number does not directly correlate with the reduction of cell viability, which would suggest cytostasis occuring. An appropriate suggestion is that both cytolysis and cytostasis are occurring simultaneously.

A common feature of MCT and previously described macrophage-derived cell-lytic materials is their instability in supernatants (*7, 21, 22*). Once released, MCT is unstable at 37°C, which might contribute to the fall in supernatant activity levels. At −20 or 4°C, activity is partially preserved for an additional 2–4 days (data not shown). However, the activity is stable enough for various parameters of production and release from the PEMM to be examined.

The release of MCT after stimulation appears to require cellular protein synthesis and an active secretory system, because treatment of stimulated PEMM with emetine (to block protein synthesis), colchicine (to disrupt microtubules), and iodoacetic acid (an alkylating agent to block phagocytosis) at levels that were shown not to significantly affect cell viability in a 3-hour period dramatically affected the secretion of MCT. Treatment with cytochalasin B affected release to a lesser extent, and SBTI had no measurable effect. However, trypan blue at a concentration of 2.2×10^{-3} *M* inhibited release by approximately 55% while decreasing macrophage viability to 70%. With a twofold-higher concentration, release of MCT was still approximately 50% while cell viability dropped to 55%; these results obtained with trypan blue might indicate existence of both lysosomal and nonlysosomal release mechanism(s). In other words, the inhibition by trypan blue would indicate that an alternative secretory route might exist—possibly one that does not require a vacuolar system.

There are several parameters that are operative and control the in vitro release of MCT by murine PEMM. The first raises macrophages to a particular state of activation, which permits them to respond to further stimulation. In our experiments this is represented as an ip injection of tumor cells or thioglycollate. As an alternative explanation, these treatments may induce responsive cells to migrate into the peritoneum from other tissue sites. The second is a stimulating signal in vitro represented in our studies by tumor or poly I·poly C treatment. This treatment induces rapid release of cell-lytic material(s). Removal of the stimulating signal results in cessation of secretion. Resident or naive macrophages did not release MCT under any in vitro conditions we used. While the data are not shown, starch- or glycogen-induced PEMM also could not be induced to release MCT, in vitro, with the agents we employed. In our studies, poly I·poly C or LPS treatment stimulated both alloimmune and thioglycollate-elicited macrophages to release MCT. In contrast, we were unable to induce MCT release by thioglycollate-induced macrophages via tumor stimulation. Thus poly I·poly C and LPS appear to be stronger, less-selective inducers in stimulating the release of MCT. However, mitogens Con-A or PHA-P cannot apparently serve as a second signal to stimulate MCT release from any of the PEMM we tested.

The three classes of peritoneal macrophages we examined appear to be at different stages of activation and capable of eliciting differential responses to a second stimulus. Macrophages from alloimmune mice are at an advanced stage, inasmuch as contact with tumor cells or poly I·poly C can potentiate the release of MCT. However, thioglycollate-elicited macrophages may be at an intermediate stage and thus require a stronger signal (i.e., poly I·poly C or LPS) to release. Finally, the resident macrophage appears to represent an early stage and does not respond even to strong signals.

Inducible Macrophage Cytotoxins. II. Tumor Lysis Mechanism Involving Target Cell-Binding Proteases[1,2]

Thomas H. Reidarson,[3] Gale A. Granger,[3] *and* Jim Klostergaard[3,4,5,6]

ABSTRACT—Thioglycollate-elicited C57BL/6 peritoneal exudate macrophage monolayers (PEMM) stimulated with poly I·poly C or LPS released a macrophage cytotoxin (MCT) that rapidly bound to syngeneic (EL 4) or allogeneic (NS-1, YAC-1) tumor cells but did not bind to normal splenocytes. No binding to human (K562) tumor cells was observed. PEMM stimulated with poly I·poly C destroyed allogeneic tumor cells (NS-1) when separated by cell-impermeable Millipore filters in vitro; in contrast, PEMM *not* stimulated with poly I·poly C were incapable of lysing targets when separated by membranes. The reversible inhibitors *Nα-p*-tosyl-L-arginine methyl ester and soybean trypsin inhibitor and the irreversible inhibitors *Nα-p*-tosyl-L-lysine chloromethyl ketone and phenylmethylsulfonyl fluoride, of trypsin-like proteases, significantly or totally inhibited MCT cell-lytic activity for L-929 cells in vitro. Furthermore, modification of MCT-associated arginine residues by 1,2-cyclohexanedione completely blocked lytic activity. MCT was concluded to be an inducible nonspecific cell-lytic effector molecule elaborated by activated macrophages, which could bind to potential target cells, and was itself or was associated with a protease.—JNCI 1982; 69:889–894.

Activated peritoneal macrophages from mice are capable of inducing nonspecific cytotoxicity to a variety of syngeneic, allogeneic, and xenogeneic tumor targets in vitro (*1–3*). The cytotoxic reaction occurs within a microenvironment existing at the contact region(s) between the effector and the target. One mechanism of lysis has been proposed to involve a vectorial release of a monokine (e.g., lysosomal enzymes) from the macrophage to the target cell (*4–5*). Yet very little is known about the putative cytotoxic molecule(s) involved in this reaction and the mechanism by which they act on tumor cells.

In the previous manuscript of this series (*6*) we demonstrated that PEMM from alloimmune C57BL/6 mice and thioglycollate-elicited macrophages from nonimmune C57BL/6 mice can be induced in vitro to release a cell-lytic material known as MCT. This is an inducible toxin, and activated macrophages can be stimulated to release MCT when briefly exposed to tumor cells or poly I·poly C in vitro. Release begins within a few hours after stimulation and then rapidly ceases. Physical studies have indicated that MCT from macrophages obtained from alloimmune or thioglycollate-induced mice appears on molecular sieving columns principally as one species of 140,000–160,000 daltons. Biochemical studies indicated that MCT is homogeneous with respect to charge and is heat- and pH-labile (Klostergaard J, Reidarson TH, Granger GA: Manuscript in preparation).

We report here that MCT binds rapidly to murine tumor targets but not to normal cells. Additional studies reveal that stimulated PEMM can destroy NS-1 allogeneic targets in the absence of effector-to-target cell contact. Both reversible and irreversible inhibitors of trypsin-like proteases block MCT activity. Modification of MCT arginine but not lysine residues also blocks lytic activity. These findings suggest that a proteolytic reaction is necessary for the cell-lytic event. Several model(s) are proposed to explain how MCT may act as an effector of in vitro tumor cell lysis mediated by macrophages.

MATERIALS AND METHODS

Culture media and cell lines.—Culture media consisted of RPMI-1640 medium supplemented with 3 or 10% heat-inactivated (56°C, 60 min) FCS (GIBCO, Grand Island, N.Y.) or newborn calf serum (GIBCO), 100 μg streptomycin/ml, and 100 U penicillin/ml. Murine C3H L-929 (H-2^k) transformed fibroblasts were grown in 32-oz prescription bottles in RPMI-1640 with 3% serum at 37°C in 95% air and 5% CO_2 atmosphere and passed twice a week. C57BL/6 EL 4 (H-2^b) lymphoma, BALB/c NS-1 (H-2^d) myeloma, A-Sn YAC-1 (H-2^a) lymphoma, and human K562 erythroid leukemia cell lines were grown in RPMI-1640 supplemented with 10% FCS. Naive BALB/c (H-2^d) spleens were asceptically removed and prepared on the day of the experiment as previously described (*6*).

Binding of MCT to target cells.—Tumor and normal cells, 15×10^6 and 3×10^6, respectively, which were 93–98% viable, were pelleted by centrifugation at 300×*g* for 5 minutes and washed four additional times with serum-free RPMI-1640. The cells were then resuspended in 300 μl MCT obtained from supernatants of poly I·poly C-stimulated PEMM containing 39–62 U lytic activity and incubated at 4°C. After 30 minutes the cells were pelleted by centrifugation, and

250 µl supernatant was removed and then assayed for lytic activity on L-929 cells. Percent adsorption or removal of units of activity was determined by comparison of the control level of activity with the activity remaining after the supernatants were removed from the target cells.

Lysis of NS-1 targets by poly I·poly C-activated macrophages through membrane filters.—Cellulose nitrate membranes with 0.2 µm-pores (Sartorius membrane filter; Science Essentials, Fullerton, Calif.) were cut into circles and washed with sterile PBS, and then one or two were fitted tightly over 0.5×10^6 adherent macrophages in wells of Costar plates 15 minutes before 50×10^3 target cells were added. After 12- and 36-hour incubation periods at 37°C in a CO_2 incubator, the remaining tumor cells were enumerated and viability was determined by eosin Y exclusion in a hemacytometer.

Protein modification reactions.—MCT partially purified by molecular sieving, as previously described (*6*), was used for protein modification studies. The active fractions were pooled, concentrated on an Amicon PM10 membrane to 5 ml, and then dialyzed overnight against more than 100 volumes of approximately 0.2 *M* (pH 9) carbonate buffer. Aliquots of this pool (250–1,500 µl) were used in the chemical modification reactions described below.

MA (0.2–4.0 mg; Aldrich Chemical Co., Milwaukee, Wis.) was dissolved directly in the MCT preparation. The solution was agitated until dissolution was complete (≈60 sec). After 30 minutes at room temperature, the preparation was dialyzed against approximately 1,000 volumes of PBS for 4–16 hours. The dialyzed preparation was then assayed for toxicity on L-cells.

MAI (Pierce Chemical Co., Rockford, Ill.) was either added directly to the buffered MCT or first diluted in PBS and then an aliquot was added to the MCT. The final level was 0.1–11 mg/ml. After 30 minutes at room temperature, the preparation was dialyzed and assayed as above.

We reacted MCT with CHD (Pierce Chemical Co.) by making the MCT preparation 0.06 *M* in CHD. The reaction was quenched at various times (30 min–5 hr) by dialysis; after dialysis against more than 1,000 volumes of PBS for 4–16 hours, cytotoxic activity of the modified MCT was determined by assay on L-cells, as above.

Protease inhibitors.—MCT was purified as described before. Similarly, the active fractions were pooled, concentrated, and dialyzed overnight against 100 m*M* (pH 7.2) phosphate buffer. Aliquots (250–1,500 µl) were employed in the reaction described below.

SBTI at 0.1 and 1.0 m*M* (Sigma Chemical Co., St. Louis, Mo.) was dissolved in the MCT preparation of 6–15 U/ml. After 30 minutes at room temperature, the sample was assayed directly on L-cells. As a toxicity control, SBTI was diluted in PBS to the concentration used for the protease-inhibition experiments and added directly to L-cells.

Modification of MCT by TLCK and PMSF (Sigma Chemical Co.) was conducted according to the following protocol. Aliquots (400–1,500 µl) of MCT corresponding to approximately 10–40 U/ml *were reacted directly* with TLCK at final levels of 0.4–10 m*M*. The modification was performed at 37°C for 1 hour. The samples were then dialyzed against approximately 1,000 volumes of PBS for 4–6 hours at room temperature. After dialysis, the lytic activity of each sample was determined by assay on L-cells, as previously described.

TAME and ALME (Sigma Chemical Co.) were used in inhibition studies by *concurrent incubation* of MCT prepared as above, with various levels (10^{-4} to 10^{-2} *M*) of the inhibitor on L-cells. After 20 hours, the level of MCT lysis in the presence of TAME was compared to the level of control MCT lysis. TAME was not toxic to L-cells at levels up to 10^{-2} *M*; ALME was occasionally toxic at this level.

MCT was prepared as above and treated with various levels (1–10 m*M*) of IAM (Sigma Chemical Co.) for 2 hours at room temperature. After dialysis against 500 vol PBS for 24 hours, the samples were assayed on L-cells and their titers determined.

The percent inhibition of MCT by MA, MAI, CHD, PMSF, and TLCK was calculated according to the following equation: Percent inhibition=[(control MCT, U/ml − experimental MCT, U/ml)/control MCT, U/ml]×100%. The percent inhibition of MCT by SBTI, TAME, or IAM was expressed as follows: Percent inhibition=1−[(control L-cell No. − experimental MCT L-cell No.)/(control L-cell No. − MCT L-cell No.)]×100%.

RESULTS

Reduction of MCT activity by adsorption of whole macrophage supernatant on various target cells.—Cell-free whole supernatants containing approximately 39–102 U L-cell lytic activity ml were collected from poly I·poly C-stimulated macrophages as described in "Materials and Methods" and treated as follows: Supernatant, 300 µl, was incubated with various targets or left untreated for 30 minutes at 4°C. The cells were then removed by centrifugation, and supernatants were retested for lytic activity. Shown in tables 1 and 2 are four separate experiments. Both EL 4 and NS-1 removed approximately the same amount of MCT (40–50%), and YAC-1 adsorbed an even greater amount (≈60%). In contrast, the human K562 targets and normal BALB/c spleen

TABLE 1.—*Removal of supernatant MCT activity from poly I·poly C-stimulated C57BL/6 PEMM on normal BALB/c spleen cells in vitro*[a]

Expt No.[b]	Target cell	Percentage of MCT activity adsorbed on targets:	
		3×10^6	15×10^6
1	Normal BALB/c spleen	15.7	12.1
	NS-1	18.7	54.2
2	Normal BALB/c spleen	−2.4	7.9
	NS-1	27.4	38.6

[a] A 300-µl sample of whole supernatant from poly I·poly C-stimulated PEMM containing various levels of MCT activity was added to 3×10^6 and 15×10^6 target cells, allowed to incubate at 4°C for 30 min, and then rendered cell-free. A 250-µl sample of this cell-free supernatant was collected and assayed for MCT as described in "Materials and Methods."

[b] Total numbers of MCT (U/ml) in supernatant were 52 for expt 1 and 102 for expt 2.

TABLE 2.—*Removal of supernatant MCT activity from poly I·poly C-stimulated C57BL/6 PEMM on various target cells in vitro*[a]

Expt No.[b]	Target cell	Percentage of MCT activity adsorbed on targets:	
		3×10^6	15×10^6
1	EL 4	27.8	43.9
	NS-1	20.8	42.8
	YAC-1	22.2	62.5
	K562	13.0	10.8
2	EL 4	24.3	52.8
	NS-1	25.1	38.8
	YAC-1	19.7	54.3
	K562	6.7	7.2

[b] Total numbers of MCT (U/ml) in supernatants were 62 for expt 1 and 39 for expt 2.

cells had little effect; neither target cell type removed greater than 16% of the MCT activity.

Cytolysis and/or cytostasis of allogeneic NS-1 target cells in vitro through Millipore membranes by poly I·poly C-stimulated macrophages.—The preceding results raised the question of whether stimulated macrophages could inhibit growth or kill tumors in the absence of direct cellular contact. We separated effector macrophages and target tumor cells by a 0.2-μm Millipore membrane. After the macrophages were stimulated with poly I·poly C, as described in "Materials and Methods," the filter was placed over the macrophage monolayer and tumor targets were added at a 10:1 effector-to-target cell ratio. In both experiments shown in table 3, little effect was seen after 12 hours, whether or not effectors and targets were separated by filters. However, after 36 hours, reduction in the number of viable tumor cells was evident in control cultures without filters (47–75%) as well as in tests separated by filters (40–55%).

Effect of protease inhibitors on MCT activity.—Several investigators have suggested that serine proteases are involved in the expression of lytic activity by activated macrophages (*5, 7-9*). We tested the effects of several inhibitors of trypsin-like proteases: SBTI, TLCK, PMSF, TAME, and ALME on α-MCT-containing fractions, as described in "Materials and Methods." The results are presented in table 4. α-MCT showed a very striking susceptibility to direct treatment with TLCK. Although TLCK blocked MCT activity, it was important for us to establish whether this blockage occurred by inactivation of a trypsin-like protease or by modification of a vital sulfhydryl group (*10-13*). IAM at levels as high as 10 m*M* was totally without effect on the lytic activity (table 4), which suggested that the former mechanism (trypsin-like protease) and not the latter (vital sulfhydryl group) was operative. This probability was further supported by the blocking observed with PMSF. Higher doses of PMSF (>2.5 m*M*) could not be examined due to insolubility of the drug.

When MCT was incubated with TAME during target cell lysis, as described in "Materials and Methods," a dose-dependent inhibition of lysis was observed (table 4). When MCT was co-incubated with SBTI during target cell lysis, as described in "Materials and Methods," there was a decrease in lytic activity (table 4). If inhibition were occurring at the same active site as that affected by TLCK and TAME, inhibition beyond that seen at 0.1 m*M* (40%) should be attainable. However, at levels higher than this (table 4), toxicity of SBTI for the cells was apparent, thereby overriding the effect of MCT-mediated cytolysis being inhibited. The specificity of the protease was further probed with ALME. No blocking could be observed up to 10^{-2} *M*, the highest dose usually nontoxic for the L-cell (table 4).

Protein modification of MCT.—The effects of modification of MCT partially purified by being sieved on Ultrogel AcA 44 with amino acid side chain-specific reagents MA (which modifies lysine and tyrosine), MAI (which modifies lysine), and CHD (which modifies arginine) are presented in table 5. In none of these modification experiments were we able to quantitate the extent of reaction with a particular type of amino acid side chain, because the MCT preparation was impure and the lytic moiety present was in extremely low amounts; these factors precluded the necessary total amino

TABLE 3.—*Cytolysis and/or cytostasis of NS-1 tumor cells by poly I·poly C-stimulated C57BL/6 PEMM through Millipore membranes*[a]

Expt No.	Treatment	Percent targets[b] remaining after incubation time[c]:	
		12 hr	36 hr
1	Macrophages	93.6±3.2	53.4±4.8
	Macrophages + filters	96.7±1.2	59.8±3.9
2	Macrophages	92.1±1.8	25.6±5.8
	Macrophages + filters	91.3±10.0	44.8±5.6

[a] NS-1 target cells, 5×10^4, were added to 5.0×10^5 PEMM (poly I·poly C treatment described in "Materials and Methods"). An intact Millipore filter with 0.2-μm pores was placed over the macrophages 15 min before the targets were added.

[b] Expressed as percent of tumor targets incubated in the presence of untreated macrophages.

[c] After 12 and 36 hr, the remaining cells were removed and enumerated on a hemacytometer, as described in "Materials and Methods."

TABLE 4.—*Effect of protease inhibitors on lytic activity of α-MCT*[a]

Inhibitor	Concentration, m*M*	Reaction factors	Percent of inhibition[b]
TLCK	0.4	1 hr, 37°C	2
	2		96
	10		100
IAM	1	3 hr, ambient temperature	0
	10		0
PMSF	1	1 hr, 37°C	53
	2.5		61
TAME	0.1	Simultaneous incubation on L-cells	10
	1		52
	10		100

	1		23[c]
ALME	0.4	Simultaneous incubation on L-cells	0
	2		0
	10		0

[a] α-MCT was purified by molecular sieving, as described in "Materials and Methods." Concentrated, pooled fractions were dialyzed against 100 m*M* (pH 7.2) phosphate buffer and then treated with the reagents.

[b] Calculated as described in "Materials and Methods."

[c] Toxicity of SBTI on L-cells reduced apparent inhibition of MCT.

TABLE 5.—*Effect of chemical modification on lytic activity of α-MCT*[a]

Reagent	Amino acid modified	Reagent concentration	Reaction time	Percent inhibition[b]
MA	Lysine and tyrosine	0.2 mg/ml	30 min	88.8
		4 mg/ml		98.7
MAI	Lysine	0.1 mg/ml	30 min	15.1
		0.4 mg/ml		39.2
		1.0 mg/ml		43.1
		11 mg/ml		59.1
CHD	Arginine	60 m*M*	30 min	65.6
			3 hr	75.7
			5 hr	89.3

[a] α-MCT purified by molecular sieving was used. The active fractions were pooled, concentrated, and dialyzed overnight against 0.2 *M* (pH 9) carbonate buffer. Various protein modifiers were dissolved directly in the MCT preparation and then assayed for lytic activity, as described in "Materials and Methods."

[b] Various percentages are representative of several experiments in which 10–70 U control MCT activity/ml was observed.

acid analysis for determination of the extent of modification. However, in an attempt to obtain reasonable levels of substitution, we used wide ranges of exposure to the reagents.

Modification of MCT with MA was achieved with the use of a twentyfold range of MA (0.2–4.0 mg). Although multiple experiments were performed, only the results from the extremes of reagent concentration are shown. In every case, total, or nearly total, abrogation of lytic activity was observed (table 5).

When MCT was allowed to react with the lysine-specific reagent MAI, there was an initially progressive loss of lytic activity, which tended to plateau. However, even at extremely high reagent concentrations, blocking of lysis was incomplete.

The guanido-specific reagent CHD caused progressive loss of MCT lytic activity. Loss of activity corresponded to increased time of exposure to and reaction with the CHD, until after 5 hours when lytic activity was abolished. This was a remarkable rate of modification, when one considers that the pH of the reaction (9) was at least 3 U lower than the pK of arginine side chains (≈12).

DISCUSSION

In the first manuscript of this series (*6*), we demonstrated that alloimmune macrophages stimulated with tumor cells, poly I·poly C, or lipopolysaccharide release MCT in vitro. The principal form of MCT from this source appeared to have biochemical and functional characteristics indistinguishable from those of MCT obtained by poly I·poly C or LPS stimulation of thioglycollate-elicited macrophages. MCT had selective cytotoxic effects for murine tumor cells when compared to normal cells.

In this report, we demonstrate that when supernatants from C57BL/6 (*H-2*^{b}) thioglycollate-elicited PEMM stimulated with poly I·poly C are added to normal BALB/c (*H-2*^{d}) spleen cells, syngeneic EL 4 (*H-2*^{b}) lymphoma, allogeneic NS-1 (*H-2*^{d}) myeloma, YAC-1 (*H-2*^{a}), and human K562 erythroid leukemia targets, approximately 10, 48, 44, 57, and 9%, respectively, of the MCT activity is removed (tables 1, 2). This removal occurs rapidly at 30 minutes and 4°C, suggesting that adsorption, rather than degradation, has occurred. Adsorption of MCT to the target cell appears to be a prerequisite for cell cytotoxicity. That the human K562 targets were not affected by the levels of MCT used in these studies might be explained by either target insensitivity or target selectivity on the part of MCT. Target insensitivity is most likely, in view of the work by Kramer and Granger (*14*), who have demonstrated that another human target cell (HeLa) was destroyed by activated murine macrophage supernatants. It is also possible that a mechanism not involving MCT is used by the macrophage in cytolysis of K562.

Although direct cell-to-cell contact is considered necessary for cytolysis of targets by activated macrophages (*1–5, 7–9, 15–17*), this contact appears not to be necessary in certain situations, provided the effectors are appropriately activated. We separated poly I·poly C-stimulated macrophages from the NS-1 targets by a membrane filter with a 0.2-μm pore and found that normal levels of cytolysis and/or cytostasis are observed in 36 hours (table 3). To control for the possibility that effector macrophages could project a cytoplasmic process(es) through the filter and affect target cells through direct contact, we separated the cells by two filters and observed identical results (data not shown). Clearly, the signal presented to the macrophage by poly I·poly C overrides the necessity for contact with the tumor in this system. In contrast, when non-poly I·poly C-stimulated macrophages were employed, they were unable to induce cell lysis through the filter. If MCT is involved in tumor cell lysis, these studies suggest that contact between a tumor and effector macrophage is a necessary first step to provide the inducing signal for MCT release, followed by rapid binding of MCT to the target. However, poly I·poly C alone is capable of triggering; once induced, effector macrophages may not require contact with the target cell to induce lysis. The rapidity with which the MCT binds to the tumor target might explain why MCT was not observed to be spontaneously released into the supernatant from alloimmune macrophages if residual tumor cells were present in the exudate (*6*). This rapid binding is compatible with a role for MCT only in the immediate microenvironment between a macrophage and its conjugated tumor target.

Our evidence further suggests that the manner in which MCT expresses cell-lytic activity involves protease-dependent steps. Previous in vitro studies by Hibbs and co-workers (*5*) and by other groups (*7–9*) have suggested a role for serine proteases in the expression of cytolysis by activated macrophages. In particular, the reagent TLCK, which alkylates proteases with trypsin-like specificity, has been shown to effectively block cytolysis in these cell-lytic reactions. This blockage suggested to us that, if MCT were in fact a toxic mediator employed by the activated macrophage in cytolysis, MCT's activity might also be protease dependent. Experiments with partially purified MCT and TLCK do show that this alkylating reagent destroys lytic activity of the soluble molecule (table 4). The blocking of MCT activity also observed with TAME, PMSF, and SBTI and the lack of effect of the sulfhydryl alkylating agent IAM (table 4) further suggest the vital role of a trypsin-like protease in the expression of lytic activity.

On the basis of these results, we attempted to determine the nature of the specific substrate of this protease. We believe that MCT could either be a protease or be associated with a protease. Although a reasonable model for the mechanism of MCT-induced lysis could invoke direct protease action on the target cell, we favor a second model. In this model, the substrate for the protease is within the MCT itself, and it must itself be cleaved for lytic activity to be expressed. Since inactivation of MCT by TLCK suggested the protease has trypsin-like specificity, we approached the chemical characterization of the substrate by using reagents capable of modification of positively charged amino acid side chains. If the protease were juxtaposed in the MCT in such a way as to cleave an arginine- or lysine-containing loop of the polypeptide chain, then chemical modification of the arginine or lysine residue should prevent "activation" by the protease and therefore block cell lysis. We used the reagents MA (which acylates lysine and tyrosine residues), MAI (which modifies lysine), and CHD (which reacts with arginine).

Our results suggest that if MCT were associated with a protease, the protease would cleave an MCT-associated polypeptide chain containing arginine regions. The most compelling evidence for this supposition is the time-dependent reaction of MCT with CHD, which results in a progressive and virtually complete loss of lytic activity (table 5). The kinetics of this reaction appear to be similar to that reported by Toi et al. (*18*) for CHD and hemoglobin. Their studies were conducted in strongly alkaline conditions (0.05–0.10 *N* NaOH), whereas extensive modification of the MCT was successful for us in 0.2 *M* (pH 9) carbonate buffer. This hyperreactivity is fortuitous because we could not subject the MCT to such extremes of pH to promote chemical modification since the biologic activity would be lost at this pH (Klostergaard J, Reidarson TH, Granger GA: Manuscript in preparation).

In contrast to our results from modifying arginine, attempts to ascertain a role for a lysine-containing region of the protein were equivocal. MAI, which modifies lysine side chains while preserving the positive charge, showed some blocking effect on the lytic activity of MCT when a wide range of reagent levels was used (table 5). This effect appears to plateau at high reagent levels. Had, in fact, a lysine residue been the target of the protease, lytic activity should have been *totally* blocked, when the extremely high levels of MAI were used. The partial effect observed might be explained by a general denaturation effect upon modification of MCT lysine residues with MAI. In view of the report by Hunter and Ludwig (*19*), side reactions with other amino acid side chains and MAI are not likely.

In this light, the blocking of MCT by MA (table 5) does not suggest a role for lysine. On the contrary, two alternate explanations are more tenable. First, MA also modifies tyrosine and possibly serine. Thus these residues might be of importance, not as substrates, but as contact or catalytic residues in the protease. Serine is an important catalytic residue in some extensively characterized enzymes [for review, *see* (*20*)]. The other distinct and reasonable explanation for the MA inactivation of MCT is the electrostatic repulsion introduced by the negatively charged maleyl-lysine adducts where previously positively charged lysine side chains had been. This repulsion, which is widely reported for proteins reacting with dicarboxylic anhydrides (*27–33*), could easily lead to perturbation of critical tertiary or quarternary structure.

Although it is also possible that CHD and MAI react directly with the protease active site rather than the protease's substrate to inactivate MCT, we believe this model is less likely, since basic amino acids are poor candidates to occupy binding or catalytic regions of a trypsin-like protease [for review, *see* (*20*)].

The distinct effects of the two reversible inhibitors TAME and ALME further suggest that the protease cleaves at an arginine rather than lysine residue. TAME, an arginine derivative, was a very effective inhibitor (table 4), whereas ALME, a lysine derivative, had no measurable effect. We cannot discount, however, that TAME may be superior at least in part due to its hydrophobic binding in the ρ_1 region of the protease active site (*21, 22*). This hydrophobicity could account for the blocking observed by TLCK, a lysine derivative. However, TLCK and the protease may initially form complexes with only a low association constant, comparable to the poor association with ALME; the subsequent covalent bond-forming step with TLCK would then serve to effectively block the active site.

Contrast of the characteristics of MCT with those of CF described by Adams and co-workers (*8*) is noteworthy. They described CF found in the supernatants of peritoneal macrophages from BCG- or thioglycollate-treated mice, following endotoxin stimulation, to be principally approximately 40,000 daltons (*7, 8*), whereas MCT is approximately 150,000 daltons. Furthermore, the lytic activity CF is strongly blocked by serum (*17, 23*), whereas MCT can lyse all susceptible tumor targets in the presence of 3–10% bovine serum. This difference may reside in the inability of α_2-macroglobulin to effectively "bury" MCT in its cleft(s) (*24–26*). Both CF (*8*) and MCT are dependent on protease activity for expression of their tumoricidal function. Further studies for characterization and comparison of CF and MCT are warranted and their possible subunit relationship should be considered.

Finally, these reports provide initial documentation of a molecular mechanism that may be operative in the target-injury phase of macrophage-mediated cytolysis. Further aspects of this possible mechanism can be only elucidated pending the purification and characterization of the MCT itself.

Squamous Metaplasia in Organ Cultures of Vitamin A-Deficient Hamster Trachea: Cytokinetic and Ultrastructural Alterations[1,2,3]

Dharam P. Chopra[4,5]

ABSTRACT—Cytokinetic and morphologic studies were performed to elucidate the origin of epidermoid metaplasia in organ cultures of tracheas derived from vitamin A-deficient Syrian golden hamsters. Focal areas of squamous metaplasia were observed 2 days after explantation, and extensive epidermoid metaplasia and cornification were present in approximately 89% of the explants at day 10. During the first 2 days, both basal and mucous cells proliferated actively. By day 3, the total mucous cell [^{3}H]thymidine labeling index (LI) had declined and remained at very low levels during the remaining culture period. The basal cell LI also declined from its higher level, but it remained at relatively higher levels than those of the mucous cells between days 3 and 9 after culture. In the lesions, labeled cells were generally confined to the basal layer, and the LI was about thirtyfold greater than the total basal cell LI. As the lesions progressed, the surface layer containing the mucous and ciliated cells was exfoliated as a result of population pressure from the underlying actively proliferating basal cells and subsequent epidermoid differentiation of the daughter cells. These data support the hypothesis that epidermoid metaplasia of tracheobronchial epithelium caused by vitamin A deficiency originates from the generative or basal cells—JNCI 1982; 69:895–905.

Vitamin A plays an important role in the control of cellular proliferation and differentiation in a variety of epithelia. Deficiency of vitamin A in experimental animals leads to the development of keratinizing squamous metaplasia in the urinary bladder and tracheobronchial mucosa (*1–3*). In the tracheobronchial epithelium, squamous metaplasia consists of an epidermoid transformation of pseudostratified normal epithelium (*2–3*). This process can also be demonstrated in vitro. Organ cultures of trachea obtained from vitamin A-deficient hamsters and cultured in chemically defined medium for 10 days without vitamin A become squamous and keratinize. Supplementing the medium with vitamin A or an active retinoid, however, prevents the development of the lesions (*4*).

Exposure of the respiratory epithelium to carcinogens and to certain toxic inhalants also causes squamous metaplasia (*5–11*). Although histogenesis of squamous metaplasia induced by different agents including injury and infection with mycoplasma and paramyxovirus (*12–14*) have been extensively studied in experimental animals, there is a wide gap in cytokinetic evidence to define the origin of the lesions. Cytokinetic information is important since a very large fraction of squamous metaplasias and squamous cell carcinomas are generally considered mucous cell lesions (*12*), but there is evidence to indicate that certain types of squamous metaplasias in experimental animals arise from the basal cells (*2, 3, 10*). In the present study, organ cultures of tracheas obtained from hamsters that were maintained on vitamin A-sufficient and vitamin A-deficient diets were used to define the origin of squamous metaplasias caused by the deficiency. The results indicate that the lesions produced by vitamin A deficiency originate in the basal cells.

MATERIALS AND METHODS

Hamsters.—To induce vitamin A deficiency, we fed Syrian golden hamsters 11–12 days pregnant (Harlan Industries, Inc., Madison, Wis.) in individual cages a mixed diet of one part laboratory chow (Ralston Purina Co., St. Louis, Mo.) and one part vitamin A-deficient diet (Teklad, Inc., Madison, Wis.). After birth of the litters, the mothers were fed only on the vitamin A-deficient diet. The young hamsters were weaned at 21 days after birth and thereafter kept entirely on the vitamin A-deficient diet until utilized (27–30 days after birth). Six young hamsters were housed in each cage (14×12×7 inches). All animals were housed in a semi-isolated room maintained at 23–24°C with a 12-hour light–dark cycle.

All batches of vitamin A-deficient diets were checked for the deficiency before use by a group of 8 vitamin A-deficient hamsters being kept on the new diet. If the animals continued to lose weight, developed dull-matted fur and impaired vision, and subsequently died, the diet was considered deficient in vitamin A.

Normal hamsters were similarly raised except that they were fed a diet supplemented with 15,000 U of vitamin A (vitamin A–palmitate)/kg diet. Animals maintained on this diet continued to grow and reached maturity. All diets were stored at 4°C and used within 2 months after they were received.

Organ culture.—Animals with body weights between 48

and 58 g were used. At this stage most animals were gaining weight, and DH showed no external sign of vitamin A deficiency. Animals were killed with 0.5 ml of a 1% solution of Brevital Sodium (methohexital sodium; Eli Lilly & Co., Indianapolis, Ind.) injected ip, and their tracheas were excised aseptically. The tracheas were kept in the cold serum-free "holding medium" L-15, supplemented with 100 U penicillin/ml and 100 µg streptomycin/ml (Grand Island Biological Co., Grand Island, N.Y.). Each trachea was cleaned to remove any adherent tissue, opened longitudinally along the membraneous dorsal wall, and cultured individually in 60-mm plastic culture dishes (Falcon Plastics, Oxnard, Calif.). Each dish contained 2 ml of CMRL-1066 serum-free medium (Grand Island Biological Co.), supplemented with 1.0 µg crystalline bovine insulin/ml (Sigma Chemical Co., St. Louis, Mo.), 0.1 µg hydrocortisone hemisuccinate /ml (The Upjohn Co., Kalamazoo, Mich.), 2 m*M* glutamine, 100 U penicillin/ml, and 100 µg streptomycin/ml (Grand Island Biological Co.) (*4*). The cultures were gassed with a mixture of 50% O_2+45% N_2+5% CO_2 (Matheson Gas Products, Morrow, Ga.) in a rocker chamber (Bellco Glass, Vineland, N.J.) at 35-36°C and rocked approximately 8-10 times per minute. Each experiment was repeated and the data were pooled.

Morphologic observations.—For each experiment 45-50 tracheal organ cultures were prepared. To follow the development of squamous metaplasia and keratinization, we terminated groups of seven cultures at different intervals. Each explant was cut into two pieces, one to be processed for light microscopy and one for electron microscopy. For light microscopy, explants were fixed in 10% neutral buffered Formalin and embedded in paraffin. Serial sections (4 µm each) were cut through the middle of each trachea and stained in AB-PAS or H & E. Sections were analyzed according to the degree of squamous metaplasia and the presence or absence of keratohyalin granules and keratin as described previously by Sporn et al. (*4*).

For electron microscopy, specimens were fixed in 3% glutaraldehyde in phosphate buffer at pH 7.3. These specimens were cut into 1×2-mm pieces, postfixed in osmium, dehydrated in acetone, and embedded in polybed 812 (Polysciences Inc., Warrington, Pa.). Sections (1 µm each) were cut and pertinent areas localized by the examination of thick sections with a light microscope. Thin sections were cut with a diamond knife in a Porter-Blum ultramicrotome, stained with uranyl acetate and lead citrate, and examined with a Philips-300 or Hitachi HU12 electron microscope.

LI at different times after culture.—Twentyfive to 30 organ cultures were prepared. At different times after culture groups of three cultures each were pulse labeled with [^{3}H]-dThd (sp act, 6.7 Ci/mmol, 2 µCi/ml) for 1 hour and fixed in Formalin for histologic examination. From these specimens 4-µm sections were cut, deparaffinized, stained in PAS, and dipped in Kodak NTB2 emulsion diluted 1:1 with distilled water. Autoradiograms were exposed for 2 weeks at 4°C, developed in D-19, and counter stained in hematoxylin (*15*). The number of mucous (PAS-positive) and basal (PAS-negative) cells with four grains or more over their nuclei were counted in two sections (covering ≈6 mm mucosal surface) from each trachea. The LI were expressed as the number of labeled cells per centimeter length of epithelial surface.

The identification of basal and mucous cells was essentially based on the stainability of cells with AB-PAS reagents. Although this method is extensively used for identification of cells containing mucopolysaccharides, some cells that stain negatively may contain very small amounts of mucin and are not detected at this level. In the present study, basal cells were identified by the PAS-negative cytoplasm and their distribution along the basal lamina. The apexes of basal cells did not reach the tracheal lumen. These observations correlated with the ultrastructural findings.

In addition to analysis of total LI (labeled cells in the epithelial mucosa, including areas of squamous metaplasia), LI was also determined exclusively in areas exhibiting squamous metaplasia and keratinization in explants derived from the DH.

Changes in MGC at different intervals after a single [^{3}H]dThd pulse.—For each experiment 25-30 cultures were prepared. Twenty-four hours later, all cultures were pulse labeled with [^{3}H]dThd (2 µCi/ml) for 1 hour, thoroughly rinsed by three changes of fresh medium to displace free [^{3}H]dThd, and reincubated in the fresh culture medium. Groups of three cultures each were terminated at 1 hour and at 1, 2, 3, 4, and 5 days after the pulse labeling and processed for autoradiography. To estimate their proliferative potential, we enumerated the numbers of grains over mucous and basal cell nuclei. In these experiments allowance had to be made for halving of grain counts that would occur at the division of labeled nuclei. Nuclei with two grains above the background level were classified as labeled. Background count was approximately one grain per nucleus. Groups of 25 labeled basal or mucous cells were scored from each trachea, and the mean value and the standard error were calculated for each group. The significance of the difference between two groups was determined by Student's *t*-test.

RESULTS

Normal Hamster Trachea

The detailed structure of the tracheobronchial epithelium of normal hamster trachea has been described in (*2, 3, 9, 16*). Organ culture of the NH trachea for 10 days maintained typical morphology. The pseudostratified epithelium contained a row of PAS-positive columnar-cuboidal mucous and ciliated cells that extend from the basal lamina to the tracheal lumen and an intercalated row of PAS-negative basal cells that lie on the basal lamina and do not reach the lumen (fig. 1). At the ultrastructural level, the basal cells contained large, centrally located nuclei and prominent nucleoli (fig. 2). Their cytoplasm was electron-dense and contained polysomes, scant RER, and a few small mitochondria (fig. 3). Microfilaments were scant and were not commonly seen in the basal cells. The mucous cells that varied somewhat in structure according to the degree of mucus secretion showed microvilli facing lumen and their cytoplasms contained extensive RER and mucus droplets (fig. 2). Adjacent luminal cells showed junctional complexes between them. Desmosomal junctions were present, but their number was reduced after 10 days of culture. The ciliated cells showed irregular nuclei, numerous mitochondria, and RER.

Development of Squamous Metaplasia in vitamin A-Deficient Hamsters

At the initiation of cultures, the morphology of the DH trachea was essentially similar to that of the NH trachea. Organ culture of the vitamin A-deficient hamster trachea showed rapid alterations in the structure of the epithelial mucosa. Within 48 hours, focal areas of altered epithelium consisting of two distinct rows of cells were present (fig. 4). The ciliated and mucous cells of the upper row characterized by PAS-positive cytoplasms were cuboidal-flat, whereas the basal cells were round and contained large basophilic nuclei. Cells with squamous morphology extruding from the basal layer were frequently observed in the altered epithelium. At 72 hours after culture, the mucosa contained several dome-shaped structures (fig. 5) consisting of a basal layer of large, round cells, two to three layers of squamous cells, and an overlying layer of cells with PAS-positive cytoplasm. We did not see the ciliated cells in these areas. The basal and squamous cells contained PAS-negative cytoplasm. Mitotic cells were frequently observed in the basal cell layer. Subsequently, the population pressure caused by the continued proliferation of the basal cells associated with squamous differentiation resulted in rupture and, consequently, exfoliation of the surface layer of the PAS-positive cells (fig. 6).

The light-microscopic observations associated with the squamous metaplasia correlated well with alterations at the ultrastructural level. We observed the earliest sign of squamous metaplasia in a group of three to four basal cells comprising electron-dense cytoplasms that appeared to be displacing overlying mucous and ciliated cells (fig. 7). The basal cells exhibited features of active proliferation but also contained bundles of tonofilaments occasionally referred to as 'keratin' filaments (fig. 8). The presence of keratin filaments in the basal cells indicates early keratinization, since the filaments were not commonly present in the basal cells of cultures derived from NH trachea. The mucous and ciliated cells exhibited typical morphologies. We occasionally saw degenerative cells overlying metaplastic cells (fig. 7).

As the lesions progressed, metaplastic epithelium consisted of two to three layers of electron-dense squamous cells and a distinct superficial layer of cells that were electron-lucent (fig. 9). The electron-dense cells had little resemblance to the normal respiratory epithelium. The basal cells were cuboidal with large, round nuclei, predominant nucleoli, abundant polysomes, and a few bundles of keratin filament. Numerous interdigitating cytoplasmic processes occasionally ending in desmosomes projected into intercellular spaces. We frequently saw mitoses in the basal cell layer. One to two layers of electron-dense cells were in the intermediate position and resembled basal cells except that they were somewhat flatter and contained greater amounts of keratin filament. A large number of well-developed desmosomes were present between the electron-dense cells. Such a large number of well-developed desmosomes are generally observed in differentiating epidermal cells. Furthermore, vesicles containing mucous granules were not usually seen in the metaplastic basal cells.

In contrast to electron-dense metaplastic cells, the superficial electron-lucent cells continued to exhibit features characteristic of respiratory cells, although the amount of mucus granules had decreased. The boundary between the metaplastic and nonmetaplastic cells was distinct (fig. 9). The cytoplasm of superficial cells contained extensive RER, Golgi complexes, and occasionally tonofilaments. These cells had short, stubby, irregularly placed microvilli on the luminal surface. Junctional complexes were present between adjacent surface cells. Intermittent desmosomes were also present at the boundary between the electron-dense metaplastic cells and surface cells.

Continued proliferation of the basal cells and their subsequent differentiation into squamous metaplastic cells resulted in exfoliation of the surface cells. The cells at the advancing edge of metaplastic lesions contained large bundles of keratin filaments (fig. 10) and appeared to displace the overlying surface cells. Subsequently keratohyaline granules were formed in the metaplastic cells followed by cornification (fig. 11).

The percentages of explants showing various degrees of metaplasia and keratinization as a function of time are shown in table 1. Cornified squamous metaplastic areas were present after 3 days in approximately 50% of the explants. The degree and severity of the lesions progressed with the length of culture period. Keratinized lesions were present in approximately 89% of the explants after 10 days.

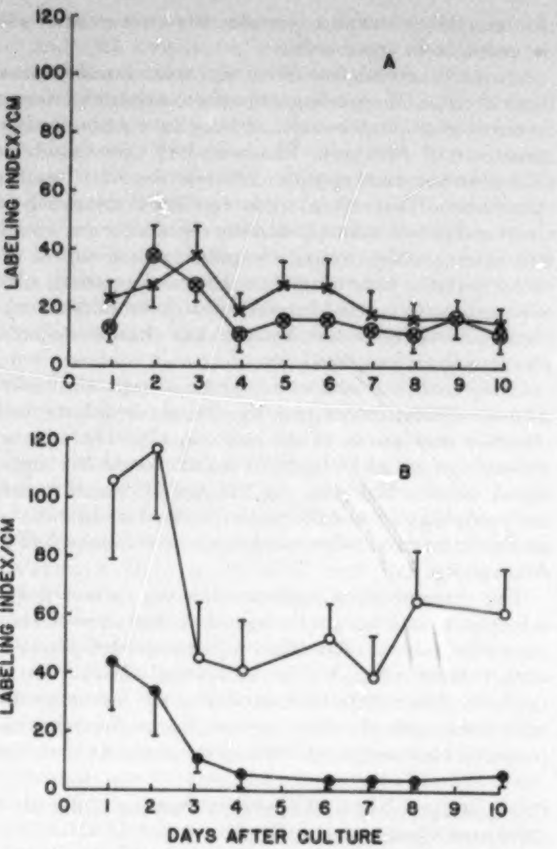
Comparison of LI of Basal and Mucous Cells at Different Times after Culture

Text-figure 1 shows total basal and mucous cell LI at different intervals after culture of tracheas from the NH and DH. The total basal and mucous cell LI refers to their respective LI in the entire epithelial mucosa including areas of squamous metaplasia that occurred only in the explants of DH trachea. Culture of NH trachea resulted in hyperplasia of both the basal and mucous cells. However, between 72 and 96 hours, the LI of both cell types returned to the original levels that were maintained for the remaining culture period (text-fig. 1A).

TABLE 1.—*Explants with different degrees of squamous metaplasia, keratohyaline granules, and keratin at different times after culture*[a]

Days in culture	Percentages of explants showing:						
	Squamous metaplasia, %					Keratohyaline granules	Keratin
	None	0–2	2–10	10–40	40		
1	42	29	29	0	0	0	0
2	28	18	14	40	0	0	0
3	8	12	40	20	20	49	43
4	0	18	62	12	8	62	62
6	0	17	50	33	0	67	67
8	0	13	25	26	36	88	58
10	0	12	13	29	46	89	89

[a] Tracheal organ cultures were prepared. Groups of explants were terminated at different intervals after incubation and processed for histologic examinations.

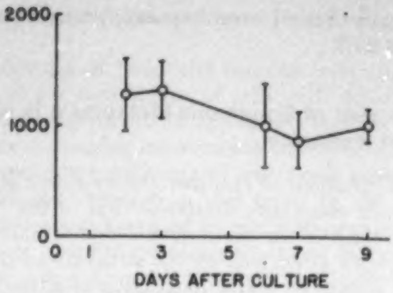


Text-figure 1.—Total LI±SD in basal and mucous cells at different intervals after culture. A) Explants of NH trachea, (X), basal cells; (⊗), mucous cells. B) Explants of DH trachea, (○), basal cells; (●), mucous cells.

Explantation of DH trachea also resulted in hyperplasia of both the basal and mucous cells, although basal cells proliferated more actively than the mucous cells (text-fig. 1B). During the first 48 hours the basal cell LI was at least twofold higher than the mucous cell LI. The mucous cell LI declined gradually after 24 hours, reached a very low level at 6 days, and remained unchanged thereafter. The basal cell LI also began to decline after 48 hours but remained at relatively higher levels between 3 and 9 days after culture. During this time the basal cell LI was approximately forty-fold greater than the mucous cell LI. The high degrees of standard deviation of total mucous and basal cell LI are caused by the variable degrees of squamous metaplasia in different explants within the same group.

Since squamous metaplasia occurs at least initially in focal areas, the LI was also determined exclusively in the lesions. Text-figure 2 shows that cells in the lesions that stained negatively with PAS proliferated actively and mainly in the basal cell layer. The basal cell LI in the lesions between 6 and 9 days after culture was approximately thirtyfold and a thousandfold greater than the total LI of basal and mucous cells, respectively (text-fig. 1).

Although squamous metaplasia originates in focal areas, it expands to involve a large part of the epithelium. The expansion of lesions appears to be associated with the expansion of the proliferative zones, since cohorts of [^{3}H]dThd-labeled cells were frequently seen at the edges of lesions (fig. 12). Furthermore, a majority of the [^{3}H]dThd-labeled cells were concentrated in the basal cell layer (fig. 13).

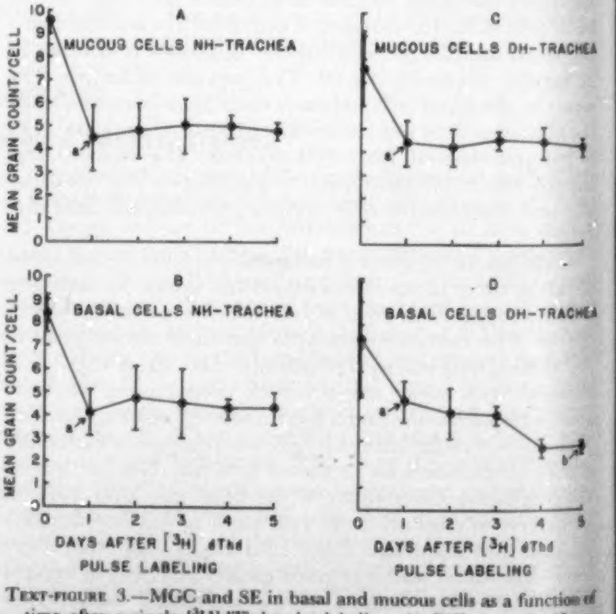


Text-figure 2.—LI±SD of PAS-negative cells in areas exhibiting squamous metaplasia of DH explants. The PAS-positive cells did not incorporate [^{3}H]dThd.

The proliferative activity of PAS-positive or PAS-negative cells in areas of normal morphology was very low.

MGC in Basal and Mucous Cells as a Function of Time After a Single [^{3}H]dThd Pulse

To determine the proliferative potential of the mucous and basal cells, explants were pulse labeled 24 hours after initiation with [^{3}H]dThd for 1 hour and terminated at different intervals thereafter. The basal and mucous cell MGC in the NH tracheal explants declined by approximately 51 and 53%, respectively, at 24 hours after the pulse labeling and remained stable thereafter for at least 5 days (text-figs. 3A, 3B). This result indicates that the basal and



Text-figure 3.—MGC and SE in basal and mucous cells as a function of time after a single [^{3}H]dThd pulse labeling. A) Difference significant ($P<0.05$) compared to the corresponding value at 1 hr after the pulse. B) Difference significant ($P<0.05$) compared to the corresponding value on day 1.

mucous cells of NH trachea have divided only once during this period.

In the explants of DH tracheas, the MGC of mucous cells dropped nearly 42% in the first 24 hours after the pulse and remained relatively constant thereafter (text-fig. 3C). In contrast, the basal cell MGC declined by 36% in the first 24 hours and again by another 43% between 24 and 96 hours after the pulse labeling (text-fig. 3D). This suggests that the basal cell population have undergone division twice, once during the first 24 hours and again between 24 and 96 hours.

DISCUSSION

Epidermoid metaplasia of the respiratory epithelium, generally considered a preneoplastic lesion (*17–19*), may be induced by different treatments (*5–11*). In tracheobronchial epithelium, metaplasias induced by various agents exhibit certain morphologic similarities; however, there apparently are some inherent differences. For instance, metaplasia induced by carcinogenic insults proceeds to develop into squamous cell carcinoma (*3, 5, 8, 9, 20*), whereas the lesions induced by vitamin A deficiency (*2, 3*), noxious gases (*6, 21*), mechanical trauma (*10, 12*), or infections (*13, 14, 22*) are merely benign states that are generally reversible. The variable characteristics of metaplasia may be associated with the nature of insults and the origin of metaplasia. Most investigators believe that the epidermoid metaplasia in tracheobronchial epithelium arises as a result of the replacement of ciliated and mucous cells by epidermoid cells that originate from the basal cells (*2, 3, 10*). For instance, on the basis of ultrastructural observations of tracheobronchial epithelium of rats maintained on a vitamin A-deficient diet, Wong and Buck (*2*) proposed that the epidermoid metaplasia involved differentiation of basal or generative cells into squamous metaplastic epithelium. In the hamster, Harris et al. (*3*) showed that metaplasia caused by vitamin A deficiency or BP–Fe_2O_3 treatment also originates from the basal cells, although the ultrastructural characteristics of lesions produced by the two treatments differed. Recently, the origin of metaplasia in the basal cells of tracheobronchial epithelium was reevaluated. On the basis of the ultrastructural observations, McDowell et al. (*23*) have proposed that epidermoid metaplasia caused by BP–Fe_2O_3 (*9*) or mechanical trauma (*23*) may originate from the mucous cells (small mucous granular cells), although several characteristic features of the mucous cells were also noted in the basal cells. In the present study cytokinetic and ultrastructural features in tracheal organ cultures derived from NH and DH were compared in an effort to define the origin of the squamous metaplasia. The results indicate that these lesions originated in the basal cells, i.e., the epithelial cells that lie along the basal lamina and do not reach the tracheal lumen.

The tracheas of animals fed vitamin A-deficient and vitamin A-supplemented diets exhibited similar morphologic characteristics at the initiation of organ cultures. However, they exhibited different patterns of proliferation and differentiation in culture. During the 10-day culture period, while the NH trachea maintained morphologic integrity typical of normal tissue, the tracheas derived from the DH developed extensive squamous keratinizing metaplasia. Accordingly, the epithelial cell composition of the NH trachea changed little in organ culture, but in the tracheal explants of DH, the differentiation of ciliated and mucous cells was inhibited while the production of squamous cells characteristic of epidermoid metaplasia was enhanced. Similar results have previously been reported in the respiratory epithelium of animals maintained on the deficient diet for prolonged periods (*2, 3*). Furthermore, the transitory regenerative hyperplasia that occurs in many tissues after injury or on organ culture (*24–27*) also occurred in the basal and mucous cells of normal and deficient animal tracheas. However, whereas the hyperplasia of basal and mucous cells in NH and of the mucous cells in DH tracheas subsided after 3 days of culture, hyperproliferation of basal cells in the DH trachea continued during the entire culture period. Higher LI in the tracheobronchial epithelium of vitamin A-deficient hamsters than that of the normal hamster has been reported previously (*28*). Thus the data suggest that the variable patterns of proliferation and differentiation exhibited by tracheal cultures derived from the NH and DH animals are related to the vitamin A status of the donor prior to organ culture.

The ultrastructural observations on organ cultures showed that the basal, mucous, and ciliated cells of NH and the mucous and ciliated cells of DH trachea retain typical characteristics of the respiratory epithelium. In contrast, the hyperplastic foci of basal cells in the DH trachea showed epidermoid characteristics, such as keratin filaments in the cytoplasm and well-developed desmosomes between cells. These epidermoid characteristics were not seen in the tracheal cultures of NH. The hyperplastic epidermoid foci then spread over a larger area, and the superficial layer that consisted of cells distinctly different from the basal cells in ultrastructure and staining properties was undercut and subsequently sloughed off. The secretory cells may have discharged mucous granules at organ culture (*29*), but these cells were not responsible for the induction of lesions since the ultrastructural characteristics of the electron-dense metaplastic cells differed from those of the electron-lucent surface cells right from the initiation of the cultures. In addition, squamous lesions were not present in cultures of NH tracheas. The hyperplastic basal cells differentiated into flatter cells toward the surface, and these exhibited more prominent features of epidermoid lesions. The development of lesions occurs by altered differentiation beginning in the basal cells, which apparently have the capability to divide and flexibility for variable differentiation. The result that mucous and ciliated cells showed no tendency to keratinization indicates that their potential for keratinization was absent or not expressed. The observation that fully differentiated mucous cells exhibit transitory proliferative potential in the tracheal organ culture is consistent with other reports (*30–33*).

Tracheal grafts in isogenic rats exposed to pellets of BP or MCA resulted in the induction of hyperproliferation of the basal cells, which remained elevated as squamous metaplasia progressed (*34*). In the present study, hyperplasia of basal cells after 72 hours of culture of DH trachea was mainly confined to the areas that exhibited squamous metaplasia. Labeling data showed that $[^3H]$dThd incorporation in the lesions was approximately fortyfold greater than in the epithelium that exhibited normal morphology. When the LI in the metaplastic lesions was compared with that of the mucous cells, the former was almost a thousandfold greater than the latter. The MGC data further showed that unlike basal and mucous cells of NH trachea and mucous cells of DH tracheas that divided only once, basal cells of DH trachea divided repeatedly. These results thus support the hypothesis that basal cells with their extraordinary proliferative potential in the areas that exhibit lesions are responsible for the development and progression of the lesions. The factors that cause these cells to alter their differentiation pathway remains to be defined.

The increase in the number of basal cells in areas that exhibit epidermoid lesions is most likely to occur as a result of the division of basal cells and retention of daughter cells in the basal layer, although the possibility of dedifferentiation of mucous cells cannot be ruled out (*9*). However, the division of a mucous cell is likely to produce daughter mucous cells, and the result that mucous cells in the tracheal organ cultures only divide once strongly indicates that squamous lesions originate as a result of continued proliferation of the basal cells and subsequent differentiation of daughter cells into keratinizing cells. In addition, metaplastic cells did not exhibit any feature characteristic of the secretory cells. We frequently saw exfoliation of an overlying layer of mucous cells in metaplastic areas.

An increase in the number of basal cells has been observed commonly in tracheobronchial epithelium of human smokers (*6, 35*) and in tracheas of hamsters treated with BP-Fe_2O_3 (*3*) or 7,12-dimethylbenz[*a*]anthracene (*36*). However, recently Becci et al. (*9*) were unable to detect any significant increase in the basal cell population after exposure of hamster tracheal epithelium to BP-Fe_2O_3. The reason for this discrepancy is not clear, although it may be related to differences in specific definitions of various cell types used by different authors. In the present study, a continuous layer of basal cells (cells overlying the basal lamina, not reaching the lumen, and containing PAS-negative cytoplasm) was regularly observed in areas of epidermoid lesions, whereas the uninvolved epithelium exhibited typical pseudostratified morphology. Although squamous metaplasia starts in focal areas, the lesions progress as a result of expansion of proliferative zones, since cohorts of labeled cells were frequently observed at the edges of lesions. Expansion of proliferative zones has been reported in the gastrointestinal epithelium after treatment of mice with 1,2-dimethylhydrazine (*37*).

Vitamin A deficiency and other manipulations of tracheal epithelium with carcinogenic and noncarcinogenic insults have inherent differences and may therefore elicit variable responses by the tissue. Whereas vitamin A deficiency does not cause any physical damage to the tissue, other treatments, such as BP-Fe_2O_3 instillation, inhalation of noxious gases, or mechanical trauma, inflict direct damage to the superficial and, probably, to the deeper components of the mucosa. Vitamin A deficiency that involves sequential alterations probably allows the tissue sufficient time to respond by the initiation of programmed changes in the generative cells as has been shown by the present and other investigations (*2, 3*). Alternatively, direct insults that cause tissue damage may require immediate response involving both the basal and mucosa cells (*9, 11*). Hyperproliferation of both the mucous and basal cells after carcinogenic treatment may render them more susceptible to neoplastic transformation.

In conclusion, the present study indicates that although both the mucous and basal cells are capable of proliferation when suitably stimulated, epidermoid metaplasia in the organ cultures of vitamin A-deficient hamster trachea is produced mainly as a result of repeated proliferation of basal cells and subsequent epidermoid differentiation of daughter cells. The cytokinetic data associated with the squamous metaplasia correlated well with alterations at the ultrastructural level.

Primordial Germ Cell Proliferation in Fetal Testes in Mouse Strains With High and Low Incidences of Congenital Testicular Teratomas[1,2,3]

Takehiko Noguchi[4,5] *and* **Leroy C. Stevens**[6,7]

ABSTRACT—The development of genital ridges in mouse strains was compared with high and low susceptibility to teratocarcinogenesis. The number of dividing primordial germ cells (PGC) was low at 12 days of gestation. The number increased sharply at 13 days and decreased precipitously by 15 days of gestation. The period of high mitotic activity closely paralleled the period of susceptibility to experimentally induced teratocarcinogenesis. Testes that had a long proliferative period had a higher incidence of teratomas than those that had a short proliferative period. A group of fetuses was identified that had markedly fewer than normal PGC. The incidence of teratomas in this group was very high, and nearly all growths were bilateral.—JNCI 1982; 69:907–913.

Spontaneous testicular teratomas are common only in inbred strain 129 mice and in congenic and recombinant inbred strains derived from it (*1–5*). The incidence is high in strain 129/Sv-*ter* (*4*) and low in strains 129 (*2*) and A^y.

Testicular teratomas are derived from PGC (*6*) that begin to develop as a result of a process akin to parthenogenesis within the seminiferous tubules of fetuses of about 12 days of gestation (*7*). The earliest recognizable foci were observed in 15-day fetuses for strain 129 and in 16-day fetuses for strain 129/Sv-*ter*. It seems likely that the initiation of teratocarcinogenesis occurs about 2 or 3 days earlier. PGC can first be observed at the base of the allantois at 8.5 days of gestation (*8*). PGC proliferate at a high rate during migration to the genital ridge (*9*) and for a short time after arrival on about the 12th day of gestation. After that, PGC enter a mitotically quiescent stage (*10*).

Several genetic and environmental factors influence susceptibility to teratocarcinogenesis (*2, 3, 5*). In strain 129 (*2*) there are twice as many teratomas in the left testis as in the right one. Bilateral teratomas are rare. Teratomas are also twice as frequent in the left testes (13%) as in the right one (7%) in strain 129/Sv-*ter*; however, they occur bilaterally (12%) as frequently as in the left testes (*4*). If teratocarcinogenesis in the left testis is independent of that in the right one, then the frequency of bilateral tumors should be the product of the frequencies of unilaterality: $0.13 \times 0.07 = 0.0091$ or 0.9%. A partial explanation for the unexpected high incidence of bilateral teratomas in 129/Sv-*ter* is presented here.

Testicular teratomas can be experimentally induced in some strains of mice by grafting of male genital ridges into the testes of adults (*11, 12*). The grafted genital ridges develop into testes, and teratomas were observed in most of them 5–6 days after grafting. The age of the genital ridge is crucial (*13*). For strain 129, when 11- or 12-day genital ridges were grafted, about 80% of them developed into testes with teratomas; with 13-day genital ridges 16% developed teratomas, and with 14-day ridges 8% developed them. For 129/Sv-*ter*, about 85% of grafted 11- and 12-day genital ridges developed into testes with teratomas. The incidence dropped to 61% for 13-day genital ridges and to 0.0% for 14-day ridges (*4*).

We compared the development of genital ridges in strains with high and low susceptibility to teratocarcinogenesis. We found that, in general, the absolute number of dividing PGC in a testis was low at 12 days of gestation, but shortly thereafter the number increased sharply. The number peaked at 13 days and decreased precipitously by 15 days of gestation. The mitotic activity of PGC, as revealed by MI, closely paralleled the susceptibility to experimental teratocarcinogenesis. We also found that low numbers of PGC and a prolonged proliferative period correlated well with a high incidence of spontaneous testicular teratomas.

MATERIALS AND METHODS

Mice.—Strain 129/Sv-*ter* males have a higher incidence of spontaneous teratomas (33%) than any other strain (*4*). Even though this subline has been inbred for more than 30 generations of brother×sister matings, some matings produce offspring with fewer teratomas (10%) than others. All descendants of these matings retain the low incidence and will be referred to as the "Lo-line." Families with a high incidence (33%) will be referred to as "Hi-line." To maintain the incidence of 33% in the 129/Sv-*ter* colony, it is necessary to select for Hi-line families.

Three percent of strain 129 and 0.7% of strain A^y males had teratomas. The A^y colony was maintained by $A^y/+ \times +/+$ matings.

Determination of developmental stage of fetuses.—To detect

ABBREVIATIONS USED: A^y=129/Sv-A^yCP with <1% teratomas; Hi-line=strain 129/Sv-*ter* with ≈33% teratomas; Lo-line=strain 129/Sv-*ter* with ≈10% teratomas; MI=mitotic index (indices); PGC=primordial germ cell(s); 129=129/Sv with 3% teratomas.

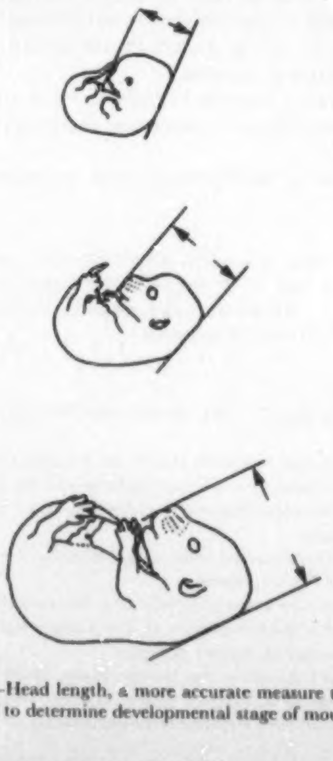
differences in mitotic activity in PGC between fetuses in strains with high and low incidences of teratomas, we had to determine their developmental stage more precisely than by the number of days of gestation. In addition to gestational days, we used the maximum length of the head as a criterion of developmental stage. Head length was measured as shown in text-figure 1 with a micrometer accurate to 0.01 mm. Two stainless steel microsyringe needles were glued parallel to the beaks of the micrometer. Text-figure 2 shows the relationship between head length and days of gestation. A head length of 4.0 mm corresponded to early (12 days) gestation. The head length increased by 1 mm/day of gestation thereafter.

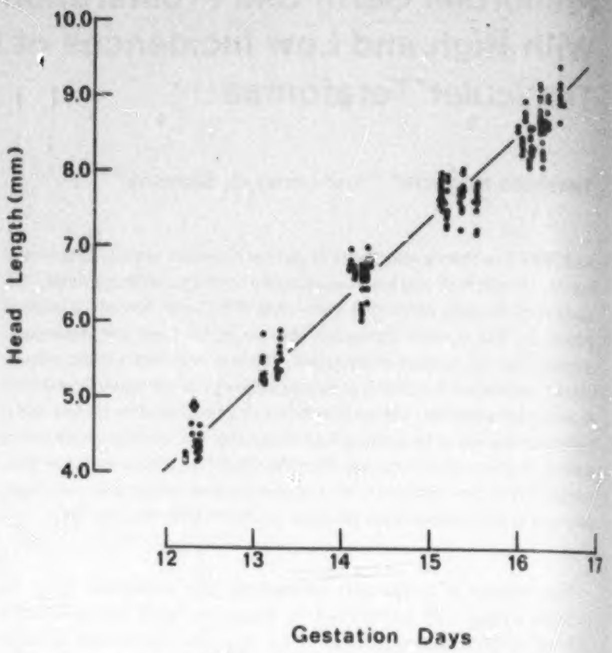
Dissection of specimens.—After dislocation of cervical vertebrae of pregnant females, fetuses were dissected from the uterus, washed with Hanks' balanced salt solution that contained 1% glucose, and transferred to a petri dish with Hanks' solution. Fetuses were secured ventral side up by insect pins on a paraffin bed stained with Sudan black. The gonads were removed with watchmakers forceps. The sex of the gonad could be identified in fetuses with head lengths of 4.5 mm and longer.

Histology.—Gonads were fixed in Vandegrift's solution, embedded in paraffin, serially sectioned at 7 µm, and stained with hematoxylin and eosin.

Identification of PGC.—The criteria adopted for the discrimination of PGC from supporting cells in the seminiferous tubules were similar to those described for the rat by Clermont and Perey (*14*). Dividing PGC could easily be discriminated from supporting cells at the head length stage of 4.5 mm. Identification of nondividing PGC and supporting cells was more difficult in fetuses at stages of up to 5.5-mm head length. In fetuses of 6.5-mm head length and larger, however, most of the supporting cells were located near the periphery of the seminiferous tubules and identification was easy. Nondividing PGC were larger than most of the supporting cells and had lightly stained spherical nuclei with two nucleoli or more. The supporting cells had darkly stained oval or coffee bean-shaped nuclei and most were smaller than those of PGC.



TEXT-FIGURE 1.—Head length, a more accurate measure than gestational days, was used to determine developmental stage of mouse fetuses.



TEXT-FIGURE 2.—Relationship between head length and days of gestation.

Sl^J/Sl^J fetuses have very few or no PGC (*15*); they were used as reference to help identify supporting cells.

Determination of proliferative activity of PGC.—The proliferative activity of PGC was determined by two methods: 1) by counting the number of PGC in every other histologic section of each testis and 2) by the MI (dividing cells:dividing plus nondividing cells).

In some fetuses the seminiferous tubules in both testes were very sparsely populated with PGC. There were only about 200 PGC determined by counting in each or in every other section. When testes appeared normal, the number of PGC estimated were 800–3,500 by counting in every four to six sections. Cells were counted by slides being projected onto a high-resolution glass screen.

In fetuses with head lengths greater than 7 mm, the number of dividing PGC was so small and the total number of PGC was so large (30,000–50,000) that the MI could not be precisely determined.

RESULTS

Developmental Change in the Proliferative Activity of PGC

The dividing PGC in serial sections of 547 testes were counted in fetuses with head lengths ranging from 4.2 to 9.0

mm. Text-figure 3 shows the pattern of PGC proliferation in 111 testes in A^y fetuses. There was a sharp increase in the number of dividing PGC in testes of fetuses from 4- to 6-mm head length. The number of dividing PGC peaked between 5.0 and 6.0 mm of head length and then decreased precipitously. Most PGC became mitotically quiescent at the head length stage of about 7 mm.

Text-figure 4 shows the proliferative pattern of 142 testes of Lo-line fetuses. The pattern was approximately the same as for the A^y except that the peak at 5.0–6.0 mm appeared lower.

Text-figure 5 shows the proliferative pattern of PGC in 294 testes of Hi-line fetuses. The counts were more broadly scattered than those for the A^y and Lo-line fetuses.

At the peak of mitotic activity (5.0- to 6.0-mm head length), the average number of dividing PGC was highest in A^y testes (381), intermediate in Lo-line testes (267), and lowest in Hi-line testes (196) (table 1). The differences between A^y and Lo-line and between A^y and Hi-line were significant ($P<0.001$) as well as the difference between Lo-line and Hi-line ($P<0.005$), as determined by Student's t-test.

The pattern of change in MI in 160 developing Hi-line testes was compared with 55 A^y and 48 Lo-line testes (text-fig. 6). The rate of decline in MI was similar in A^y and Lo-

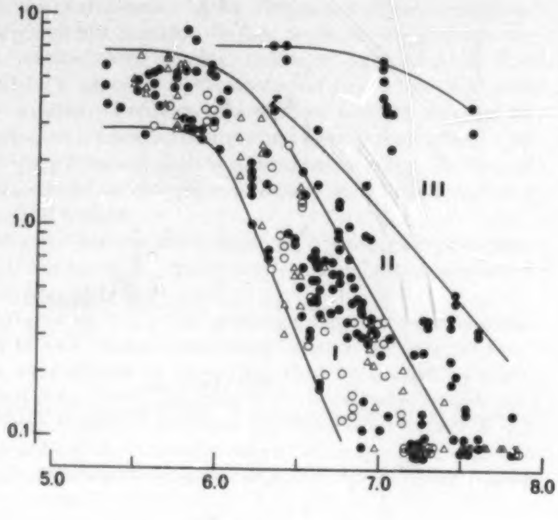
	No. of testes	26	72	53	23	96



TEXT-FIGURE 6.—Developmental change in MI of PGC in fetal testes of A^y, Lo-line, and Hi-line. △, A^y; ○, Lo-line; ●, Hi-line.

line testes. The area where most of the values fell is schematically shown in text-figure 6 (zone I). In the head length stage between 5 and 6 mm, the MI were high (3–6%), and after the head length stage of 6 mm, the MI decreased sharply. At the head length stage of 7 mm, most of the MI were less than 0.5%.

The pattern of change in MI in Hi-line testes differed from that in A^y and Lo-line testes (text-fig. 6). The MI of many Hi-line testes fell in zone I, but others were higher after the head length stage of 6 mm. Most of the testes in zone II had normal numbers of PGC, whereas most of the testes in zone III had markedly reduced numbers of PGC. This suggests that PGC in some Hi-line testes have a longer proliferative period than those in testes of the other strains.

Incidences of Teratomas in Hi-line Testes With Short and Long Proliferative Periods of PGC

Teratomatous foci could be first recgonized in 16-day fetuses (8- to 9-mm head length). Some Hi-line testes had more dividing PGC than A^y and Lo-line as late as this stage. The number of dividing PGC in A^y testes ranged from 0 to 12 (average=1.9; SD=3.4), in Lo-line testes from 0 to 16 (average=4.1; SD=4.0), and in Hi-line from 0 to 100 (average=17.7; SD=17).

Hi-line testes with teratomatous foci tended to have more dividing PGC than those without foci. For example, 7% (3/41) of testes with 0–9 dividing cells had teratomatous foci; 17% (6/35) of testes with 10–29 dividing cells had teratomas, and 60% (12/20) of those with 30–100 dividing cells had teratomas. These figures indicate that testes with prolonged proliferative periods had a much higher incidence of tumors than those with shorter proliferative periods.

Incidence of Teratomas in PGC-Deficient Testes

A striking observation was independently made both at the National Institute of Genetics in Misima, Japan, and at The Jackson Laboratory in Bar Harbor, Maine. About 12% of the Hi-line fetuses of 16–18 days of gestation examined in Misima had testes with very few PGC. All of these fetuses had teratomas, and most (5/6) were bilateral (table 2). Fourteen percent of strain 129/Sv-*ter* fetuses at 16–18 days of gestation examined in Bar Harbor were deficient in PGC, and all of them had teratomas. Most of these fetuses (8/10) had bilateral teratomas.

Only strain 129/Sv-*ter* testes were deficient in PGC. No PGC-deficient testes were observed in 419 testes of fetuses of other sublines of 129 and in 80 testes of 129×A/HeF$_1$ mice.

In some cases, germ cell deficiency in 129/Sv-*ter* persisted at least until weaning age. Parts of testes of 16 males with bilateral teratomas were examined histologically, and both

TABLE 2.—*Incidence and laterality of teratomas in Hi-line fetuses with testes with normal numbers of PGC and with PGC-deficient testes*

Location of expt	No. of fetuses examined	No. of fetuses with teratomas (%)	No. of fetuses with bilateral teratomas (%)
No. of fetuses with normal No. of PGC			
Mishima	44	13 (30)	6 (14)
Bar Harbor	60	18 (30)	3 (5)
Total		31 (30)	9 (9)
No. of PGC-deficient fetuses			
Mishima	6	6 (100)	5 (83)
Bar Harbor	10	10 (100)	8 (80)
Total		16 (100)	13 (81)

testes in 10 were found to be germ cell-deficient. PGC-deficient testes in weaning age males were always affected bilaterally, whereas their littermates usually had normal numbers of PGC. Photomicrographs of PGC-deficient and normal testes are shown in figure 1.

DISCUSSION

The proliferative activity of PGC was determined in 3 groups of inbred mice derived from strain 129, that differed in susceptibility to testicular teratocarcinogenesis. About 0.07% of the males in one group, designated A^y, had teratomas. Ten percent of the Lo-line and 33% of the Hi-line mice had teratomas. The mitotic activity remained high until late (13th-day) gestation and decreased precipitously therafter. By day 15 or 16 the PGC in most testes were mitotically quiescent.

This decline in mitotic activity paralleled exactly the decline with age in susceptibility to experimentally induced teratocarcinogenesis. When male genital ridges from strain 129 fetuses of 12.5 days of gestation were grafted to adult testes, about 80% of them developed into testes with teratomas (*12*). When genital ridges from 13.5- to 14.5-day fetuses were grafted to adult testes, the incidence of teratomas in testes that developed from the grafts declined to about 15 and 8%, respectively (the incidence of spontaneous teratomas in this strain) (*13*). Apparently, as the PGC cease to proliferate, they lose susceptibility to teratocarcinogenesis.

The PGC in the Hi-line mice proliferated for a longer period than in the groups with lower incidences of teratomas. A significant fraction of the PGC in the testes of many of these mice continued to proliferate even through the 15th and 16th day of gestation, whereas nearly all of the PGC in the testes of the two strains with lower incidences of teratomas had stopped proliferation by the end of the 14th day of gestation. The extension of the proliferative period in the Hi-line PGC correlated well with the higher incidence of teratomas.

Compared to A^y, the extension of the proliferative period of the PGC in Hi-line fetuses became apparent from the 14th to 16th days of gestation (6- to 8-mm head lengths). Another phenomenon that correlated with high incidence of teratocarcinogenesis was observed in fetuses at the 13th day of gestation (5.5-mm head length) when proliferation was at its peak. The testes of some Hi-line fetuses had fewer dividing PGC than A^y testes. These Hi-line fetuses included both PGC-deficient testes and testes with normal numbers of PGC. Perhaps the period of high proliferation began later and lasted longer in Hi-line testes.

Independent observations on the correlation between PGC deficiency and high incidence of bilateral teratomas were made at the National Institute of Genetics in Japan and at The Jackson Laboratory in the United States. Serial sections of testes of 70 fetuses of 16–19 days of gestation were examined histologically at The Jackson Laboratory. Of 60 fetuses with normal numbers of PGC, 18 (30%) had teratomas (table 1). Fifteen teratomas (25%) were unilateral and 3 (5%) were bilateral. Of 10 fetuses with markedly reduced numbers of PGC, all had teratomas, 2 were unilateral, and 8 bilateral. In all cases, the deficiency in PGC was bilateral. MI were not determined.

At the National Institute of Genetics, 4 of 29 (14%) fetuses with normal numbers of PGC and a normal proliferative period had teratomas and none were bilateral. Nine of 15 (60%) fetuses with normal numbers of PGC and a prolonged proliferative period had teratomas, and 6 (40%) were bilateral. All 6 fetuses that were deficient in PGC and had a prolonged period of proliferation had teratomas, and 5 (83%) were bilateral. PGC deficiency was also observed bilaterally in ovaries of some Hi-line females.

These are four possible explanations for the PGC deficiency in the gonads of Hi-line mice: 1) PGC fail to form; 2) some PGC form, but fail to proliferate; 3) some PGC are abnormal and cannot migrate or survive; and 4) the environment is hostile and some PGC do not survive. It is possible that PGC are damaged and most are killed, but some PGC that survive the damaging influence are changed in a way that transforms them into embryonal carcinoma cells. That this might be the case is suggested by the response of PGC to transplantation in the experimental production of teratomas. When 12.5-day genital ridges of some strains are grafted to the testes of adults, most of them develop into testes with few PGC and many foci of teratomas. They appear histologically similar to the PGC-deficient gonads of Hi-line mice.

This high correlation between PGC-deficient testes and a high incidence of bilateral teratomas may partially explain an unusual laterality in the distribution of spontaneous teratomas in Hi-line mice (*4*). Thirty-two percent of the males of this strain had teratomas. Of these, 13% were in the left testis, 7% in the right, and 12% were bilateral. If teratocarcinogenesis in the right testis was independent from that in the left, then the frequency of bilaterality should have been the product of the frequencies of unilaterality. This product, 0.9%, is far below the 12.5% observed for bilaterality. Our observations show that for PGC-deficient testes, teratocarcinogenesis in the right testis is not independent from that in the left one. Susceptibility to teratocarcinogenesis in both testes is highly correlated with PGC deficiency.

Epizootic Neoplasms in Fishes From a Lake Polluted by Copper Mining Wastes[1,2]

John J. Black,[3] Elwin D. Evans,[4] John C. Harshbarger,[5] *and* **Robert F. Zeigel[6,7]**

ABSTRACT—Examination of fishes from Torch Lake, Houghton County, Mich., revealed epizootic neoplasms of several types in two closely related species. Saugers, *Stizostedion canadense*, and walleyes, *Stizostedion vitreum*, were commonly affected with hepatocellular carcinomas, dermal ossifying fibromas, and perivisceral masses resembling mesotheliomas that were usually associated with the mesenteric capsule of the spleen. Saugers were 100% affected with liver neoplasms. Histopathologic and ultrastructural aspects of the neoplasms are described. Torch Lake has been used as a repository for copper mining waste to the extent that an estimated 20% of the original lake volume has been filled in by these materials. Several direct and indirect etiologic roles for the mine waste as causative agents of the fish tumors are discussed.—JNCI 1982; 69:915–926.

Torch Lake is a large, deep lake (surface area, 1077 ha; mean depth, 17 m; maximum depth, 35 m) located near the middle of the Keweenaw Peninsula of Michigan in Houghton County (Lat 40° N, Long 88° W) and is a tributary to Portage Lake and thus to Lake Superior (*see* text-fig. 1). The watershed is about 300 km^2 and mostly covered with second-growth hardwoods. Soils are predominantly spodosals, with agriculture limited to a few dairy and potato farms.

Copper associated with ancient metamorphic and igneous bedrocks of this region once supported a major copper mining industry. Since the turn of the century, copper ore extracted from mines northeast of Torch Lake was crushed at mills along the lake's shoreline. The almost pure native copper was separated from the ore, processed, and shipped by rail or barge. Tailings were dumped into the lake near the mills. Finer tailings were dispersed by currents throughout Torch Lake and into much of Portage Lake. During the latter part of this mining period, as it became profitable, the tailings or coarse stampsands that settled near the shore were dredged from the lake, ground to a powder, and leached with cupric ammonium carbonate to remove additional copper. The remaining very fine tailings were again discharged into Torch Lake.

At least 20% of the original volume of Torch Lake has been filled with copper tailings. In addition to the discharge of tailings, mine water pumpage and raw municipal sewage were discharged into the lake for years. Chloride concentrations in tributary streams receiving mine water has been as high as 5,000 mg/liter, with lake concentrations exceeding 200 mg/liter before mine dewatering ceased.

Municipal sewage from the small communities along the lake is now collected and treated in lagoons and spray irrigated on grass established on mine tailings. Water quality in Torch Lake has improved since mining ceased and municipal sewage receives better treatment. The water has changed from turbid reddish-brown to a clear brown, with a concurrent increase in transparency (secchi disk, ≈3.0 m). The lake presently has soft water and low concentrations of dissolved substances. Nutrients are not sufficient to result in depletion of hypolimnetic oxygen. An orthograde dissolved oxygen curve exists, and the lake would be considered oligotrophic. Average total phosphorous concentrations are about 0.02 mg/liter. Nitrate nitrogen concentrations range from 0.2 to 0.4 mg/liter, and they increase with water depth. Chlorophyll a concentrations are generally less than 3.0 µg/liter.

Cadmium, nickel, and lead in the water column are at or near the levels of detectability. Zinc ranges from 5.0 to 25.0 µg/liter. Copper is markedly elevated over Lake Superior average concentrations of 3.4 µg/liter. Total copper ranges from 30 to 45 µg/liter, with higher concentrations near the lake bottom.

Copper concentrations as high as 910 µg/liter were found in an embayment that received a large but unknown amount of cupric ammonium carbonate during the fall of 1971 and the early summer of 1972 (*1*). Although copper concentrations remain high in Torch Lake at the present time, obvious lethal conditions are not apparent. Dissolved humic substances—as indicated by water color and total organic carbon concentrations—moderate alkalinity, and circumneutral pH's may contribute to the formation of copper complexes that greatly alter copper toxicity.

Sediments in Torch Lake and Portage Lake are largely composed of extremely fine, reddish, clay-like tailings covered with a dark-brown compacted layer of organic material approximately 4 cm thick. In 1970, a flocculent, light-brown ooze covered the reddish tailings (*2*). Copper concentrations in this upper dark-brown layer range from 1,700 to 2,400 mg/liter dry weight. Lower concentrations, found beneath the upper layer, range from 300 to 1,700 mg/kg. Lead (80–270 mg/kg) and zinc (≤180 mg/kg) in the upper dark-

brown layer follow a similar pattern to that of copper in their distribution in sediments. Chromium (30–40 mg/kg) and nickel (90–120 mg/kg) had higher concentrations in the reddish clay-like layer. Cadmium was less than 2 mg/kg sediments. Apparently, copper, lead, and zinc still are entering this aquatic ecosystem, being bound by biota or particulate materials, and are settling to the bottom. Mineral recycling—from sediments, erosion, and percolation of water through shoreline soils—and deposited tailings are probable continuing sources of heavy metals within the watershed.

Except for low densities of benthic macroinvertebrates, Torch Lake does not appear to be an extremely disturbed aquatic system. Only very low densities of midge larva and aquatic worms were found in most bottom samples (*2*). Diatoms dominate the phytoplankton community, but blooms of green and blue-green algae have been observed (*1*). A rather diverse zooplankton community exists. Macrophytes are present in some littoral areas of the lake and reach greatest densities where tributaries deposit organic materials.

A diverse fish population is present. Walleye, sauger, and northern pike are the dominant species in terms of weight. Smallmouth bass, yellow perch, lake sturgeon, sea lamprey, brook trout, rainbow trout, burbot, alewife, smelt, cisco, white sucker, bullhead, trout-perch, sculpin, coho salmon, bluegill, rock bass, and redhorse sucker also have been collected in Torch Lake since 1970. Both Torch Lake and Portage Lake have supported a productive sauger fishery since the 1930's. Since the time that mining ceased, walleye and northern pike appear to be replacing sauger as the dominant larger predator species. In records maintained by the Fisheries Division, MDNR, the average ages of saugers, walleyes, and northern pike collected in 1979 were 11, 6, and 5 years, respectively (Juetten R: Personal communication). Reproduction of the sauger population as evidenced by the presence of juveniles has not been noted for at least 10 years (Juetten R: Personal communication). Whether recent changes in water quality or critical habitat destruction during the 1960's caused the decline in sauger population is not known.

Reports of abnormalities in fishes from this lake, including tumors in saugers and walleyes, prompted us to initiate a preliminary study of the light microscopic histology and ultrastructure of three different neoplasms that were found to be epizootic in these two fish populations.[8] In summary: Compelling circumstantial evidence exists that mine-waste pollution plays a causal role.

MATERIALS AND METHODS

Fishes were collected by gill nets in September 1979 and July 1980. They were examined externally and after a lengthwise incision was made in the left flank, the internal organs were removed and examined for gross signs of neoplasms.

For light microscopy, samples of tissue from organs exhibiting evidence of gross pathology were fixed in 10% buffered Formalin. After fixation and dehydration, specimens were embedded in paraffin, sectioned at 5-μm thickness, and stained with H & E. The following special stains were used: oil red-O for lipids, Mayer's mucicarmine for mucus, and periodic acid–Schiff for carbohydrates (*4, 5*).

For electron microscopy, tissues were minced with a razor blade to 1.0-mm^3 pieces or smaller. Aliquots were transferred to vials containing 2.0 ml cacodylate-buffered 2.0% glutaraldehyde (*6*). This prefixation was performed in the field, and specimens were kept on ice for 48 hours. When the specimens arrived at the laboratory, the glutaraldehyde was removed and the tissues were rinsed briefly in cold cacodylate buffer before fixation in Dalton's chrome–osmium fixative (*7*). After fixation, tissues were rapidly dehydrated, embedded in Epon–Araldite, and sectioned at 0.05- to 0.9-μm thickness on diamond or glass knives with an LKB model 3 ultramicrotome. Thin sections were picked up on 200-mesh carbon-coated or bare grids and were stained with lead citrate and uranyl acetate (*8*). Specimens were examined by transmission microscopy in a Siemens 1A electron microscope.

RESULTS

Various fish species from Torch Lake were necropsied and examined for tumors. In 8 northern pike (*Esox lucius*), 8 white suckers (*Catostomus commersoni*), 5 smallmouth bass (*Micropterus dolomieu*), 4 rainbow trout (*Salmo gairdneri*), and 1 brook trout (*Salvelinus fontinalis*), no tumors, either internal or external, were observed. In saugers and walleyes several types of abnormal growths were present. Although a statistical survey per se of the incidence of neoplasms was not made among the 20 saugers and 11 walleyes necropsied and examined in 1979, the most striking and consistent finding involved the livers of the saugers, which universally exhibited widely varied gross signs of neoplastic disease. The livers, ranging in color from pale yellow with a slightly greenish tinge to a normal reddish-tan, contained variably sized, raised nodules, and some were simultaneously affected with multiple, subcapsular, fluid-filled cysts (figs. 1, 2). Nodules ranged from single foci, barely discernible with the naked eye (≈2 mm in diameter), to large, raised (1- to 8-mm) neoplastic-appearing nodules (>2 cm in diameter) (fig. 1). Nodule color varied from reddish-brown to grayish-tan to gray. On fixation, the neoplastic nodules were paler than the surrounding liver tissue. On the basis of the presence of nodules found at gross examination, liver neoplasms apparently were present in every sauger examined, i.e., 100%. Similar nodules were present in some of the walleye livers, but nodule prevalence in walleyes was not determined in 1979.

Affected livers from 8 saugers and 3 walleyes were examined microscopically. The livers were all similar in their histologic appearance, with neoplasms appearing as single-to-multiple nodules that exhibited increased basophilia and moderate anaplasia (fig. 3). Cord structure was typically many cells thick and in some areas was replaced by a cobblestone type of growth pattern. Tumors were composed of hepatocytes that exhibited only mild pleomorphism. Tumor cells had large nuclei with prominent nuclear membranes, marginated chromatin, and large nucleoli (fig. 4). Few mitoses were present, and tumors appeared to be slow growing with only slight bands of compression atrophy surrounding the liver nodules. Fibrosis was not a prominent finding, but parasitic cysts and melanin macrophage centers were present in most sections. The tumors were diagnosed as hepatocellular carcinomas, a well-differentiated type.

In addition to hepatocellular carcinomas, dermal neoplasms were also present in saugers and walleyes. Three of these neoplasms (2 from saugers, 1 from a walleye) were examined microscopically, and all appeared as unencapsulated dermal fibromas with variable degrees of ossification (fig. 5). Some sections had an inflammatory infiltrate, usually more prominent in the area of the dermis. Examination of thin sections by electron microscopy did not indicate any obvious virus particles as reported in walleye dermal fibromas by Walker (*9*).

---

[8] Abnormalities diagnosed as lipogranulomas and ossifying fibromas in Torch Lake fishes were initially discovered and subsequently reported to the MDNR by Mr. David A. Tomljanovich, a graduate student at Michigan Technological Institute, Houghton, Mich. [*see* (*3*)]. The present follow-up study resulted when one of the authors (E. D. E) requested the assistance of the senior author in confirming the nature of the abnormalities.

A third type of growth observed in these two species frequently took the form of large perivisceral masses that were frequently attached to the spleen but sometimes appeared to be attached to mesenteric fat and/or mesenteries (fig. 6). On palpation, these masses were somewhat gelatinous or rubbery, and when cut they exuded a scant amount of clear viscous fluid. These perivisceral neoplasms varied in size and color. Sizes ranged from large polypoid growths (4–6 cm in diameter) to smaller, solitary pedunculated nodules (≥1 cm in diameter). Colors ranged from an opaque tan through a translucent pinkish-tan to a colorless, somewhat hyaline appearance. Within the masses were grossly visible septa that partitioned the masses into multiple microcystic structures that corresponded to the larger follicles seen by light microscopy. An occasional fish had more than one mass arising from different parts of the viscera, e.g., mesentery versus spleen (fig. 6).

Recognition was not immediate that these masses were sometimes hidden by large accumulations of visceral fat and, therefore, no figure can be advanced for their prevalence in the 1979 fish sampling. However, they may have been common, inasmuch as several masses were sufficiently exposed so that they were detected in viscera examined in the field. In one other case, later dissection of viscera preserved en bloc in 10% Formalin revealed the presence of a large mass attached to the spleen.

By light microscopy, these growths were seen to be composed of large follicles (figs. 7, 8) that contained a pale-staining (H & E), proteinaceous-appearing material. This material was negative for both lipid and mucin but was weakly positive in some areas for the periodic acid–Schiff reaction. When associated with the spleen, the neoplasms were covered by a thin capsule that appeared continuous with that of the spleen capsule. In some sections, a distinct subcapsular layer of large uniform follicles was present (fig. 8). In this area, tumor cells frequently appeared to be continuous with the cells of the spleen capsule (fig. 9), suggesting that the neoplasms may have originated from the spleen component of the visceral mesentery.

Electron microscopy of these neoplasms indicated several types of cells. Those bordering the follicles were extremely elongated epithelioid cells with obvious tonofibrillae. Evidence of secretion by these cells was seen. Elements of rough endoplasmic reticulum were found near the cell surface, appearing in some sections to be emptying their contents directly into the large colloid-like areas contained within the follicles (fig. 10). Cellular elements of the blood system, perhaps sequestered from the spleen, plus neuronal elements and connective tissue were observed in areas between the secretory cells. Although with the light microscope the appearance of these masses resembled myxoma, the combination of morphology and secretory activity in the elongate epithelioid cells of possible visceral mesenteric origin suggested a diagnosis of mesothelioma. Differential diagnosis also included lymphangioma.

Idiopathic intercellular and intracellular crystalloid profiles, similar in appearance to Auer bodies (*10*), were observed in some sections. These were variably shaped rhomboid and rod-like forms up to 2.0 µm in length, usually enclosed by a membrane (fig. 11). They appeared within or in association with cells that resembled granulocytes and lymphocytes. The suggestion has been advanced that the crystalloids are generated in the cisternal region of the rough-surfaced endoplasmic reticulum. Crystalloids were not observed in the elongate follicular cells of these tumors and were not observed in either hepatomas or the dermal ossifying fibromas.

TABLE 1.—*Neoplasms in Torch Lake saugers and walleyes, 1980*

Neoplasm	No. of lesions/total No. of fish	
	Sauger	Walleye
Hepatocellular carcinoma	3/3	3/11
Dermal ossifying fibroma	1/3	2/11
Perivisceral masses	2/3	2/11

To quantify the incidence of the various types of neoplasms, an additional sampling of Torch Lake fishes was made in July 1980. The numbers and kinds of tumors present in the saugers and walleyes from this collection are shown in table 1. Some of the saugers and walleyes examined in 1980 had more than one type of tumor in the same individual; e.g., 1 sauger and 1 walleye had both hepatocellular neoplasms and the mesothelioma-like spleen masses, 1 sauger had both hepatocellular and dermal neoplasms, and 1 sauger had all 3 types of neoplasms. Occasional fishes with multiple neoplasms were also observed among the 1979 group, but the frequency with which multiple neoplasms occurred was not determined.

DISCUSSION

The data from numerous investigations have indicated an association between water pollution and elevated tumor frequencies in fishes (*11–18*). Although direct proof of a causal role for pollutants is presently lacking for any spontaneous tumors in teleosts, a pollutant chemical hypothesis is supported indirectly by laboratory experiments which indicate that a number of chemical carcinogens readily cause tumors in fishes (*19–24*). In addition, most teleosts also appear to activate chemical carcinogens by enzymatic reactions similar to those of higher vertebrates (*25–28*). However, not all fish tumors are caused solely by exposure to chemicals. Strong experimental evidence exists that viruses are causative agents for lymphosarcoma in northern pike, and virus particles have been observed in several other fish neoplasms (*9, 29, 30*).

Sauger and walleye are important Great Lakes predator species that are valued as food and as sport fishes. Preliminary examination of two modest samples of these two species from Torch Lake indicated that they were commonly affected with three types of neoplasms: hepatomas, dermal fibromas, and multiloculated gelatinous masses possibly originating from the visceral peritoneum. The precise classification of the perivisceral lesions is unknown, but myxoma, lymphangioma, and mesothelioma were included in the differential diagnosis. No virus particles were observed in any of the tumor tissues when examined by electron microscopy. Livers were heavily parasitized with trematodes, but any relationship these organisms may have had to the liver tumors was inapparent.

Tomljanovich (3) described numerous lesions in Torch Lake saugers, including dermal fibromas and the mesothelioma-like lesions that were interpreted variously as lipomas and fat necroses. The hepatomas were not reported. Although hepatic neoplasms possibly were not present then (1974), more likely the liver tumors were missed inasmuch as the prevalence of hepatomas in saugers appeared to be 100% in our samples that were taken only 5 and 6 years later. This constitutes the highest frequency of spontaneous tumors occurring in any species and is seldom achieved even in laboratory attempts to induce hepatomas.

Tomljanovich (3) thought that the high concentration of copper very possibly was responsible for the neoplasms. We accept the hypothesis that the observed fish pathology is related to the presence of mining wastes; however, at present no evidence is available that copper is carcinogenic intrinsically. Conversely, copper ores may contain metals, such as selenium and arsenic (31), that are considered carcinogenic. Despite a lack of evidence of copper carcinogenicity, conceivably there is a link through cirrhosis to copper as a possible causative agent of liver tumors, in that human patients with cirrhosis are predisposed to develop liver cancer (32). Cirrhosis is a component of two metal-induced diseases (33, 34), i.e., hemochromatosis (excessive loading of iron in tissues, especially the liver) and Wilson's disease (excessive storage of copper in the liver and brain due to a metabolic defect). Against this line of reasoning is the fact that relatively few cases of Wilson's disease eventuate in liver tumors, and none of the sauger and walleye livers were cirrhotic.

A possible carcinogenic role for the physical nature of the mining waste might also be considered. These copper tailings are extremely fine particles that readily suspend in water; however, their exact physical form and their possible relationship to any of the observed neoplasms are presently unknown. Other mining-related physical agents, such as hematite, silica dust, and asbestos, have been implicated in health problems and in some kinds of cancer (35–37). Among these agents, asbestos has been shown to cause mesothelioma in laboratory animals and is implicated by epidemiologic evidence in human cancers of this type (38, 39). Although some mineral-bearing ores found in the North Central United States contain asbestos, the presence of this mineral fiber in Torch Lake has not been ascertained. No obvious asbestos bodies or birefringent asbestos-like crystals were seen in the spleen tumors.

An alternative indirect action may also be postulated for mine waste pollution. Copper or other metals may be acting to catalyze the formation of a new compound(s) that is carcinogenic in fishes. One possible route may be the metal-catalyzed formation of carcinogenic nitrosamines from secondary amine compounds contained in domestic sewage effluent or perhaps from naturally occurring amines (40). As stated previously, the lake has received some domestic sewage which may have provided precursor molecules. Nitrosamines may be plausible candidates for the putative agents inasmuch as they are potent liver carcinogens (41–43).

Another interesting aspect of the problem is that Torch Lake saugers are extremely old fish. The average length of specimens examined in our preliminary survey was in excess of 20 inches. Specimens from Torch Lake have been estimated to exceed 12 years in age (Juetten R: Personal communication), and no small saugers were reported in recent surveys conducted by the MDNR. Presently, considerable doubt exists that any sauger reproduction is occurring. This observation is consistent with our pathology studies in which gonads in this species frequently appeared atrophic. In addition, some gonads were heavily infiltrated with lipogranuloma-like lesions that consisted of aggregations of macrophage-like cells containing a yellow crystalloid-appearing material. Our pathology findings, though preliminary, indicated that a similar pattern of lesions was occurring in Torch Lake walleyes but at a lower incidence. It would not be surprising, therefore, if survival of the walleye population also will be effected.

Although the tumors in Torch Lake fishes circumstantially appear to be related to the presence of copper-mining wastes, further study will be required to determine the precise identity of the causative factor(s). The extent of this problem beyond the immediate waters of Torch Lake is presently unknown. The scientific, human health, and economic implications of these findings argue strongly for further study.

Electron Microscopic Autoradiography of the Trachea in Fetal Syrian Golden Hamsters Treated Transplacentally With *N*-Nitrosodiethylamine[1,2]

Hildegard M. Reznik-Schüller[3,4]

ABSTRACT—Tritiated *N*-nitrosodiethylamine (DENA) was administered to female Syrian golden hamsters on each of the last 4 days (days 12–15) of pregnancy. The intracellular distribution of bound radioactivity was monitored by electron microscopic autoradiography in the epithelium of the fetal tracheas, from which transplacentally induced tumors arise in this system. Most of the bound radioactivity was concentrated in the rough endoplasmic reticulum of undifferentiated stem cells and mucous cells. The level of binding on the various days of pregnancy appeared to reflect the degree of differentiation of the endoplasmic reticulum in these cells. Basal cells, which were identified as the origin of DENA-induced tracheal tumors in adult hamsters by one of our earlier studies, demonstrated only little bound radioactivity in the fetal tracheas. The pathogenesis of DENA-induced tracheal tumors in this transplacental system may hence be different from that in adult animals.—JNCI 1982; 69:927–931.

DENA, a potent respiratory tract carcinogen in Syrian golden hamsters (*1–8*), induces tumors in the trachea, nasal cavities, and lungs of adult animals. When administered to pregnant hamsters, it crosses the placenta and induces neoplasms of the trachea in up to 100% of the offspring (*9, 10*). Such a transplacental carcinogenic effect does occur, however, only if the compound is administered to the mother on one of the last 4 days of gestation. Treatment at an earlier time does not induce any such tumors (*10*). Using liquid scintillation counting after transplacental administration of tritiated DENA on different days of gestation, we found no binding in the fetal tracheas before day 12, whereas binding was high (*11*) on the last 4 days (days *12–15*). By light microscopic autoradiography, we were later able to demonstrate that mucous cells and their precursors, as well as undifferentiated stem cells, contained most of the bound radioactivity in the fetal tracheas (*12*). We have now investigated the subcellular distribution of [^{3}H]DENA in target cells by electron microscopic autoradiography. Our data show that the amount of binding is clearly linked to the level of differentiation of selected organelles in the target cell types.

MATERIALS AND METHODS

[^{3}H]DENA was prepared as reported (*13*). It had a specific activity of 48 mCi/mmol. We used a concentration of 2 mCi/ml dissolved in 1 ml ethanol (2 mg). Syrian golden hamsters mated at 3 months of age were given the compound on days 12–15 of the pregnancy. On each of these days, 2 animals received a single intragastric dose by intubation of 0.5 ml DENA in alcohol (1 mCi/animal). Under pentobarbital sodium anesthesia (Diabutal; Diamond Laboratories, Inc., Des Moines, Iowa), the animals were exsanguinated 1 hour after treatment. They were then fixed in situ by vascular perfusion with 2% cacodylate-buffered glutaraldehyde (pH 7.4). The uteri were removed and immersed in the fixative. With the use of a stereomicroscope the fetal tracheas (8–14 fetuses/mother) were excised and processed for electron microscopic autoradiography (for detection of bound radioactivity) as previously described (*14*). Quantitative evaluation of electron microscopic autoradiographs was done by the method of Williams (*15*). Twenty-five cells of each type per animal (trachea: nonciliated stem cells, ciliated cells, basal cells, mucous cells) were examined. To ensure that different cells and not merely serial sections of the same cell were examined, we used only one section per tissue block in the evaluation. To check the validity of the autoradiographic findings, we compared grain counts with the percent distribution of the various organelles in the cells. Labeling was considered significant when grain counts on an organelle were significantly higher (Student's *t*-test) than the percent amount of this organelle per cell (*15*). The percent distribution of organelles per cell and the percent distribution of the grains over various organelles in the cells were measured with the aid of an image analysis system (A.S.M. Image Analysis System; E. Leitz, Inc., Rockleigh, N.J.).

RESULTS

Our grain count results and morphometry data are summarized in table 1. On day 12 of gestation, the epithelium of the fetal hamster trachea consisted of a single layer of tall columnar undifferentiated stem cells (fig. 1). The cytoplasm of these cells was deficient in organelles; the ER was especially scanty and present only in its earliest developmental form as short individual tubules. The nuclei contained little heterochromatin. On this day, the level of radioactive labeling was low and the few autoradiographic grains present were localized on the short ER tubules (fig. 2) and peripheral areas of the nuclei (fig. 3). Whether this labeling in the nuclei was attributable to radioactivity bound to heterochromatin or to the nuclear membrane was not clear.

ABBREVIATIONS USED: DENA=*N*-nitrosodiethylamine; ER=endoplasmic reticulum.

On day 13, the epithelium of the fetal hamster trachea consisted of nonciliated stem cells and basal cells. At this time, the differentiation of cytoplasmic organelles in the stem cells appeared improved, whereas the cytoplasm of basal cells contained few organelles. Radioactive labeling was still low, although higher than on day 12. In the stem cells, autoradiographic grains were again mainly associated with the ER and areas of the nuclear periphery, whereas in the basal cells grains were restricted to the nuclei, mainly the euchromatin.

On day 14, epithelial differentiation in the fetal tracheas had progressed further with a few short cilia becoming noticeable. However, such ciliated cells contained so few grains that quantification was not possible. In basal cells and nonciliated stem cells, more bound radioactivity was seen than on the 2 earlier days. Generally, the distribution of grains within these cells was much as before, with the only difference being that the mitochondria were now also labeled in the stem cells.

One day before birth (day 15), mucous cells were discernible in addition to ciliated, basal, and stem cells in the fetal tracheas. These mucous cells contained mucus droplets in their apical cytoplasm and demonstrated a well-developed rough ER. Mucous cells were the most heavily labeled at that time. Autoradiographic grains in their cytoplasm were associated mainly with mucus droplets and ER (fig. 4). In the other cell types, the grain distribution over the various organelles was similar to that seen on the preceding days of gestation, but labeling in general had increased (table 1).

DISCUSSION

Our data suggest that transplacental carcinogenicity of DENA in the fetal Syrian hamster trachea depends on the level of functional competence of enzyme systems necessary for the metabolic activation of this compound in the target fetal organ. Before day 12 of gestation, when DENA is noncarcinogenic in this system (*10*), the poorly differentiated epithelia of the fetal tracheas do not yet possess any ER (*12, 16*) and accordingly do not bind DENA and/or its metabolites (*11*). When administered to hamsters on day 12 of pregnancy, DENA induces tracheal tumors in 43% of the offspring (*10*). At this time, the first short tubules of rough ER were reported to develop from blebbings of the nuclear membranes in the epithelia of the fetal tracheas (*17*). Our study showed that transplacental administration of [^{3}H]-DENA on this day resulted in binding of radioactivity only to the few ER tubules and periphery of nuclei in the target epithelia. Since nitrosamines are carcinogenic only after metabolic activation (*18, 19*), a reasonable assumption is that these areas are the site of intracellular activation of these compounds. Although this method does not identify the nuclear membrane (with certainty) as one of the binding sites (autoradiographic grains on the nuclear periphery could indicate binding of radioactivity to nuclear membrane or to marginally condensed heterochromatin), the development of ER tubules from this organelle described above (*17*) suggests that the nuclear membrane may possess some of the enzymes generally associated with the ER. Our results are supported by several biochemical studies (*20–22*), which found cytochrome P_{450}-related enzyme systems in nuclear fractions of liver cells and demonstrated their localization in the nuclear envelope (*23*). Together with an increase of transplacental carcinogenicity of DENA for the fetal hamster tracheas during later stages of gestation (*10*), the amount of binding in the target epithelia increased when [^{3}H]DENA was given on one of the last 2 days (days 14, 15) before birth. The increase in binding probably reflects only the increase in ER in stem cells and mucous cells. In addition, basal cells were now also labeled; but in agreement with their known low levels of metabolic competence (*24*), only their nuclei demonstrated autoradiographic grains, whereas their cytoplasm remained unlabeled. Serial sacrifice studies of DENA-induced tracheal carcinogenesis have shown that it is in the basal cells of the respiratory epithelium from which tumors arise, whereas the mucous cells develop intracytoplasmic changes that suggest they can activate the compound (*8*). Our autoradiographic data support this interpretation by showing that the ER is the principal site of binding in the mucous cells and their precursors. The presence of bound radioactivity in mucus droplets suggests that the labeled compound and/or its products are incorporated in the synthesis of mucus.

The low level of binding found in the basal cells appears to contradict the role of this cell type as progenitor cell of DENA-induced tracheal tumors, as revealed in our pathogenesis study in DENA-treated *adult* hamsters (*8*). The histogenesis of tumors in this transplacental system may hence be different from the pathways followed in the adult animal. However, we found in an autoradiographic study with [^{3}H]DENA in adult hamsters that binding to basal cells was substantially lower than that in mucous and ciliated cells (*25*). In that paper (*25*) we suggested that the compound may be metabolically activated in those cells with high levels of binding, whereas the adjacent basal cells are later transformed into tumor cells. It still remains to be clarified if such a transformation is caused by the binding of an active metabolite to macromolecules of basal cells at a time different from the 1-hour interval after administration of [^{3}H]DENA, as selected in our experiment, or if perhaps some yet unknown indirect mechanisms (e.g., feedback between basal cells and mucous cells) are involved.

Comparison of Biologic Behavior and Histology of Transplanted Mammary Tumors in GR Mice[1,2,3]

Dean H. Percy,[4,5] Vincent L. Morris,[4,6] *and* Janet I. MacInnes[4,7,8,9]

ABSTRACT—Mammary tumors that arose spontaneously in inbred GR mice were transplanted into syngeneic castrated males. The hormone responsiveness of the transplants was studied in mice treated with estrone and progesterone and was compared with the hormone responsiveness in mice that received no hormone treatment. Microscopic examination of hormone-responsive and hormone-independent tumors revealed similar histologic patterns in both groups. It was evident that pale cells, which are classically associated with hormone-responsive tumors, may also be present in transplanted hormone-independent tumors in this strain. No correlation was found between the histologic pattern of these transplanted tumors and the biologic behavior, hormonal status, or presence of a specific murine mammary tumor virus (MuMTV) proviral fragment. Mammary tumors also appeared capable of undergoing differentiation into more than one morphologic type. Two cotransplanted tumors (derived from the same parental tumor) had markedly different histologic patterns; however, analysis of MuMTV proviral fragments indicated that the MuMTV-infected cells were of the same parentage.—JNCI 1982; 69:933–938.

MuMTV is associated with mammary carcinomas in high-tumor-incidence strains of mice such as GR and C3H (*1*). Examination of GR mammary tumor DNA reveals that, in addition to ten endogenous MuMTV copies per diploid cell, there are from one to approximately ten acquired proviral copies stably integrated into the genome (*2, 3*). It has been observed that DNA's extracted from spontaneous mammary tumors produce a unique pattern of MuMTV-specific fragments for each tumor when digested with restriction endonucleases (*4*). This result indicates that while there are many possible integration sites for acquired MuMTV copies, none of these sites appear to be strongly preferred (*4*).

Hormone-responsive tumors rarely occur in most strains of mice (*1, 5*). However, in the GR strain, as in the human counterpart, both hormone-independent and hormone-responsive neoplasms are found (*6–8*). To evaluate the biologic behavior of tumors arising spontaneously in GR mice, we transplanted tumor cell suspensions into pairs of syngeneic castrated male recipients (*7, 9*). Estrone and progesterone were administered to one group to determine whether the transplanted tumor was hormone-independent or hormone-responsive (*7, 9*). On the basis of the work of Sluyser and van Nie (*9*), a tumor was deemed hormone-responsive if transplanted cells gave rise to a palpable tumor at least 14 days earlier in the hormone-treated animal.

In a previous study, analysis of acquired MuMTV proviral copies in transplanted mammary tumor from GR mice revealed differences between hormone-responsive and hormone-independent cells derived from the same tumor (*7*). It was concluded that the spontaneous tumors were composed of a limited number of populations of hormone-responsive and hormone-independent cells; however, specific MuMTV fragments could not necessarily be correlated with the hormone responsiveness of the tumor (*7*).

In this study, we were interested in determining whether the histologic patterns of the tumors were related to their hormone responsiveness or to other factors, such as the presence of specifically acquired MuMTV proviral fragments. Like Dunn and others (*10, 11*), we found that the tumors displayed a significant degree of histologic heterogeneity. In contrast to reports by Strum and others (*5, 11, 12*), though, we found that many pale cell carcinomas were not hormonally responsive. Our data suggest that the histology of these tumors is very complex and might be influenced by many factors. The histologic pattern was not directly related to the hormone status of the tumor or to the presence or absence of hormone treatment. In addition, using the acquired MuMTV proviral fragments as markers for cell populations, we have evidence that neoplastic epithelial cells may be able to undergo differentiation into more than one morphologic type.

MATERIALS AND METHODS

Source of animals and tumor transplantation scheme.—Inbred GR mice used in this study were obtained from Dr. E. Y. Lasfargues. The methods of tumor collection and transplantation have been described previously (*7*). Spontaneous tumors from multiparous GR females were aseptically removed and homogenized, and approximately 2×10^6 cells were administered sc into the lower flank of pairs of synge-

[9] We thank Dr. E. Y. Lasfargues and Dr. G. Mackie for materials cited in the text and Dr. B. Sass for examining the histologic slides of some of the tumors discussed in this paper. Murine mammary tumor virus (C3H) RNA and avian myeloblastosis virus DNA polymerase were supplied by the Office of Program Resources and Logistics, National Cancer Institute. We also thank Mr. E. C. M. Lee Chan, Ms. U. Jorch, Ms. A. Orosz, and Ms. E. M. Seaman for their technical assistance.

neic castrated male mice. One mouse was given an injection weekly of 3×10^{-3} g progesterone (Sigma Chemical Co.), and estrone at 0.5×10^{-6} g/ml was administered in the drinking water. The other hormone-untreated mouse was housed under identical conditions. With each passage, the histology and hormone responsiveness of the tumors were assessed. Following the criterion of Sluyser and van Nie (*9*), a tumor was deemed hormone-responsive if it appeared at least 14 days earlier in the hormone-treated animal. Most hormone-responsive tumors, however, appeared 8–30 weeks earlier in the hormone-treated animals.

Restriction endonuclease analysis of tumor DNA's.—DNA was extracted from tumors at selected passages, digested with restriction endonucleases Eco RI or Bam HI, and separated by electrophoresis in agarose gels (*7, 13*). Eco RI cuts the provirus approximately midway in the genome and at the nearest Eco RI site in the flanking cell sequences (*2, 14*). Since integration of MuMTV appears to occur in general at different sites in the genome, a proviral copy cut with Eco RI generates two unique-sized fragments (*4*). In a similar manner, digestion with Bam HI generates two unique fragments in addition to a 1.1-Kb internal piece (*14*). These enzymes, therefore, can be conveniently used to determine the number of integrated proviral copies. After transfer of fragments from the agarose gels to nitrocellulose filters (*7, 13*), the MuMTV-specific sequences were annealed with MuMTV ^{32}P cDNA (*7*). Unhybridized cDNA was washed away, and the MuMTV-specific sequences were visualized by autoradiography (*15*). The details of the procedures for the restriction endonuclease analysis, Southern transfer procedure, and hydridization reactions have been described previously (*7*).

Histologic and ultrastructural studies.—Tissues collected for light microscopy were fixed in Bouin's fluid, embedded in paraffin, sectioned at 6 µm, and stained with hematoxylin and eosin and periodic acid–Schiff (*16*). Selected specimens were collected for electron microscopy. Tissues were fixed in 3% glutaraldehyde, minced, dehydrated, and embedded in Spurr's medium. Sections (1 µm) were stained with toluidine blue for light microscopic examination. Thin sections were stained with uranyl acetate and Reynold's lead citrate and examined in a Zeiss EM 9S electron microscope.

RESULTS

Morphologic Studies

The histologic characterization of mammary tumors seen in most strains of mice has been described in detail by Dunn, Sass, and others (*10–12*). In this study, particular emphasis was placed on the identification of pale cell tumors that are associated with GR mice (*5, 11, 12*). Most of the tumors examined were classified as either type B adenocarcinomas (*10*) or pale cell carcinomas (*11*). The type B tumors demonstrated a variety of architectural features ranging from acinar structures to anastomosing trabeculae or solid sheets of cells. In the pale cell tumors, characteristically, cords or nests of pale cells were found close to clusters of dark cells (fig. 1). Occasionally, glandular structures were observed. Electron microscopic examination of pale cell tumors revealed large cells with electron-lucent cytoplasm and scattered cytoplasmic organelles (figs. 4A, 4B). In addition to the pale cells, there were darkly staining cells with electron-dense cytoplasm, closely packed cytoplasmic organelles, and clearly delineated cell outlines (figs. 4A, 4B). Intercellular desmosomes were observed (fig. 4A), and typical A-type MuMTV particles were frequently demonstrated, particularly in the cytoplasm of the dark cells (fig. 4B).

In many cases, the tumors displayed some heterogeneity with respect to cell and architectural types. In some tumors that were predominantly type B adenocarcinomas, isolated islands of pale cells could be detected. Similarly, in pale cell tumors, scattered areas of cells typical of those of type B tumors were observed in some cases. This heterogeneity is consistent with the fact that spontaneous tumors contain multiple populations of cells; however, the presence of a particular cell type cannot necessarily be correlated with any biologic property.

Pale cell tumors in the GR mouse are classically considered to be hormone-responsive (*5, 11, 12*). Hormone-treated mice, however, did not always develop hormone-responsive tumors. We were unable to correlate the histologic type with hormone responsiveness or hormone treatment (table 1). In general, there were no obvious differences seen in the histologic pattern of those tumors passaged in the presence of hormones (76 vs. 74%) or in tumors determined to be hormone-responsive or hormone-independent (74 vs. 82%).

Relationship of Carcinoma and Myoepithelial Tumor

We have examined approximately 170 transplanted GR tumors in this study and in related studies. In one instance we found that 2 transplanted tumors derived from the same hormone-independent parental neoplasm had distinctly different histologic patterns. On the basis of the criteria previously described (*5, 11, 12*), transplant 4483 D (passaged in a hormone-treated recipient) was classified as a pale cell carcinoma (fig. 2). Conversely, the cotransplant 4525D (passaged in a recipient without hormone treatment) contained interlacing bands of fusiform cells. Individual cells had flattened nuclei with rounded poles and finely fibrillar, elongated cytoplasmic outlines (fig. 3). With the use of Hamperl's criteria (*17*), this neoplasm was interpreted to be of myoepithelial origin. The architecture and cell type were

TABLE 1.—*Morphologic classification of transplanted mammary tumors in GR mice according to treatment with, and response to, hormones*

Parameter	No. of animals so classified/total No. of animals (%)		
	Pale cell tumor	Type B adenocarcinoma	Myoepithelial tumor

consistent throughout, and no typical epithelial elements were observed. Despite the differences in histologic type, the time of appearance and gross morphology of the 2 tumors were very similar. The myoepithelial tumor was palpable 37 days post injection in the animal that did not receive hormone treatment; the pale cell tumor appeared 34 days post injection in the hormone-treated corecipient.

Examination of the 2 tumors with the Southern transfer procedure revealed that both tumors contained the same pattern of acquired proviral Eco RI fragments (fig. 5). Similar results were obtained with Bam HI analysis. Since both tumors gave identical patterns, we concluded that the MuMTV-infected cells in the myoepithelial tumor and the pale cell carcinoma very likely originated from the same parental tumor cells. If the myoepithelial tumor had arisen independently, then the pattern of MuMTV-specific fragments would have been different because, to date, data indicate that none of the many possible sites of integration for acquired MuMTV DNA copies appear to be preferred (*4*).

The parental spontaneous tumor has a pattern of major MuMTV-specific, acquired DNA sequences that differs from the pattern seen in the transplanted tumors 4525D and 4483D (fig. 5); this observation occurs because spontaneous GR mammary tumors are made up of more than one population of cells that can be distinguished by their MuMTV proviral restriction fragments (*7*). The relative proportion of these cells can vary as the tumor is passaged in mice in the presence or absence of hormones (*7*).

DISCUSSION

The distinctive pale cell mammary tumors seen in GR mice have been reported to be hormone-responsive (*5*, *11*, *12*). However, in our transplantation study, both hormone-responsive and hormone-independent neoplasms were of the pale cell type. In fact, no distinctive differences could be detected between the histologic patterns seen in hormone-responsive and hormone-independent mammary tumors (table 1). Similarly, the histologic findings were comparable in the transplanted tumors whether or not the recipient mice were treated with hormones. These data suggest that pale cells may persist in hormone-independent tumors and that their presence is a reflection of a coincidental or obligatory cell heterogeneity in these tumors. Alternatively, the degree of hormone responsiveness of a tumor may have little or no bearing on the histology of the tumor. Studies of human breast carcinomas indicate that the histologic type is generally a poor prognosticator of hormone responsiveness (*18*). Thus many influences, including genetic, immunologic, hormonal, and physiologic factors, may determine the histologic pattern of a neoplasm.

Our data also suggest that mammary tumor cells may be able to undergo differentiation into more than one morphologic type. In this study, 2 transplanted tumors derived from the same parental tumor had distinctly different histologic patterns. Transplant 4483D was classified as a pale cell carcinoma, whereas the cotransplant 4525D was interpreted to be a myoepithelial tumor (figs. 2, 3). Despite their differences in histology, both tumors shared the same pattern of acquired MuMTV proviral fragments (fig. 5). Since both tumors appeared within 4 days of each other and within 37 days post injection, selection of a single mutated cell would not likely account for the appearance of the myoepithelial tumor. In addition, it is unlikely that the appearance of the myoepithelial tumor was due to the selection of preexisting cells with the same pattern of acquired MuMTV proviral fragments since there appears to be no strongly preferred integration sites (*4*). The role of hormone treatment or, in the case of the myoepithelial tumor, lack of treatment is not clear, but hormonal influences are likely important under certain conditions for the selection of different morphologic types.

This observation provides molecular evidence to support the contentions of Hamperl (*17*) and Foulds (*19*) that the varied types of epithelium (seen in mammary tumors) may be different growth forms of divergent differentiations in cells of a common ancestry. In our experiments, however, this differentiation may be a relatively rare event in vivo. Dulbecco et al. (*20*) have reported a similar differentiation process in vitro in Rama 25 cells derived from a chemically induced rat mammary carcinoma. They were able to isolate fusiform myoepithelial-like cells from rapidly differentiating F-precursor cells. They suggested that the differentiation of the F-precursor cells in vitro into various cell types (including myoepithelial-like elements) may correspond to processes occurring in vivo.

FIGURE 5.—MuMTV-specific proviral sequences in transplanted tumor series. Mammary tumors grafted into castrated GR male mice were extracted, and 5 µg of DNA was digested with Eco RI. After complete digestion, MuMTV-specific sequences were separated and visualized as described in "Materials and Methods." The major acquired MuMTV fragments are indicated by a lower-case letter. *Lane A* (4525D), myoepithelia tumor with predominant acquired MuMTV fragments a and b; *lane B* (4483D), cotransplant with predominant acquired MuMTV fragments a and b; *lane C*, original spontaneous tumor with predominant acquired proviral fragments c and d; and *lane D*, GR normal organs (heart, liver, spleen, lungs, and kidneys). Molecular weights of the MuMTV-specific fragments were determined by comparison with those of Eco RI fragments of ^{32}P lambda DNA, *lane E* (provided by Dr. G. Mackie).

Regulation of Cell-Mediated Immunologic Reactivity to Moloney Murine Sarcoma Virus-Induced Tumors.
III. Further Characterization of Tumor-Specific Serum Blocking Factors[1,2,3]

William J. Halliday,[4] **Thelma A. Koppi,**[4] *and* **Ian F. C. McKenzie**[5]

ABSTRACT—Blocking factors in the sera of inbred CBA mice bearing either Moloney murine sarcoma virus-induced tumors or transplanted 3-methylcholanthrene-induced tumors specifically blocked in the leukocyte adherence inhibition reaction between tumor-sensitized peritoneal cells and tumor antigens. These factors were absorbed from serum by treatment with anti-Ia antibodies and could be eluted in a partially purified form. Chromatography on Sephacryl S-200 columns demonstrated blocking activity in fractions of high and low molecular weight (>100,000 and 40,000–50,000, respectively) derived from whole sera or eluates. Active fractions from serum appeared to retain the tumor specificity of the original material.—JNCI 1982; 69:939–944.

Specific BF have been defined as any humoral factors that can in a specific way impair an immune response to tumor antigens independently of their site of action (central, afferent, or efferent) and their molecular composition (*1*). The most intensively studied BF are those found in the sera of tumor-bearing hosts and that block in vitro reactions of specific cell-mediated antitumor immunity by an efferent mechanism. These BF were first detected by the lymphocyte cytotoxicity reaction, the destructive effect of immune lymphocytes on tumor cells being abrogated by the sera of subjects bearing the same type of tumor (*2*).

The earliest assumption that BF were antibodies (*3*) was soon supplanted by the hypothesis that BF were antigen-antibody complexes, derived at least in part from the tumor. Much of the more recent work on the nature of BF supports this concept. Investigations by the Hellström group (*4*) showed that BF could be split into low and high MW fractions, and activity was reconstituted when these fractions were combined. Baldwin and co-workers (*5*) prepared artificial BF by mixing tumor antigen with antibody in suitable proportions. Free tumor antigen was also found to interfere with cell-mediated cytotoxicity under some conditions (*6*).

Further evidence for the existence of BF distinct from antibodies came from studies with sera of mice bearing MCA-induced sarcomas. Fractionation of these sera on immunoadsorbent columns and by gel filtration on Sephadex G-200 yielded specific BF of MW 56,000. These materials had affinity for the corresponding tumor cells and properties of glycoproteins (*7*). The existence of this form of BF was reconciled with evidence for antigen–antibody complexes with blocking properties by the proposition that the 56,000-MW factor may exist in serum as a complex with immunoglobulin or that it may be formed by cells stimulated by specific immune complexes (*1*).

Serum BF have obvious affinities with antigen-specific suppressor factors found in other circumstances. A relevant example is the factor extracted from thymuses of tumor-bearing mice (*8*); this factor enhanced tumor growth in vivo and contained determinants coded by the I-J subregion of the MHC.

Several in vitro reactions other than lymphocyte cytotoxicity are susceptible to blocking by serum factors. The BF in different systems may be identical, but this is not necessarily so. LAI with soluble tumor antigens can be blocked by sera from the appropriate tumor-bearing subjects (*9–12*). Specific BF related to M-MuSV-induced tumors were recently shown to contain Ia determinants related to the I-J subregion of the MHC (*13*). These BF were removed specifically from serum by anti-Ia antibodies. Similar studies have now been conducted with MCA-induced tumors, the BF suppressing LAI have been partially purified by immunoadsorption with anti-Ia antibodies followed by elution, and the molecular size distribution of BF in sera and eluates has been determined.

MATERIALS AND METHODS

Mice.—Inbred CBA mice were procured from the Central Animal Breeding House, University of Queensland. They were 2–6 months old when used.

MCA-induced tumor.—Fibrosarcomas were induced in CBA mice by sc injection of MCA as previously described (*9*). One of these tumors was passaged by serial sc transplantation in syngeneic mice and had passed through 12 generations before this study was done. Tumors grew to 10 mm in diameter in 10–15 days. Tumor tissue for extraction was removed when the tumors reached 10 mm in diameter and was frozen at −50°C until required.

Virus-induced tumor.—M-MuSV (lot #B-156, #110, and

#160) was donated by the National Cancer Institute (Bethesda, Md.) through M.A. Bioproducts (Walkersville, Md.). The undiluted material (0.1 ml) was injected im into the thighs of mice to produce regressing tumors as previously described (*12, 14*). Tissue for extraction was removed at the height of tumor growth and frozen as detailed above.

Tumor extracts (antigens).—Fresh or frozen tumor tissue was homogenized in PBS (pH 7.2), and a soluble extract was prepared according to the published procedure (*9, 12*). Before use the extracts were titrated and diluted to give optimal LAI reactions (final dilutions of 1:20 in the reaction mixtures) (*12*).

PC.—We killed donor mice with ether and obtained PC by injecting heparinized Hanks' solution into the peritoneal cavity and then collecting the fluid after opening the cavity. The fluid was centrifuged at $200\times g$ for 5 minutes, and the erythrocytes in the pellet were lysed with $0.15\ M$ ammonium chloride solution. The PC were washed three times with Eagle's basal medium containing 10% fetal calf serum (Commonwealth Serum Laboratories, Melbourne, Australia). The cell concentration was adjusted to 1×10^7/ml for use in LAI. PC were obtained from M-MuSV-inoculated mice (5–10 days after inoculation) and from mice with MCA-induced tumors (10–12 days after transplantation).

Mouse serum.—Mice were anesthetized and bled from the tail, the blood was allowed to clot, and the serum was either used fresh on the same day or stored frozen at −20°C for a few days. Serum was obtained from normal mice and from mice bearing either M-MuSV-induced tumors (5 days after inoculation) or MCA-induced tumors (10–12 days after transplantation).

Preparation of anti-Ia antibodies.—Antiserum was prepared by the alloimmunization of suitable mouse strains (A.TH anti-A.TL) and is described elsewhere (*13*). The Ia antibodies recognized products of the I-region (*k*-haplotype as in the MHC of CBA mice).

Absorption of serum with anti-Ia antibodies and elution of serum factors.—Anti-Ia antiserum was coupled to Sepharose 4B (Pharmacia Fine Chemicals, Uppsala, Sweden) as described (*13*). The coupled gel was used to absorb CBA mouse serum (normal mouse and tumor-bearing mouse) by the column method. The gel (3 ml) was poured into a 5-ml plastic syringe barrel, and the serum (3–4 ml) was poured into the resulting column. The serum was washed through with 3–4 ml of PBS, and the effluent was collected. The column was washed with about 20 ml of PBS. To elute the absorbed material on the gel, we poured $0.1\ M$ glycine-HCl buffer at pH 2 through the column until the eluate became acidic. This eluate was collected and neutralized with saturated sodium bicarbonate solution. The neutralized eluate (Ia eluate) and the initial effluent (Ia effluent) were concentrated to one-third of the original serum volume on Minicon B-15 concentrators (Amicon Corp., Lexington, Mass.).

Column chromatography (gel filtration).—A column (90×2.5 cm) of Sephacryl S-200 superfine (Pharmacia Fine Chemicals) was equilibrated with PBS and calibrated with proteins of known MW. The material to be fractionated (2 ml) was run into the column, and 5-ml fractions were collected and then stored frozen at −20°C until required to be assayed for BF. The fractions were then thawed and 2-ml quantities of each fraction were pooled as specified below. The fraction pools and some individual fractions were finally concentrated to 1/100 volume with Minicon B15 concentrators. Fractions were collected in this way from sera (normal mouse and tumor-bearing mouse) and Ia eluates (normal mouse and tumor-bearing mouse).

LAI technique.—The hemacytometer method was used throughout (*9–12*). Mixtures for the determination of leukocyte adherence contained 10^6 PC, diluted tumor extract as antigen (or medium only as control), and 25% mouse serum (normal serum or material to be tested for BF), all in a total volume of 0.2 ml. These mixtures, in duplicate, were coded, preincubated at 37°C for 30 minutes, then introduced into hemacytometers. After incubation at 37°C for 1 hour the cells were counted, the hemacytometer slides were washed to remove nonadherent cells, and the remaining cells were recounted. A significant reduction in mean percent adherence, consequent upon the inclusion of tumor extract in a mixture of PC and normal serum, was interpreted as a positive LAI reaction.

The quantitative expression of LAI in the tables of results was calculated by simple subtraction of the relevant mean percent adherence from the control mean; the statistical significance of the difference between these means was then determined by Student's *t*-test (modified for unequal variances), inasmuch as the individual values of percent adherence were normally distributed. An LAI value of 10 or greater was usually significant ($P<0.05$).

We determined the ability of a test material (serum or some derivative) to block LAI by comparing the adherence (X) of sensitized PC incubated in the presence of antigen and this test material with the adherence (Y) of the same PC incubated in the presence of antigen and a control material. The difference (X−Y) was the blocking value, and the statistical significance of the difference was determined as above. When the test material was whole tumor-bearing mouse serum, the control was whole normal mouse serum. When the test material was a fraction or derivative of tumor-bearing mouse serum, the control was a similarly derived material from normal mouse serum. In this case, inasmuch as the material was often deficient in serum protein, normal mouse serum was added to the incubation mixtures.

RESULTS

Specific serum effects on LAI.—When PC from tumor-bearing mice were incubated with normal mouse serum, a normal adherence to glass was determined (table 1, mixtures 1 and 5). Addition of the corresponding tumor extract induced significant LAI (mixtures 2 and 6). With the same mixtures of PC and extract, LAI was blocked by the corresponding tumor-bearing mouse serum (mixtures 3 and 7) but not by unrelated tumor-bearing mouse serum (mixtures 4 and 8). The results presented in table 1 establish the tumor specificity of BF in serum and illustrate the procedures and calculations used throughout the present investigation. Substantial negative blocking values (as in mixture 4) were occasionally observed.

Absorption and elution of BF.—In table 2 are shown the data

TABLE 1.—*Specificity of blocking serum activity in LAI as related to tumor type*

Mixture No.	Source of PC[a]	Tumor extract	Source of serum[a]	Percent adherence, mean ± SE	LAI value[b]	Blocking value[b]

for blocking activity of whole sera from tumor-bearing mice (mixtures 3 and 10) and materials derived from these sera by treatment with anti-Ia antibody coupled to Sepharose 4B. The absorbed sera (anti-Ia column effluents, mixtures 5 and 12) were no longer blocking when compared with the relevant controls (mixtures 4 and 11, respectively). BF were recovered by treatment of the columns with pH-2 buffer as demonstrated by the significant blocking activity of Ia eluates (mixtures 7 and 14, compared with mixtures 6 and 13, respectively). In all experiments the Ia effluents (absorbed sera) had no residual blocking activity (table 2).

Molecular size distribution of serum and eluate BF.—Sera from mice bearing either M-MuSV-induced or MCA-induced tumors were passed through columns of Sephacryl S-200; fractions were collected, pooled as required, and assayed for BF (by comparison with equivalent fractions from normal serum). Concurrently, Ia eluates were prepared from the same sera by absorption to and elution from immobilized anti-Ia antibody; these eluates were fractionated, pooled as required, and assayed for BF (by comparison with equivalent fractions from Ia eluates of normal serum).

The results are expressed diagrammatically for the original unfractionated materials and the column fractions in which BF were found. Text-figure 1 illustrates the results for whole serum and Ia eluate before being placed on the column (original) and the fraction pools where blocking activity was detected. These materials are related to mice bearing the MCA-induced tumor. In the upper part of text-

best copy available

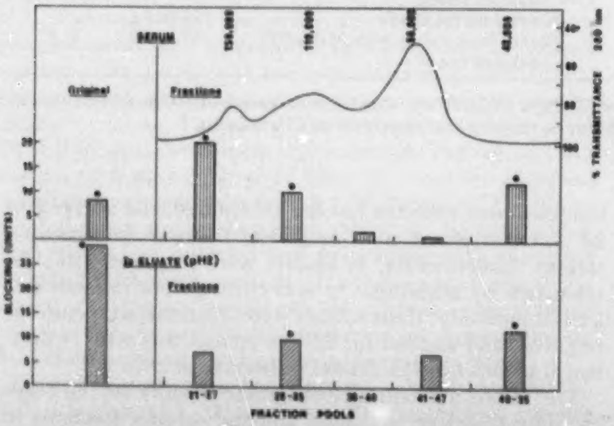
figure 1 there is a UV transmittance curve for the serum fractions with calibrated MW marked. The whole serum (original) was significantly blocking. After fractionation, high (>100,000) and low (<50,000) MW pools were blocking. In the lower part, the text-figure shows the properties of the Ia eluate and its fractions. The Ia effluent was not blocking (data not shown), which indicated that the active factor was absorbed completely by anti-Ia antibody. The pH-2 eluate (original) was blocking, and the active factor appeared in the fraction pools at an approximate MW of 100,000 and 50,000. There was not enough protein in the eluate to give a transmittance curve.

Examination of pairs of fractions from the same serum as in text-figure 1 confirmed the presence of BF of two different molecular sizes in sera from mice with MCA-induced tumors. This is illustrated in text-figure 2 (upper part). The lower part of text-figure 2 shows the analysis of single fractions from the Ia eluate in the low MW area (fractions 48–55) rather than pools. The smaller factor had an apparent MW of about 40,000. The reason for the absence of activity from fraction 54 is not known.

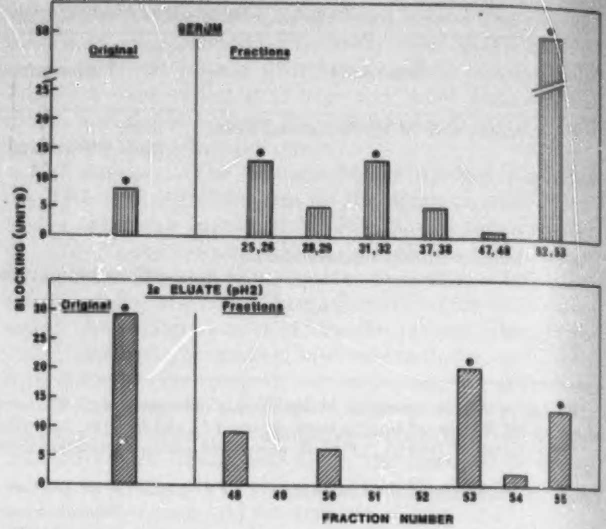
Text-figures 3 and 4 show the blocking of LAI by sera from mice bearing M-MuSV-induced tumors, the corresponding Ia eluates, and their Sephacryl S-200 fractions. With the first serum (text-fig. 3), both high and low MW activities were found when the whole serum was fractionated, but the original Ia eluate was not significantly blocking. On fractionation of this eluate, high MW blocking material was detected, but there was no significant blocking activity in other fraction pools.

With a second serum of the same type, both the whole serum and Ia eluate were blocking, but only low MW fraction pools had significant activity (text-fig. 4).

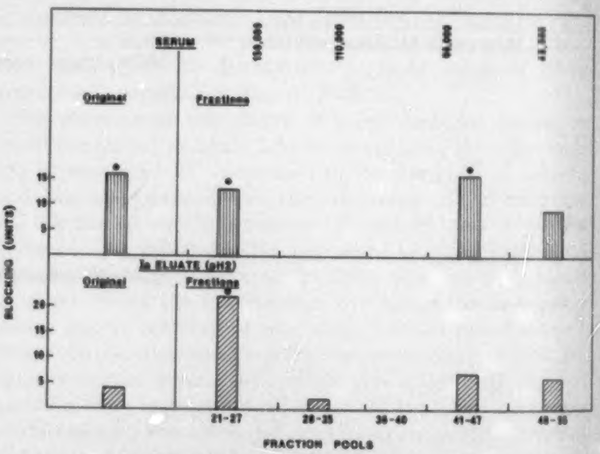
Tumor specificity of BF in serum fractions.—To confirm that the blocking fractions found above were specific for tumor type (as previously demonstrated for whole serum), we tested known blocking fractions related to the MCA-induced tumor on PC from mice bearing M-MuSV-induced tumors. The three fractions used were those from serum that showed blocking in text-figure 1; blocking values of 19.8, 9.9, and 11.3, as in the text-figure, were obtained with PC from mice bearing the corresponding tumor. Table 3 presents the results of testing the same pooled fractions on M-MuSV tumor-sensitized PC. These cells gave significant LAI in the presence of normal serum (data not shown) and could be blocked by whole serum from mice with M-MuSV-induced tumors. When the three fraction pools related to the MCA-induced tumor were tested, no blocking reactions occurred. Thus blocking activity of both the high and low MW fractions appeared to be antigen-specific. The reverse test (for nonspecific blocking by serum fractions related to M-MuSV-induced tumors) was not done.



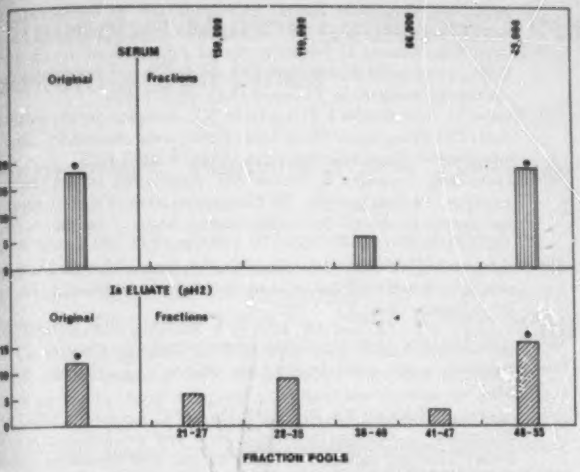
TEXT-FIGURE 1.—Blocking of LAI by sera of mice bearing MCA-induced tumors, by Ia eluate, and by Sephacryl S-200 fraction pools. Tests were performed with PC from similar mice and MCA-induced tumor extracts. A UV transmittance curve for serum fractions is shown, and MW of known proteins are marked. *=significant blocking. Pool 36–40 (eluate) had no blocking activity.



TEXT-FIGURE 2.—Blocking of LAI for certain fraction pairs (from serum) and single fractions (from Ia eluate), from the same experiment as for text-fig. 1. *=significant blocking. Fractions 49, 51, and 52 had no blocking activity.



TEXT-FIGURE 3.—Blocking of LAI by sera of mice bearing M-MuSV-induced tumors, by Ia eluate, and by Sephacryl S-200 fraction pools. Tests were performed with PC from similar mice and M-MuSV-induced tumor extracts. *=significant blocking. Pools 28–35 and 36–40 (serum) and 36–40 (eluate) had no blocking activity.



TEXT-FIGURE 4.—Blocking of LAI by sera of mice bearing M-MuSV-induced tumors, by Ia eluate, and by Sephacryl S-200 fraction pools. Text-figs. 3 and 4 show data from different experiments. *=significant blocking. Pools 21–27, 28–35, and 41–47 (serum) and 36–40 (eluate) had no blocking activity.

Normal mouse	69.1±5.1	−13.1
Mouse with MCA-induced tumor	56.0±5.0	
Fraction pools 28–35 from:		
Normal mouse	69.7±3.2	−6.5
Mouse with MCA-induced tumor	63.2±4.1	
Fraction pools 48–55 from:		
Normal mouse	64.6±4.7	−3.6
Mouse with MCA-induced tumor	61.0±2.6	

[a] The same serum fraction pools were significantly blocking when tested with PC and antigen related to MCA-induced tumor (text-fig. 1).

[b] Sera from mice with M-MuSV-induced tumors were obtained 5 days after M-MuSV inoculation. Sera from mice with MCA-induced tumors were obtained 10 days after tumor transplantation and fractionated as for text-fig. 1. Corresponding fractions were obtained from normal serum.

[c] Adherence of PC from mice with M-MuSV-induced tumors; the PC were incubated with M-MuSV-induced tumor extract and the serum or fractions specified.

[d] *** $P<0.001$; unmarked values are not significantly blocking.

DISCUSSION

The LAI assay has previously been shown to be susceptible to blocking by serum factors (*9–13*). BF are detectable in tumor-bearing subjects and have a specificity similar to that of the tumor antigens employed in the assay. When added to PC whose adherence has been inhibited through reaction with antigen, BF restore the adherence toward the normal level. This effect is a result of the prevention of lymphocyte activation, rather than a direct modification of cellular adherence (*12*). Sera from tumor-bearing animals nevertheless often have a nonspecific depressing effect on adherence, as revealed in situations in which BF have been removed or cannot operate; examples of this phenomenon are seen in tables 1–3 of this paper as negative blocking values and also in our other publications [e.g., (*12*)].

Previous studies of the molecular size of tumor-specific BF have yielded conflicting data. Early estimates (*14*) indicated that BF accompanied 7S immunoglobulins when serum was fractionated; more recently (*7*), molecules of MW 56,000 were isolated. The present results are compatible with both observations in that high (>100,000) and low (40,000–50,000) MW forms of BF were obtained from serum, either singly or together. Both tumor types studied (M-MuSV-induced and MCA-induced) gave comparable results. The active fractions of serum from mice with MCA-induced tumors appeared to be tumor-specific (as was the original serum) in their blocking action.

Low and high MW fractions of BF (detected by their effect on lymphocyte cytotoxicity) were previously described (*4*) as the products of dissociation at acidic pH; only the lower MW material (<100,000) had any blocking effect alone, and full activity was restored only when the fractions were recombined. The active factors reported in the present work appeared to exist individually in serum and required only gel filtration and not low pH treatment for their separation; each had independent blocking activity.

An additional distinctive property of at least some BF, their possession of Ia antigenic determinants (*13*), permitted a selective immunoadsorption of BF from serum. These determinants were shown previously to be related to the I-J subregion (*13*). Within the limits of the assay methods, it appeared that all BF were removed from serum by combination with anti-Ia antibodies. Other kinds of BF, if present at all, must have been in small amounts or not detectable by the assay system. Elution of BF with an acidic buffer yielded material with blocking activity; these eluted BF were then shown to have an MW distribution broadly similar to that of the serum BF from which they were derived. An exception was found in one instance (text-fig. 3) in which BF of low MW were not recovered in the eluate. The tumor specificity of active eluate fractions was not determined, nor was it shown that all recovered active fractions retained Ia determinants. It is possible that acid elution dissociated some of the BF, but this seems unlikely since both high and low MW forms were recovered after neutralization and fractionation.

The estimate of MW for BF in fractions from a Sephacryl S-200 column is tentative, inasmuch as the shape of the molecule influences its chromatographic behavior and the protein standards used may not have been ideal for calibration. There was lack of agreement in some details between the results for the same tumor on different occasions (text-figs. 3, 4). It seems that BF in distinct molecular forms can have similar biological activity.

The low MW factors resemble antigen-specific T-cell suppressor factors (*8*) in possessing Ia determinants and a molecular size of approximately the same range. They may also correspond with the factor of Nepom et al. (*7*). The larger factors may be the complexes described by earlier workers. As suggested previously (*1, 13*), the smaller factor might be expected to combine with tumor antigen and then with antibody. The contribution of these entities to the composition of Ia-containing BF remains to be studied.

An area of current interest concerns the cellular origin of BF. It is already known that BF are produced in cultures of spleen cells from tumor-bearing mice and that the responsible cells are T-lymphocytes (*15*). We have further characterized the markers on BF-producing spleen cells and have identified Thy-1, Ly-2, and I-J (Koppi TA, Halliday WJ: Unpublished data). These cells therefore resemble the T-suppressor cells found in other situations.

The regulatory molecules revealed in serum by the present investigation probably have their counterpart in human cancer, where LAI techniques have consistently detected specific BF (*11*). Whether human BF are HLA related is not yet known.

Trisomy 15 and Other Nonrandom Chromosome Changes in Rauscher Murine Leukemia Virus-Induced Leukemia Cell Lines[1,2]

Anne Hagemeijer,[3] Elisabeth M. E. Smit,[3] Francine Govers,[4] *and* Nico J. de Both[4]

ABSTRACT—The cytogenetics of Rauscher murine leukemia virus-induced erythroid, myeloid, and lymphatic leukemias were studied in BALB/c and DBA/2 mice. In primary virus-induced leukemias, no chromosome abnormalities were found. However, in tumors derived from transplanted leukemia tissue and in cell lines obtained from these tumors, euploidy and mostly aneuploidy were observed that varied according to the type of tumor cells and the number of passages. Eleven erythroleukemia cell lines showed aneuploidy from the first in vivo transplant stage on. Nonrandom abnormalities were found: trisomy 15 in 9 of 11 lines, followed by trisomy 3 in 8 of 11 lines and monosomy 6 in 5 of 11 lines. Subsequent evolution of the karyotypes was frequent (10 of 11 lines) and rapid. In vivo cell lines established from these tumors showed many structural rearrangements. Three myeloid lines revealed a stable karyotype with no or only minor changes: trisomy 15 in 1 line and normal diploid in 2 lines. One lymphatic leukemia cell line established in vitro presented with a very stable karyotype: trisomies 14 and 15. Another in vivo transplantable line showed trisomies 11, 9, and 17. These results suggest that trisomy of chromosome 15 plays a significant role in tumors derived from different types of mouse leukemias.—JNCI 1982; 69:945–951.

Cytogenetic abnormalities are a common feature in cancer cells, but so far the role of these chromosome aberrations in cancer has remained elusive and is the source of controversial hypotheses. During the last decade, studies of human leukemias have shown *a*) that a few chromosomes were preferentially involved in abnormal karyotypes, *b*) that additional cytogenetic changes occurred with progression of the disease, and *c*) that some chromosome translocations were specifically associated with certain types of leukemia, e.g., the t(9;22) in chronic myeloid leukemia, the t(8;21) and t(15;17) in acute myeloid and promyelocytic leukemias, respectively, and the 14q+, often resulting from a t(8;14) in B-cell lymphomas (*1–4*). Solid tumors, like meningiomas or breast carcinomas, also showed nonrandom occurrences of chromosome abnormalities (*4*). Animals with experimentally induced tumors were also studied. In the rat, it was found that chromosome aberrations tended to be specific for the oncogenic agent rather than for the histologic type of tumor; i.e., chemically induced sarcomas and leukemias were characterized by trisomy of chromosome 2, whereas similar sarcomas virally induced showed trisomies 7, 12, and 13 (*5–7*). In contrast, in the mouse, there was a tendency to relate the type of aneuploidy with the cytologic type of leukemia: Plasmacytomas and B-cell leukemias showed a specific translocation of #15 with #12 or with #6 (*8, 9*), myeloid leukemia showed a deletion of #2 (*10, 11*), and thymomas were characterized by trisomy 15 (*12–16*).

Trisomy of chromosome 15 is claimed to be highly specific for murine T-cell lymphomas, and its specificity is independent of whether the lymphoma occurs spontaneously as in the AKR mouse (*12*) or is induced by exposure to virus, radiation, or carcinogens (*13–16*). In a previous study (*17*) we found that in a myeloid cell line derived from a myeloid leukemia induced by R-MuLV, trisomy of chromosome 15 was the only karyotypic abnormality. Since the same oncogenic virus under appropriate experimental conditions can induce different types of leukemia, we decided to analyze cytogenetically these cytologically different leukemias.

We report here the cytogenetics of Rauscher virus complex-induced erythroid, myeloid, and lymphatic leukemias, of tumors derived from transplantation of the corresponding leukemias, and of in vitro cell lines derived from transplantable leukemia cells. We found that trisomy 15 was the most frequent aberration among the different types of leukemia blast cells after at least one in vivo transfer.

MATERIALS AND METHODS

Virus and animals.—The Rauscher virus complex was obtained both from cell-free extracts of hyperplastic leukemic spleens of BALB/c mice with erythroid leukemia and from cultured JLS-V5 cells that by their constitution produce large amounts of virus (*18*). The Rauscher virus complex consists of the helper independent component (R-MuLV) that induces a lymphatic leukemia and the replication-defective R-SFFV associated with erythroid leukemia. In some experiments mice were infected with the cloned lymphatic leukemia-inducing component (R-MuLV). This component was obtained by end-point dilution and infection of 3T3 cells (Stoof TJ: Unpublished data). BALB/c and DBA/2 mice 6–8 weeks old were used for infection and transformation studies. As a rule, tumors were serially transplanted into animals of the opposite sex from the one in which the leukemia had been induced. In most cases leukemia induction occurred in female mice and tumor transplantation occurred in male mice.

Induction and characterization of primary leukemias.—Erythroid leukemias were induced as previously described (*19*). The infection is always lethal within 30 days for BALB/c mice and within 45 days for DBA/2 mice. The leukemia blast

cells showed the features of proerythroblasts and basophilic erythroblasts (*20, 21*). Myeloid and lymphatic leukemias were induced by the injection of 0.5 ml of supernatants of subconfluent cultures of JLS-V5 cells or infected 3T3 cells harvested 24 hours after renewal of the culture fluid. After a latent period of about half a year, most of the animals became leukemic. The most frequent leukemia was lymphatic leukemia, but occasionally myeloid leukemia was induced. The myeloid leukemia was identified by the greenish color of the lymph nodes (chloroleukemia). The blast cells showed horseshoe-shaped nuclei and in their cytoplasm azurophilic granules stained peroxidase-positive. Organs affected by lymphatic leukemia appeared white, and the cells could be classified as T-cells and B-cells with the use of the binding of fluorescein-conjugated antibodies directed against theta antigens or against membrane-bound immunoglobulins (Nordic Immunological Laboratories, Tilburg, The Netherlands).

Transplantations of leukemia tissue.—Infiltrated hyperplastic spleens, livers, or lymph nodes from primary leukemic animals were removed, dissected in small pieces, and transplanted sc into syngeneic mice of the opposite sex from the mice in which the leukemia had been induced. A few weeks later, tumors appeared at the injection sites. We removed these tumors aseptically, and we obtained single cell suspensions by mincing the tissues and filtering them through nylon gauze. We used these cells suspensions 1) for serial tumor transplantation by injection of 5×10^6 cells sc, 2) for cytogenetic analysis, 3) for long-term in vitro culture in order to establish permanent cell lines, and 4) for morphologic characterization of these leukemia lines. Sometimes in erythroid leukemias, not all studies could be done satisfactorily on the first tumor due to simultaneous transfer of virus which shortens the life-span of the host mouse. In such instances, the analyses were done on the second or third tumor obtained by serial in vivo transplantation and/or on the derived permanent cell lines. In a few instances, serial cytogenetic analysis was done to study sequential chromosome changes during in vivo and in vitro passages.

Long-term cultures.—We initiated long-term cultures by placing about 2×10^6 tumor cells in petri dishes in RPMI-1640 medium or in Dulbecco's medium (Flow Laboratories Ltd., Irvine, Scotland) supplemented with 20% fetal calf serum. We incubated the mixture at 37°C in a humidified atmosphere of 5% CO_2 in air. When growth occurred, the cells were initially passaged once a week and later, depending on their growth rate, twice a week.

Cytogenetic analysis.—We analyzed tumor cells and the cell lines after 24 hours of culture by using methotrexate treatment as described previously for human leukemia cells (*22*). Colcemid instead of colchicine was used for mitotic arrest. The harvesting method was standard—hypotonic shock with 0.075 *M* KCl, three successive fixations in methanol:acetic acid (3:1), and spreads on dry slides. A few lymphoid tumors could not be cultured. To obtain metaphase plates, we gave mice bearing these tumors ip injections of 100 μg colchicine and removed the tumors after 1 and 4 hours for direct analysis.

All metaphases were analyzed with the use of banding techniques: R-banding with acridine orange and G-banding with trypsin-Giemsa staining. Karyotyping was done according to the recommendations of the Committee on Standardized Genetic Nomenclature for Mice (1972) (*23*) and the system proposed by Nesbitt and Francke (1973) (*24*).

Differentiation lineage.—We verified the differentiation lineage of the cell lines established from transplanted tumors by using different specific markers. Erythroid cell lines were cultured in a plasma clot assay (*25*) and tested for their ability to form benzidine-positive colonies after treatment with EP and/or DMSO (*26, 27*). Myeloid cell lines were identified by a number of properties described earlier (*17, 28*). Lymphatic cell lines were characterized by the presence of Thy 1 antigens (T-cells) or by the presence of immunoglobulins on their plasma membranes (B-cells).

Designation of the different leukemia cell lines.—This designation followed a code that summarized the cell line's origin, differentiation lineage, and the mouse strain from which it was derived, e.g., RED- (*R*auscher MuLV, *E*rythroid leukemia, *D*BA/2 mouse strain), followed by the number of sequential cell lines. In this study the beginning of a line is at the first transplant stage (T1). Tumors that originated from a transplant of the same primary leukemia tissue in different animals are indicated as clusters in the tables.

RESULTS

Primary Leukemias

Cytogenetic analysis of the erythroleukemic spleens and of enlarged lymph nodes appearing in the animals given injections of R-MuLV or of R-MuLV plus R-SFFV was done repeatedly. The karyotype of these cells was always found to be normal diploid without deviation (table 1). Many attempts at karyotyping the primary lymphoid leukemias with the use of short-term cultures failed to produce metaphase plates suitable for analysis. The few cells studied were also normal diploid.

Erythroleukemia Cell Lines

Twelve erythroleukemia cell lines were isolated at T1 after sc transplantation of spleen or liver cells from erythroleukemic mice. With the exception of RED-3, all tumors were serially transplanted, established as permanent in vitro cell lines, and kept frozen in liquid nitrogen. The origin of the cell lines and their differentiation characteristics are given in table 2. Results of cytogenetic analysis are given in table 3. RED-4, RED-5, and RED-6 and RED-7, RED-8,

TABLE 1.—*Cytogenetic analysis of Rauscher virus complex-induced primary leukemias*[a]

Mouse strain	Organ	Leukemia type	No. of cells analyzed
BALB/c	Spleen	Erythroid	200
DBA/2	Spleen	Erythroid	16
DBA/2	Spleen	Erythroid	20
BALB/c	Lymph node	Myeloid	20
BALB/c	Lymph node	Myeloid	30
BALB/c	Lymph node	Lymphoid	2

[a] In all instances, the karyotype was 40,XX.

and RED-9 are clusters, which means that they originated from the same leukemia tissue but that they developed first as subcutaneous tumors on different hosts. All cell lines except one (RED-12) were still able to form benzidine-positive colonies in plasma clot assays when stimulated with either EP or DMSO or both in combination. RED-12 proliferated in vitro as undifferentiated blast cells.

TABLE 2.—*Origin and differentiation response of the Rauscher virus complex-induced erythroid lines*

Cytogenetic analyses were done mainly at T1 and T2 or on the in vitro cell lines. More than 270 metaphases obtained from freshly harvested tumors were analyzed, and only one cell showed the karyotype of the host (40,XY in RED-7 T1); all others showed sex chromosomes consistent with those of the donor of the leukemia cells. An abnormal karyotype was found in all the erythroid lines studied. The most frequent abnormality observed was trisomy 15, either as isochromosome 15 or as an extra chromosome, which was found in 9 of the 11 lines. Trisomy 3 [either as iso(3) or +3] came a close second most frequent (eight times) and monosomy 6 a third most frequent (five times). Random additional aberrations were particularly frequent in the in vitro cell lines with many structural rearrangements (RED-1 and RED-9) and in the two lines that were mainly hypotetraploid (RED-6 and RED-11). In some of the lines many endoreduplications and tetraploid and octoploid mitotic cells were observed. Clonal progression was also very common (RED-4, RED-7, RED-10, RED-11, and RED-12).

From RED-12, 2×10^6 cells were transplanted at each in

				42,XX,+9,+11(20%)//
				43,XX,+9,+11,+17(20%)

[a] Animals were given injections of cell suspension from the same T3 tumor and inoculated with colchicine 1 and 4 hr before the T4 tumors were harvested.

vivo passage and cytogenetic analysis of the successive tumors was performed so that we could follow the chromosome evolution and the eventual increase in the tumor growth rate. In this experiment, the karyotype of the primary leukemia (erythroblastic spleen) was studied and was found to be normal diploid: 40,XX as always. The time required to obtain the first subcutaneous tumor with a diameter of approximately 2 cm was 62 days. The cell karyotypes at T1 were 40,XX(60%) and 41,XX,+15(40%). After 49 days the cells at T2 were harvested. The karyotype had become hyperdiploid with trisomies of chromosomes X, 3, 4, 9, 10, 14, 15, 16, 17, and 18. Subsequent transplants from T3, T4, and T5 were obtained after a delay of about 3 weeks after sc injection of 2×10^6 cells. Their karyotypes were essentially similar to the T2 karyotype. The T3, T4, and T5 transplants had, in addition, some structural rearrangements [t(4;14),10L+,17L+,Df(2)], random variation around the main karyotype in about 80% of the metaphases, and an increased percentage of tetraploid cells (25%).

Myeloid Lines

Three myeloid lines were studied (table 4). The karyotype and differentiation characteristics of the RMB-1 cell line have already been reported (*17*). The RMB-2 and RMB-3 lines constituted a cluster, meaning that they originated from the same chloroleukemia injected in 2 animals that developed tumors. RMB-2 could not be further transplanted, whereas RMB-3 was serially transplanted in the male syngeneic host and remained female diploid (40,XX) as did the original tissue. In contrast to the karyotypes of the erythroid lines, the karyotypes of the myeloid lines appeared stable: Clonal progression and random changes were not seen. The myeloid tumors also remained slow-growing, and 2–4 months were necessary for tumors to arise at the sc injection site.

Lymphoid Lines

One line induced in the DBA/2 mouse was serially transplanted and was also established as a permanent cell line in vitro (table 4). It showed membrane characteristics of T-cells (Thy 1 and Lyt 1 binding). The karyotype appeared very stable: 42,XX,+14,+15. Two other lines were induced in BALB/c mice. They were readily transplantable and very rapidly formed tumors on the host, but the tumor cells could not be cultured in vitro. Even short-term cultures for cytogenetic analysis failed. To obtain mitoses, we gave animals bearing tumors (T4 of RLB-2 line) injections of colchicine in vivo and harvested the tumors 1 and 4 hours after injection. In 1 animal the tumor had a female diploid karyotype: 40,XX. In the other animal the main karyotype showed trisomy of chromosome 11 with two sublines showing, in addition, trisomies 9 and 17.

DISCUSSION

The Rauscher virus complex consists of R-SFFV and a lymphatic leukemia helper virus (R-MuLV), which together induce an erythroid leukemia in 100% of infected susceptible mice (*21, 29*). When virus preparations are used from cell lines that by their constitution produce virus, the R-MuLV may predominate and infection results after a long latent period in lymphoid leukemia in most of the animals or in myeloid leukemia in a few animals. The same is true when cloned R-MuLV is used. For these reasons the number of erythroid leukemias analyzed surpasses the number of lymphoid and myeloid leukemias. In primary leukemias, only normal diploid numbers of chromosomes were found. In contrast, in tumors obtained after transplantation, diploid and aneuploid karyotypes were observed. Especially in the tumor obtained from transplanted erythroid leukemia tissue, there was a rapidly changing karyotype during in vivo and in vitro passages. However, in these abnormal leukemia karyotypes there was a nonrandom involvement of some chromosomes, particularly trisomy of #15 (11x) followed by trisomy of #3 (8x), then monosomy of #6, and trisomies or rearrangements in #14, 4, 8, 12, 16, and 17 and X. The myeloid lines were slow-growing, with a very stable karyotype, and RMB-3 with a 40,XX diploid karyotype has not yet been successfully established in vitro but is continuously passaged in vivo.

Despite their rapid growth in vivo, the lymphatic lines induced in BALB/c mice could not be maintained in vitro. They produced few, poorly spread metaphases with contracted, fuzzy chromosomes, not suitable for banding analysis, and reminded us of the metaphases usually obtained in cases of human acute lymphocytic leukemia.

Absence of host metaphases in the subcutaneous transplants tends to minimize the role of viral infection and induction of leukemia in host cells; clearly, there is continuous proliferation of leukemia cells from the donor.

The finding of a normal diploid karyotype in the different primary leukemias implies that although the virus causes hyperplasia of its target cells, it does not necessarily induce chromosome abnormalities. This diploid character of leukemia cells has already been reported by others for Rauscher and Friend leukemias with, however, the presence of cytogenetically abnormal cells in the late stage of the diseases (*30, 31*). The same diploid character of leukemia cells holds for infection of lymphoid target cells by Abelson and Moloney viruses (*32, 33*).

Our observations are in line with the concept that virally induced murine leukemias are "multiple-step" diseases (*34*). In the terminal phase of Rauscher virus-induced leukemias, the proliferating erythroblasts are infiltrating all hematopoietic organs, which increase dramatically in size. Most of these cells can proliferate in vitro only for a limited time (data not shown). Nevertheless, 11 of the 12 erythroblastic tissues transplanted in syngeneic hosts gave rise to transplantable leukemia cell lines. These cell lines were all aneuploid, which suggests that *a*) among the many diploid erythroblastic cells, a few develop chromosome aberrations and *b*) in vivo passaging selects for these cells which are presumably more tumorigenic or exhibit marked growth advantages.

However, as seen in the myeloid lines, permanently transformed tumor cells can be of diploid karyotype with no detectable chromosome aberrations, which indicates that chromosome changes are not a prerequisite for the induction of transformation or its maintenance.

Chromosome analysis of the erythroid tumor transplants demonstrates in all cases the presence of "stemlines" that suggest either clonal origin or in vivo selection in favor of cells carrying the same type of chromosome rearrangement. In erythroleukemia lines, clonal progression occurred rapidly (table 3, RED-4, RED-7, RED-10, RED-11, and RED-12).

Extensive chromosome rearrangements have also been reported in Friend virus-induced mouse erythroleukemia cell lines that had been maintained in vitro for long periods (*35*). The erythroleukemia cell lines RED-1, RED-6, and RED-9 that we studied after in vitro passaging were also characterized by many structural rearrangements involving, among others, chromosome 15. In contrast, RED-2 was very stable: The only deviation observed was the number of Y-chromosomes: 0 or 2 in a minority of cells.

The high specificity of trisomy 15 for T-cell lymphomas (*12-16, 33, 34*) is not supported by this study in which it was found in 9 of 11 erythroid lines: Frequently, it was the first and earliest change to appear in the leukemia karyotypes (table 3, RED-2, RED-3, RED-5, RED-7, RED-10, and RED-12). Analysis of proviral integration sites with the use of radioactively labeled copy DNA and the Southern blotting technique (*36*) showed that multiple and, in each tumor, different integration sites exist (data not shown). These results were not conclusive regarding preferential integration in a particular chromosome.

Our results stress the significant role played by trisomy of chromosome 15 in mouse cancers. In mouse leukemia, trisomy 15 could possibly occur preferentially to other karyotypic changes, as does trisomy of chromosome 8 in human myeloproliferative disorders. If, in addition, trisomy 15 leukemia cells have a much higher take in syngeneic host, they will overgrow the diploid (or non-trisomy 15) cells. The current method of in vivo passaging is probably selecting for trisomy 15 leukemia cells either from T-lymphoma or from another, e.g., erythroleukemia origin.

Induction of gp70-Specific Suppressor T-Cells in Mice Inoculated With Virus-Producing Tumor Cells[1,2,3]

Jeffrey A. Bluestone[4,5] *and* **Carlos Lopez**[4,6,7]

ABSTRACT—Inoculation of BALB/c mice with syngeneic, murine leukemia virus (MuLV)-producing (murine sarcoma virus-transformed) Balb/3T3 tumor cells resulted in diminution of alloreactivity as measured in the mixed leukocyte culture (MLC) reaction. Cells that suppressed this response were identified in the spleens of tumor-bearing mice 10–14 days after inoculation. The suppressor cells were adherent, radiosensitive T-lymphocytes of the Lyt 1^-, 2, 3^+ phenotype. Mice inoculated with Gross MuLV (G-MuLV)-producing tumor cells, but not those inoculated with a nonproducing subclone of the same tumor cells, developed suppressor T-cells. The T-cell-mediated suppression of the MLC could be augmented by the admixture of G-MuLV antigen, similar to that replicated by the tumor cell, but not by the admixture of a Rauscher-type MuLV antigen which lacked the cross-reactive, type-specific antigens of the G-MuLV. Furthermore, this augmented suppression could be abrogated by the addition of monoclonal anti-gp70 antibody. These findings indicated that antigen-specific suppressor T-cells were induced in response to leukemia virus antigen shed from and/or expressed on tumor cells and that the suppressive activity involved the specific recognition of the gp70 portion of the virus.—JNCI 1982; 69:953–959.

Suppressor cells have been shown to be a factor in the ability of a tumor to escape host antitumor responses (*1–3*) by inhibiting both nonspecific (*4, 5*) and specific (*6–8*) immune capacities. In several studies, suppressor T-cells were identified in MuSV-inoculated TBM and were reported to be antigen-specific (*7–10*). However, the precise nature of the antigen(s) responsible for triggering the suppression has not been determined.

We have recently identified suppressor T-cells induced in mice inoculated 10–14 days previously with MuSV-transformed tumor cells, which were capable of inhibiting alloreactivity in vitro (*11*). Suppressor T-cell induction was shown to be virus antigen-dependent inasmuch as subclones of the MuSV-transformed tumor cells not expressing the ecotropic virus failed to induce this early suppression.

In this report, we present further studies of the suppressor T-cells induced in mice inoculated with MuSV-transformed Balb/3T3 cells (11A-VP). Our studies indicate that the cells responsible for suppression were of the Lyt 1^-, 2, 3^+ phenotype and that these cells were induced by the major virus glycoprotein gp70, which was also expressed by these tumor cells.

MATERIALS AND METHODS

Mice.—BALB/c (H-2^d) and C57BL/6 (B6) (H-2^b) mice were obtained from Charles River Breeding Laboratories (North Wilmington, Mass.). All mice used were male, 6–12 weeks of age, and were kept under relatively clean conditions in the Sloan-Kettering Institute animal facilities.

Tumor cell lines.—The cell lines used in this study were tissue culture-grown Balb/3T3 cell lines previously transformed in the absence of virus production by a Moloney MuSV. The parent cell line, designated "11A," was provided by Dr. George Todaro (*12*), National Cancer Institute, Frederick, Md. These cells lacked detectable transplantation or Moloney serotype viral structural antigens (*13, 14*). During in vitro cultivation, the 11A cell line was found to have begun spontaneously expressing virus and virally coded cell surface antigens. Subsequent cloning of the cell line has resulted in the two sublines (11A-NP and 11A-VP) used in this study. Subline 11A-NP lacked any detectable viral antigens on the cell surface and closely resembled the nonproducer parental cell line 11A. Alternatively, subline 11A-VP was shown to be a G-MuLV VP cell by the methods discussed below.

Virus antigen preparation.—Clonal strains of R-MuLV was obtained commercially (Litton Bionetics, Kensington, Md.). The R-MuLV was propagated in BALB/c bone marrow cells (JLSV-9). AKR leukemia virus and G-MuLV preparations, propagated in Sc-1 cells, were provided by Dr. A. Pinter, Sloan-Kettering Institute. All virus preparations were double-band purified with the use of sucrose gradient zonal centrifugation (*15*) and diluted in PBS to a final concentration of 10^{10} particles/ml. Aliquots (1 ml) of each preparation were placed in 60-mm petri dishes, exposed to UV radiation (GE G8T5 lamp) for 15 minutes at a distance of 10 cm, and stored at −70°C prior to use.

Antisera and C.—Monoclonal anti-Thy 1.2 antiserum was provided by Dr. Ulrich Hämmerling, Sloan-Kettering Insti-

tute. This antiserum plus rabbit C specifically lysed 95% of BALB/c thymocytes at a dilution of 1:200 and reduced the T-cell mitogenic response to phytohemagglutinin (HA-16; Burroughs-Wellcome Co., Research Triangle Park, N.C.) by more than 90%. Antiserum directed against Lyt were obtained from Dr. E. A. Boyse, Sloan-Kettering Institute. The two antisera anti-Lyt 1.2 and anti-Lyt 2.2 were used in this study.

Several antivirus antibodies were also used in this study. Purified monoclonal anti-gp70 (35/56, 35/299, 42/94), anti-p30 (60/35, 35/270), and anti-p15(E) (42/114) were provided by Dr. Ulrich Hämmerling. These monoclonal antibodies have been described in detail elsewhere (*16*). In addition, hyperimmune anti-p30 and anti-p15(E) antisera were provided by Dr. A. Pinter.

Both prescreened rabbit C and guinea pig C were used at a dilution of 1:15. These preparations were shown to be cytotoxic for less than 10% of BALB/c spleen cells.

Characteristics of monoclonal antibodies.—Characteristics of the monoclonal antivirus antibodies used in this study are presented in table 1. In radioimmune precipitation assays, performed by Dr. P. O'Donnell, Sloan-Kettering Institute, antibodies 35/56, 42/94, and 35/299 were found to precipitate gp70 and recognize cell-associated MuLV G_{IX} antigen, whereas antibodies 60/35 and 35/270 precipitated p30 and antibody 42/114 precipitated p15(E) (*16*).

Removal of adherent spleen cells by Sephadex G-10.—Adherent spleen cells were removed by filtration through Sephadex G-10 columns (Pharmacia Fine Chemicals, Piscataway, N.J.) with the use of the method of Ly and Mishell (*17*) as modified by us (*18*).

Serologic detection of MuLV-related antigens on tumor cells.—The transformed cell lines were evaluated for the expression of MuLV antigens by two techniques: First, microcytotoxicity assays, with the use of polyvalent and monovalent anti-MuLV antisera, were performed by Dr. Albert DeLeo, Sloan-Kettering Institute, as described in (*19*). Second, absorption tests were performed by Dr. DeLeo to examine expression on the tumor cells of G_{IX} and GCSA (*20*), type-specific cell surface antigens specified by G-MuLV.

Tumor induction.—BALB/c mice were inoculated sc with 0.5×10^6 viable, VP or NP tumor cells in 0.1 ml PBS, dorsal into the deltopectoral girdle. Palpable, nonmetastasizing fibrosarcomas were detected at the site of inoculation 9–12 days PI. The tumors never spontaneously regressed and eventually caused the death of the mice 25–40 days PI.

MLC.—The preparation of mononuclear spleen cell suspensions and MLC conditions have been described (*11*). Suppressor cell function was assayed in a three-cell MLC in which 3×10^5 spleen cells from normal mice or TBM were added to an MLC between 3×10^5 syngeneic (BALB/c) responder and 3×10^5 allogeneic (B6) stimulator cells (1,500 rad of radiation).

Elimination of Lyt subclasses.—Spleen cells ($20\text{–}50 \times 10^6$/ml) were pelleted, washed, and resuspended in 1 ml of antiserum (diluted 1:20 for anti-Lyt 1.2 and 1:40 for anti-Lyt 2.2 antiserum). The suspension was incubated for 30 minutes at room temperature and washed. The packed cells were brought up in 1 ml of freshly thawed rabbit C (diluted 1:15) and incubated for 30 minutes at 37°C. Cells were washed three times, and viable counts were determined by trypan blue dye-exclusion analyses. Generally, anti-Lyt 1.2 antiserum plus C eliminated about 40% of the T-cells, whereas anti-Lyt 2.2 antiserum plus C eliminated about 25% of the splenic T-cells. All antisera were prepared and absorbed for removal of autoantibodies as described by Shen et al. (*21*).

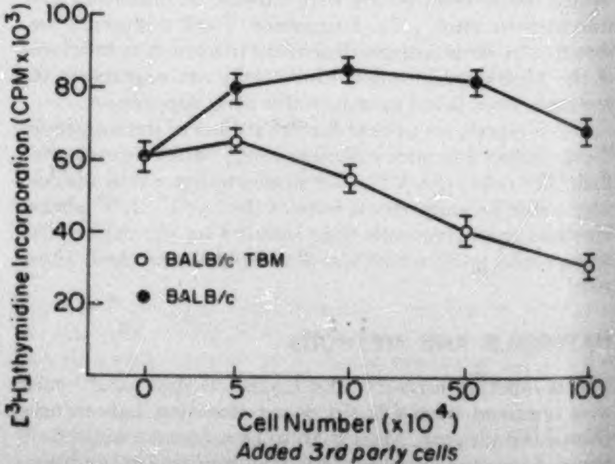
Statistical evaluation.—Mean values and standard errors were estimated from triplicate cultures. Significance was determined by a two-tailed Student's *t*-test.

RESULTS

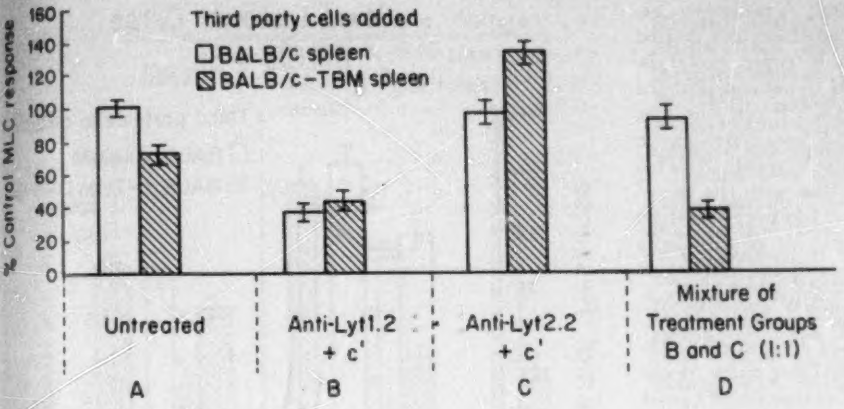
Induction of Suppressor Cells in 11A-VP TBM

In an earlier study, we showed that spleen cells isolated from BALB/c mice inoculated 10–14 days earlier with VP tumor cells had a depressed MLC response (*11*). Mice inoculated with a nonproducer subclone of these tumor cells failed to induce this early suppression. Cocultivation studies were undertaken here for confirmation that the low MLC responses were due to suppressor cells and for development of an assay system with which to characterize these cells.

The addition of increasing concentrations of spleen cells from TBM to an MLC between normal BALB/c (responder) and irradiated B6 (stimulator) cells resulted in the progressive depression of the response (text-fig. 1). In contrast, addition of up to 1×10^6 normal BALB/c spleen cells augmented the response. However, addition of more than 1×10^6 normal cells depressed alloreactivity. Removal of adherent cells from the normal BALB/c responder population abrogated the suppression found with high concentrations of added normal cells without diminishing the suppression caused by the addition of spleen cells from TBM (data not presented). Therefore, experiments to characterize the effectors of early suppression were done with the use of 3×10^5 (TBM or control BALB/c spleen) cells added to an MLC in which the adherent cells had been removed from the responder (BALB/c) population by filtration over Sephadex G-10 (*18*). Addition of 3×10^5 normal BALB/c spleen cells



TEXT-FIGURE 1.—Increasing concentrations of spleen cells from normal mice and from TBM were added to a normal MLC [BALB/c × $B6_{(irr)}$] for study of suppression in the three-cell assay.



TEXT-FIGURE 2.—Spleen cells from normal mice (*open bars*) and TBM (*cross-hatched bars*) were treated with anti-Lyt 1.2 or anti-Lyt 2.2 plus C for analysis of the phenotype of the suppressor cells. Treated and control spleen cells were evaluated for their capacity to suppress a normal MLC response [BALB/c × $B6_{\text{irrad}}$]. MLC responses are expressed as percent normal MLC response (BALB/c × $B6_{\text{irrad}}$ + BALB/c) ± SEM. *Panel A* refers to control untreated cells. *Panel B* depicts results with Lyt 1.2 antiserum plus C-treated cells. Such treatment reduced the normal control response, probably because of a decrease of responder cells. *Panel C* shows that elimination of Lyt 2^+ cells from TBM spleen cells eliminated suppression. *Panel D* presents data obtained by the mixture of equal numbers of Lyt 1.2 antiserum plus C and Lyt 2.2 antiserum plus C-treated spleen cells. Elimination of Lyt 1, 2, 3^+ cells did not diminish suppression.

to such an assay resulted in a 20–40% increase in response over the MLC without the added cells.

Cell Surface Markers of Suppressor Cells

We previously showed that suppressor cells induced 10–14 days PI with VP tumor cells were probably T-cells since they were γ-irradiation-sensitive, were absent in athymic nude mice, and could be eliminated with anti-Thy 1.2 plus C (*11*). Further studies were therefore done with the use of antisera against specific Lyt antigens to determine the subpopulation of T-cells involved (text-fig. 2). Spleen cells from normal mice and from TBM were treated with anti-Lyt 1.2 or anti-Lyt 2.2 antiserum plus C, and aliquots of the remaining viable cells were added to a normal MLC reaction. As stated previously, the addition of normal spleen cells can result in a 20–40% increase in MLC response. Treatment of spleen cells from TBM with anti-Lyt 2.2 antiserum plus C resulted in the complete abrogation of suppression (text-fig. 2) and some increase in MLC, whereas similar treatment of control spleen cells had no significant effect on the MLC response. Treatment of spleen cells from TBM with anti-Lyt 1.2 antiserum plus C did not eliminate the suppression of the MLC response. However, treatment of normal BALB/c spleen cells with anti-Lyt 1.2 antiserum plus C abrogated the 20–40% increase in response usually found with the addition of these cells to an MLC reaction. In retrospect, this observation indicated that if Lyt 1, 2, 3^+ cells were suppressive, treatment of TBM spleen cells with anti-Lyt 1.2 plus C would have abrogated the responder cells as well as suppressor cells and Lyt 1, 2, 3^+ suppressor cells would not have been recognized. This possibility was evaluated in experiments in which normal or TBM spleen cells treated with Lyt 1.2 antiserum plus C were reconstituted with an equal number of normal BALB/c spleen cells treated with Lyt 2.2 antiserum plus C. Clearly, normal BALB/c spleen cells treated with Lyt 1.2 antiserum plus C and then reconstituted with normal spleen cells treated with Lyt 2.2 antiserum plus C showed normal responses (text-fig. 2), indicating that the treatment of added normal cells with Lyt 1.2 antiserum plus C had depressed the response by reducing the number of responding cells. Reconstitution of Lyt 1.2 antiserum plus C-treated TBM spleen cells with Lyt 2.2 antiserum plus C-treated TBM spleen cells continued to show a depressed response (text-fig. 2).

Clearly, Lyt 1, 2, 3^+ cells, absent from this mixture, did not participate in suppression since their absence failed to diminish suppression. We therefore concluded that the T-cells responsible for the suppressed MLC responses in TBM were of the Lyt 1^-, 2, 3^+ phenotype.

Association of Viral Antigens With Tumor-Induced Hyporesponsiveness: In Vivo Studies

Although the parental tumor cell line (11A) had been a virus nonproducer (*12*), it spontaneously began producing

TABLE 1.—*Characteristics of monoclonal antibody products from hybridoma cell lines*

Monoclonal antibody	Antigen specificity	Characteristics and distribution of the antigenic specificity in murine oncoviruses	G-MuLV-AKR leukemia virus	FMR
35/299	gp70	Type-specific antigen: Endogenous, ecotropic MuLV	+	−
35/56	gp70	Type-specific antigen: Endogenous, ecotropic MuLV (G_{IX}^+)	+	−
42/94	gp70	Type-specific antigen: Endogenous, ecotropic MuLV (Gross passage A-negative)	−/+	−

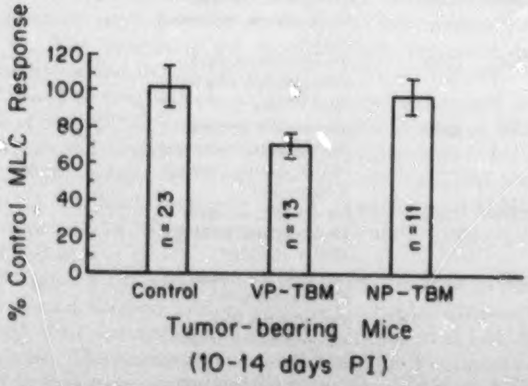
60/35	p30	Group-specific antigen: Fv-1 tropism N^+, B^-; endogenous and exogenous, ecotropic MuLV	+	+
42/114	p15(E)	Group-specific antigen: Endogenous and exogenous, ecotropic MuLV	+	+

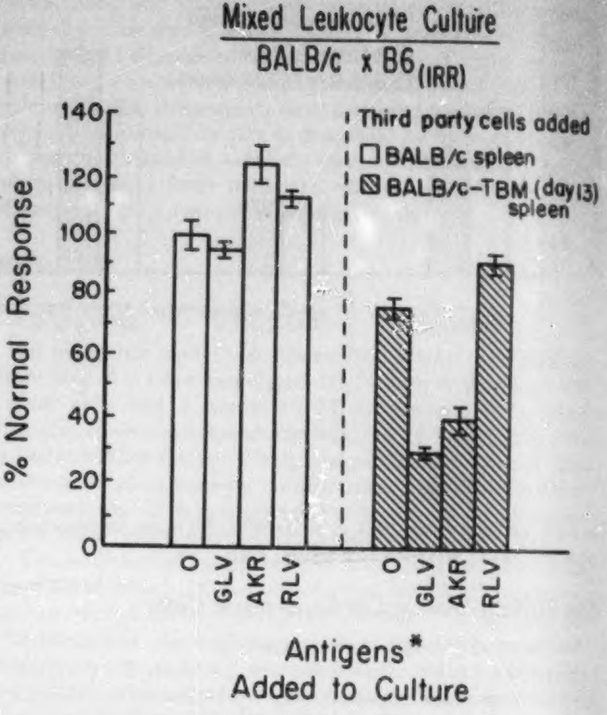
virus during the course of in vitro passage. A microcytotoxicity assay was used to show that one subclone (designated "11A-VP") of these cells produced a B-tropic, ecotropic virus and expressed gp70 and p30 viral structural proteins on its cell surface. In addition, the 11A-VP cell line was shown to express G_{IX} antigen and GCSA, two type-specific cell surface antigens specified by G-MuLV (table 1). This cell line has been extensively characterized with the use of the monoclonal anti-gp70 antibodies and has been shown to be expressing serologically detected proteins of the Gross serotype. These results suggested that the cell line had begun expressing an endogenous Gross-type retrovirus. In contrast, a second such clone was shown to lack demonstrable evidence of MuLV production and was thus designated "11A-NP." Our earlier study showed that BALB/c mice inoculated with the 11A-NP clone of MuLV-transformed tumor cells failed to induce the T-cell-mediated suppression. A compendium of mice inoculated with 11A-NP and 11A-VP is presented in text-figure 3. Only mice inoculated with 11A-VP demonstrated suppressor cell activity 10–14 days PI (mean RR=70±6%, $P<0.01$).

Since the T-cell suppression might have been caused by a systemic MuLV viremia, DEAE–dextran-treated Sc-1 monolayers were cocultivated with spleen cells from TBM, passaged blindly three times, and evaluated with the use of anti-p30 antiserum for the presence of an oncovirus by indirect immunofluorescence. The Sc-1 cells are very susceptible to ecotropic virus infection and successfully detected the MuLV infection of 11A-VP tumor cells excised from these mice. In three experiments, we failed to detect virus in the spleens of TBM, indicating that an MuLV viremia was probably not present and that viral structural antigens, expressed by or released from the tumor cells, were probably responsible for inducing the suppressor T-cells.

Augmentation of Suppressor T-Cell Activity in Vitro With Viral Antigens



TEXT-FIGURE 3.—Role of virus in the induction of suppressor T-cells. The MLC response of a compendium of mice inoculated with either VP or NP tumor cells (10-14 days PI) is presented. Suppressor T cells were identified only in mice inoculated with VP tumor cells ($P<0.005$) (*11*).



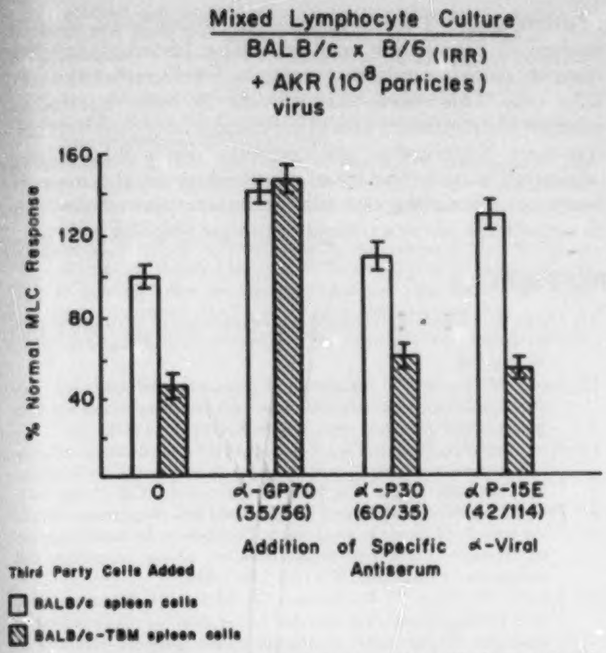
* All antigens UV-irradiated and adjusted to 10^8 particles/10 λ

TEXT-FIGURE 4.—Augmentation of suppressor cell activity by addition of specific viral antigens. Spleen cells from normal BALB/c and BALB/c mice inoculated with syngeneic VP tumor cells were added to a normal allogeneic MLC. The effects of the addition of G-MuLV–AKR leukemia virus antigen, R-MuLV antigen, or PBS without antigen were compared. Only the addition of G-MuLV–AKR leukemia virus antigen enhanced the suppressive activity of the suppressive T-cells ($P<0.001$). Neither antigen had a significant effect on the response of normal spleen cells in the third-party MLC ($P>0.1$).

Experiments were undertaken to evaluate further the role of viral antigens in the induction of suppressor T-cells. UV-irradiated preparations of virus (10^8 virus particles) were added to normal MLC reactions [BALB/c × $B6_{(IRR)}$] to which had been added either normal BALB/c mouse spleen cells or TBM spleen cells. G-MuLV and AKR leukemia virus, both B-tropic, ecotropic viruses that share type-specific antigens with the virus shed by the 11A-VP tumor cells, had no significant effect on the response of normal cells. When added to an MLC reaction containing suppressor T-cells from a TBM, both G-MuLV and AKR leukemia virus antigen preparations significantly augmented suppression from an RR of 76% to 31 and 41%, respectively ($P<0.001$; text-fig. 4). In contrast, addition of R-MuLV, a member of the FMR^+ group of MuLV that does not share type-specific antigens with the virus shed by the 11A-VP tumor cells, resulted in no augmentation of the suppression (text-fig. 4). In other experiments, virus preparations that had been disrupted by repeated freezing and thawing gave similar results (data not shown).

Identification of Specific Viral Antigen Responsible for Augmenting Suppressor T-Cell Function

Our results suggested that a specific viral antigen, ex-



TEXT-FIGURE 5.—Blocking of suppressor cell activity with the use of antisera directed against specific viral structural proteins. Spleen cells from normal mice and from TBM were added in conjunction with UV-inactivated AKR leukemia virus (10^8 particles) to a normal third-party MLC. Several antisera directed against specific viral structural proteins were added to the assay. Only the antiserum directed against the gp70 glycoprotein present on G-MuLV–AKR leukemia virus was able to block suppressor cell activity ($P<0.005$). GLV=G-MuLV; AKR=AKR leukemia virus; RLV=R-MuLV; λ=μl.

pressed on G-MuLV but not on FMR$^+$-type MuLV, triggered suppressor cell activity in vitro. If so, then addition of specific antibodies directed at these structural antigen(s) might block the augmented suppression of the MLC reaction induced by viral antigen. Text-figure 5 illustrates the effect of monoclonal antiviral antibodies on normal and suppressed MLC responses. Monoclonal anti-p30 antibody (60/35) and monoclonal anti-p15(E) antibody (42/114) had no significant effect on either the normal or the suppressed MLC responses, even in experiments in which disrupted virus preparations were used. Only monoclonal antibodies directed against gp70, the glycoprotein present on G-MuLV–AKR leukemia virus, were able to block AKR leukemia virus antigen-augmented suppression (RR=147%; $P<0.005$). Several additional monoclonal antibodies directed against gp70 (35/299, 42/94) and monovalent hyperimmune sera yielded similar results (data not shown).

TABLE 2.—*Abrogation of suppressor T-cell activity with anti-gp70 antibodies*

Responders	Stimulators	Anti-gp70	Mean ± SE	RR, %
BALB/c	BALB/c	–	2,047±142	—
BALB/c TBM	BALB/c TBM	–	2,438±263	—

BALB/c TBM	B6	+	52,433±2,518	181[b]

[a] $P<0.05$.
[b] $P<0.001$.

Studies were also done to evaluate the effect of monoclonal anti-gp70 antibodies on the capacity of spleen cells from normal mice or TBM to respond in a one-way MLC in the absence of additional AKR leukemia virus antigen (table 2). Once again, the anti-gp70 antibodies were able to significantly augment the lymphoproliferative response of spleen cells from TBM (RR=181%; $P<0.05$). In contrast, there was no significant augmentation by anti-gp70 of the normal MLC in the absence of additional viral antigen.

DISCUSSION

Antigen-specific suppressor T-cells have been identified in a number of model systems with the use of synthetic antigens (*22, 23*). Administration of certain simple antigens, such as GAT or GT, and some more complex antigens under certain conditions, has been shown to lead to the almost exclusive development of suppressor T-cells (*24*). Induction of such responses has allowed the evaluation of the specific determinants on the antigen necessary for induction, the genetics of the host immune response that dictates this response, and the cellular interactions required for this response to be expressed (*22, 23*). Tumors have also been shown to activate suppressor cells, often T-cells, operative in a variety of in vivo and in vitro assay systems (*3, 7, 8*). However, although the study of the well-defined antigens' capacity to induce suppressor T-cells has led to a much better understanding of this phenomenon, little has been learned about suppressor T-cells induced naturally, e.g., by a syngeneic tumor. The model system that we have described clearly offers the opportunity to study such a natural situation. The MuSV-transformed Balb/3T3 cells spontaneously began to produce a Gross-like MuLV during passage in culture, and subclones with and without virus expression have been selected and used. These cells have subsequently been evaluated regularly to assure that they remain either virus producers or not, since our studies have clearly shown that expression of viral antigens by the tumor cells was required for the induction of T-suppressor cells. As was found with the T-suppressor cells induced by synthetic antigens (*22*), the cells induced by the clone of VP tumor cells were of the Lyt 1^-, 2, 3^+ phenotype.

The absolute requirement for virus antigen on the tumor cells for the induction of suppressor T-cells prompted us to develop an in vitro assay system to further evaluate this association. Adding UV-inactivated, band-purified virus to MLC containing suppressor T-cells augmented suppression significantly. The specificity of this augmentation was impressive; MuLV that shared type-specific antigens with the virus produced by the tumor cells clearly augmented suppression, whereas a closely related R-MuLV or M-MuLV (data not shown), both of which belong to the FMR$^+$ group and therefore do not share type-specific antigens, failed to augment suppression. Neither viral antigen preparation induced suppression of normal BALB/c responses. These studies suggest that the type-specific, Gross-like viral antigens on the tumor cells were responsible for inducing the suppressor T-cells and that sensitized cells were triggered in vitro by the addition of the specific antigen.

Since soluble viral structural antigens were not available, the specific structural antigen of the virus responsible for the induction of suppression was delineated with the help of a series of monoclonal antibodies to G-MuLV-AKR leukemia virus proteins. When added to MLC containing T-suppressor cells and augmenting antigen only antiserum directed against the major cell surface glycoprotein gp70 blocked the induction of suppression. Thus the amplification of suppression in vitro and, perhaps, the induction of suppression in vivo were mediated by gp70. This is an interesting observation since gp70 has been found in bone marrow cells of several mouse strains tested (including BALB/c (*25*) and may indicate that the mice had been previously exposed to the gp70 molecule. Thus inoculation of tumor cells expressing the same viral antigen might result in amplification of suppressor cells or their suppressive function.

These observations of gp70-induced immunosuppression are clearly different from those of Mathes et al. (*26*), who showed suppression of concanavalin A-induced lymphocyte proliferation by p15 of feline leukemia virus. In the Mathes study, sensitization to the viral antigen did not appear to be a requirement, whereas in our study sensitization was required. In addition, anti-15E failed to inhibit the immunosuppression induced by disrupted virus particles, clearly indicating that this viral polypeptide was not required for this function.

Of great interest was the finding that two monoclonal anti-gp70's were able to augment MLC reactivity of spleen cells from TBM even in the absence of additional viral antigens. These results suggest that viral antigens, perhaps expressed by activated normal spleen cells (*27*) or shed by the tumor cells and processed by TBM host antigen-presenting cells, were present in the spleen cell suspensions. Since gp70 antigen is present in large quantities on the surface of the tumor cells, it is reasonable to assume that the antigen might have been shed and be present in the spleens of TBM and therefore carried over to the MLC. The anti-gp70 antibodies might interact with these antigen-presenting cells to prevent the induction of suppression. Preliminary experiments showed that anti-gp70 and C abrogated the gp70-augmentable function of suppressor T-cells, suggesting that this treatment might have eliminated an antigen-bearing spleen cell population. However, in several experiments treatment of spleen cells with anti-gp70 plus C had no effect on the response of these cells in the absence of additional antigen, perhaps due to a relatively low expression of the viral antigen on the spleen cells (data not shown). More extensive studies will be required to delineate these cellular interactions.

Finally, it should be reemphasized that the model of immunoregulation described in this study used a naturally occurring cell surface-associated viral antigen. Preliminary studies suggest that, like T-cell-mediated cytotoxicity of virus-infected cells (*28*), our suppressor T-cells are also genetically restricted (Bluestone JA, Lopez C: Manuscript in preparation). This may mean that presentation of gp70 antigen in conjunction with self-major histocompatibility complex antigen results in suppressor T-cells rather than T-killer cells. This system may provide the tools required to examine the regulatory arm of genetically restricted immune responses. Experiments are currently under way in our laboratory to examine these relationships in the hope of better understanding the cellular interactions involved in the regulation of the antitumor immune response.

Carcinogenicity Test of Acetoxime in MRC-Wistar Rats[1,2,3]

Sidney S. Mirvish,[4] Shahrokh Salmasi,[4] *and* **Richard G. Runge**[4,5]

ABSTRACT—Acetoxime was tested for carcinogenicity by chronic administration in the drinking water to male and female outbred MRC-Wistar rats. The dose of 1.0 g/liter was administered 5 days/week for 18 months (total dose, 6.2–7.0 g/rat). The test compound induced benign hepatocellular adenomas in 80% of the males but did not produce tumors in the females. This is the first report that oximes, which are fairly widely used in industry, are tumorigenic.—JNCI 1982; 69:961–962.

We previously tested a series of nitrosamides and related compounds for carcinogenicity in MRC-Wistar rats, mostly by administration in the drinking water (*1–4*). In continuation of this series, we report here a carcinogenicity test on acetoxime [acetone oxime, $(CH_3)_2C{=}NOH$] given in the drinking water. This compound was tested because of the resemblance of its *C*-nitroso tautomer to the carcinogen dimethylnitrosamine. We made this comparison although the generally accepted mechanism of nitrosamine activation (*1*) could not apply to the activation of acetoxime, which could not lose N_2 to generate a carbonium ion: $(CH_3)_2C{=}NOH \rightleftharpoons (CH_3)_2CHN{=}O$, compare to $(CH_3)_2N{-}N{=}O$.

MATERIALS AND METHODS

Acetoxime (Aldrich Chemical Co., Milwaukee, Wis.) was recrystallized twice from hot methanol (cooled to −20°C) to yield white crystals, mp 59.5–61.5°C (literature mp, 61°C). Analysis indicated: *a*) calculated: C, 49.3; H, 9.65; and N, 19.2% and *b*) found: C, 49.1; H, 9.88; and N, 19.3%. Solutions in water were stable for 1 day at 22°C and for 3 days at 4°C, as determined by their UV absorption at 195 nm.

Outbred MRC (Medical Research Council) Wistar rats from the breeding colony of The Eppley Institute were maintained 4 or 5/cage on Wayne Lab Blox pellets (Allied Mills, Inc., Chicago, Ill.) and were kept in the same room. The treated and untreated groups were started 8 months apart, because the untreated rats also served as controls for other treated groups not reported here. Acetoxime was weighed out twice weekly in a ventilated glove box and dissolved in distilled water. The solutions were stored at 6°C for not more than 2 days. Rats were given the test solution as drinking water (20 ml/rat/day) in brown bottles at 1–3 p.m. 5 days/week. Tap water was given when the compounds were not being administered and to the untreated rats. Treatment was started on rats from 8 to 10 weeks of age.

For selected cages, the rate of consumption of test solution per cage was measured over 24-hour periods every month. The rats were weighed monthly and maintained until they were moribund or died. After complete necropsies, organs were fixed in 10% buffered Formalin and sections were prepared of the principal organs and apparent tumors, stained with hematoxylin and eosin, and examined. For each organ, the incidence of tumor-bearing animals was compared with that for the untreated controls of the same sex by the use of the life table method (*2*), which is based on the number of rats at risk when each tumor develops. The acute LD_{50} was determined as before (*3*) after ip injection of test compound solutions in distilled water. The 7-day survival was recorded.

RESULTS

The acute LD_{50} of acetoxime was 840 mg/kg. Tables 1 and 2 show the results of the carcinogenicity test. Mean body weights reached maximum values of 650 g for the male and 400 g for the female untreated rats. The groups receiving acetoxime showed body weight curves similar to those of the controls but achieved maximum mean body weights of only 520 g for the males and 320 g for the females. In the following descriptions, mean survival periods (in wk) for tumors at each site are given *in parentheses*.

Untreated controls.—The males had a 43% tumor incidence at all sites. The females had incidences of 50% for pituitary adenomas (95 wk) and 30% for mammary gland tumors [2 adenocarcinomas and 4 fibroadenomas (105 wk)]. No liver tumors were observed. These results are similar to those for previous untreated groups of Eppley Institute MRC-Wistar rats (*3*).

Acetoxime.—Liver tumors were present, chiefly in the male rats [80% incidence (93 wk)] but also in the females [17% incidence (111 wk)]. For males only, the liver tumor incidence was significantly greater than the 0% incidence in the controls. All rats with liver tumors had hepatocellular adenomas, mostly 1–4 cm in diameter. These were composed of circumscribed masses of cells, having abundant cytoplasm and small, round nuclei. All these tumors had benign histologic criteria despite occasional differences in nuclear size, except in 1 male rat in which focal malignant degeneration was noted. Three rats (including 2 males) had liver hemangiomas in addition to the adenomas.

The male rats had a 20% incidence of squamous cell papillomas of the forestomach (98 wk), but this was not significantly raised from the control incidence of 0%. In the females, the incidences of pituitary adenomas [19% (83 wk)]

[b] ≤2 tumors/site.

and adrenal tumors [25%, mostly pheochromocytomas (108 wk)] were not significantly different from those in the controls. Hence acetoxime was a potent liver tumorigen in the male rats but was not significantly tumorigenic in the females.

DISCUSSION

The induction of benign hepatocellular adenomas by acetoxime is the first report of the tumorigenicity of oximes. The greater incidence in male rats is characteristic of several liver carcinogens, e.g., 4-*N*-dimethylaminoazobenzene (*4*). Previous research on the toxicology of oximes was connected with their ability to reactivate cholinesterase after animals were poisoned with organophosphorus compounds (*5, 6*). The LD_{50} of acetoxime was reported to be 4,000 mg/kg in mice (*5*), which is five times higher than what we observed in rats. The related compounds hydroxylamine (NH_2OH) and hydroxyurea ($NH_2 \cdot CO \cdot NHOH$) were not carcinogenic to mice (*7*). Aromatic hydroxamic acids ($ArNHO \cdot COR$),[6] such as *N*-acetoxy-2-aminofluorene, are strong carcinogens (*8*). Several O-acyl hydroxamic acids ($RCO \cdot NHO \cdot COR'$), but not the corresponding hydroxamic acids ($RCO \cdot NHOH$), were mutagenic to bacteria, possibly because they rearranged to form isocyanates (*9*).

The tumorigenicity of acetoxime is important because oximes are rather widely used in industry. Cyclohexanone oxime is produced (1.2×10^9 lb/yr) in situ as an intermediate in the synthesis of caprolactam, used to manufacture nylon. About 3×10^6 pounds/year of oximes, including methyl ethyl ketone oxime (2-pentanone oxime), butyraldehyde oxime, and cyclohexanone oxime, are used as antiskinning agents in paints and coatings, in which they constitute 0.1–0.4% of the total weight. A mixture of hydroxy-oximes is marketed for the solvent extraction of copper. Oximes are also used by organic chemists as derivatives of aldehydes and ketones.

A possible mechanism for acetoxime activation involves oxidation to 2-nitropropane: $(CH_3)_2C{=}NOH + O \rightarrow (CH_3)_2CHNO_2$. This last compound was reported (*10*) to induce hepatocellular carcinomas in 100% incidence when administered by inhalation (207 ppm for 6 mo, 7 hr/day, 5 days/wk). No tumors were induced by exposure to 25 ppm of the compound. A later test (*11*) also failed to induce tumors with 25 ppm 2-nitropropane.

β-Cyclodextrin: Promoting Effect on the Development of Renal Tubular Cell Tumors in Rats Treated With *N*-Ethyl-*N*-hydroxyethylnitrosamine[1]

Yoshio Hiasa,[2] **Masato Ohshima,**[2] **Yoshiteru Kitahori,**[2] **Noboru Konishi,**[2] **Toyohisa Fujita,**[2] *and* **Takashi Yuasa**[2,3]

ABSTRACT—Injection (sc) of β-cyclodextrin (β-C) increased the number and size of renal tubular cell tumors in inbred Wistar (W) rats treated with 1,000 ppm of *N*-ethyl-*N*-hydroxyethylnitrosamine (EHEN). The incidence of renal tumors at the end of the 32-week experiment was 50% in rats treated with 1,000 ppm EHEN for 2 weeks and 100% in rats treated with 1,000 ppm EHEN for 2 weeks and then given daily sc injections of β-C for 1 week. The incidence of renal tumors more than 3 mm in diameter was 70% in rats treated with 1,000 ppm EHEN before β-C but 0% in rats treated with EHEN alone. In addition, β-C promoted the development of renal tumors in rats treated with 500 ppm EHEN, which is a subthreshold dose for renal tubular cell tumorigenesis. These results show that β-C promotes EHEN-induced renal tubular cell tumorigenesis.—JNCI 1982; 69:963–967.

Since Berenblum (*1*) in 1941 discovered the promoting property of croton oil in skin carcinogenesis, many investigators have reported on promotion of chemical carcinogenesis (*2–21*). Croton oil was considered to be the most effective promoter and was initially judged to be noncarcinogenic (*1–6*). However, since a high incidence of skin tumors was observed in mice treated with croton oil alone, croton oil was concluded to be not merely a promoter but also an initiator of tumor formation. Boutwell et al. (*22*) and Roe (*23*) reported that croton oil is a weak carcinogen and a strong promoter.

Recently, there have been reports about promoting agents in the liver (*7–12*), lung (*13*), intestine (*14, 15*), and urinary bladder (*16–21*). However, there are few reports about promoters of renal tubular cell tumorigenesis (*24–29*). β-C is a nephrotoxic agent and is not a carcinogen (*30, 31*).

EHEN is a strong carcinogen in the rat kidney, where it induces only renal tubular cell tumors. The dose response in rats to EHEN in renal tubular cell tumorigenesis has been reported (*32*).

In the present work we tested whether β-C is a promoter of EHEN-induced renal tubular cell tumorigenesis in rats.

MATERIALS AND METHODS

Chemicals and diet.—EHEN was purchased from Nakarai Chemical Co., Kyoto, Japan, and was added to the basal diet (*33*) at a concentration of 1,000 ppm for groups 1 and 3 and 500 ppm for groups 2 and 4 for the first 2 weeks. β-C was purchased from Nakarai Chemical Co., Kyoto, and was injected sc at a dose of 45 mg/100 g body weight once a day for 7 days in week 3 of the experiment. Commercial diet (Oriental M) was purchased from Oriental Kobo Co., Osaka, Japan, and given to all rats for 30 weeks from week 3 to week 32.

Animals.—A total of 120 male W rats (Kitayama Labes Animal Co., Kyoto) 6 weeks old and weighing 150–170 g were divided into 6 groups of 20 rats each. These groups received the following diets and treatments: group 1, 1,000 ppm EHEN in basal diet; group 2, 500 ppm EHEN in basal diet; group 3, 1,000 ppm EHEN in basal diet and β-C; group 4, 500 ppm EHEN in basal diet and β-C; group 5, basal diet and β-C; and group 6, basal diet. The experimental design is shown in text-figure 1.

The animals were housed in wire cages in an air-conditioned room at 24°C and weighed weekly. Two rats in group 1 and 1 rat in group 3 died of pneumonia, and 2 rats in group 3 died of pulmonary hemorrhage and acute nephrosis due to β-C before the end of the experiment and were not included in effective numbers. Animals that survived for 32 weeks were killed with ether after food was withheld for 16 hours. Their kidneys were weighed, and the number and the diameters of the tumors on the surfaces of the kidneys were determined macroscopically. Serial cross sections of the right kidneys and serial horizontal sections of the left kidneys were embedded in paraffin. The number of tumors was also counted microscopically in serial sections and compared with that determined macroscopically. Other organs that appeared grossly abnormal were also examined histologically.

RESULTS

Body and kidney weights.—The mean weights of the body and kidneys in each group are shown in table 1. The mean final body weights in different groups were not significantly different. The right kidneys were significantly larger in group 2 than in group 4 and smaller than those in groups 1 and 5. In group 3, the weights of the right kidneys varied between 1.42 and 2.48 g except for one kidney with a large renal tubular cell tumor that weighed 8.93 g.

Incidences of renal tumors.—The incidences of renal tumors in the groups are shown in table 2. The sizes of the renal tumors shown in table 2 are diameters of the largest tumor in either kidney. In group 1, there were 12 renal tumors in 9 (50%) of 18 rats; these tumors were small (<3 mm in

TEXT-FIGURE 1.—Experimental design.

diameter). In group 3, there were 32 renal tumors. Of the 17 rats in group 3, all had tumors, 15 had renal tumors in both kidneys, and 12 had renal tumors of more than 3 mm in diameter. In group 4, there were 8 renal tumors all less than 3 mm in diameter in 6 (30%) of 20 rats. No renal tumors were found in group 2, 5, or 6. Two of 12 renal tumors in group 1, 5 of 32 renal tumors in group 3, and 1 of 8 renal tumors in group 4 were clear cell tumors. These clear cell tumors were small (<3 mm in diameter). Other renal tumors were dark cell tumors.

Macroscopic findings.—Most renal tumors in groups 1, 3, and 4 were round and were present in the cortex. A few tumors were in the medulla but not in the pelvis. These tumors were yellowish, and there was a clear border between the tumor and surrounding nontumorous tissue. A section of a large renal tumor showed necrotic and hemorrhagic changes in the central area (fig. 1).

Microscopic findings.—Histologically, the renal tumors were composed of tubular cords or papillary structures and may have been cystic. Tumors were classified into two types, dark and clear cell tumors. The cells in dark cell tumors had a large round nucleus with light nucleoplasm and abundant light or dark basophilic cytoplasm (fig. 2). The cells in clear cell tumors had a small round nucleus and abundant clear cytoplasm (fig. 3). The cells in small and large renal tumors did not differ morphologically. Hemorrhage and necrosis were seen in the central areas of large renal tumors. There was no invasive growth or metastasis of renal tumor in any rats.

Microscopic findings in nontumorous areas of the kidneys.—Histologic findings in nontumorous areas of the kidneys of each group are summarized in table 3. Dark cell dysplasias were composed of cells similar to those of dark cell tumors (fig. 4A), and clear cell dysplasias were composed of cells similar to those of clear cell tumors (fig. 4B). These dysplasias were composed of tubular structures. Dysplasia of the kidney was seen in 13 of 18 rats in group 1, in all rats in group 3, and in 10 of 20 rats in group 4. Slight cystic dilatation of tubules, tubular casts, and interstitial fibrosis were seen focally in the kidneys of a few rats treated with β-C.

Tumors in other organs.—Two of 18 rats in group 1 and 2 of 20 rats in group 3 had hepatocellular carcinomas. There were no hepatocellular carcinomas in other groups.

DISCUSSION

Renal tubular cell tumors were induced by week 32 in all 17 rats treated with 1,000 ppm of EHEN for 2 weeks and

TABLE 1.—*Mean body and kidney weights of rats treated with EHEN and β-C*[a]

Experimental group (ppm)	Effective No. of rats	Final body weight, g	Right kidney weight, g (% of body weight)	Left kidney weight, g (% of body weight)
1. EHEN (1,000)	18	561	2.0±0.3[b] (0.36)	2.0±0.2[b] (0.36)
2. EHEN (500)	20	626	1.7±0.4 (0.27)	1.7±0.4 (0.27)
3. EHEN (1,000)+β-C	17	618	2.8±2.3 (0.45)	2.0±0.5 (0.32)

then given sc injections of 45 mg β-C/100 g body weight daily for 7 days. Twelve of these 17 rats had kidney tumors of more than 3 mm in diameter. Treatment with 1,000 ppm of EHEN alone for 2 weeks induced renal tubular cell tumors in 9 of 18 rats by week 40, as reported previously (*32*), but these tumors were less than 3 mm in diameter. Injection (sc) of 45 mg of β-C/100 g body weight daily for 7 days alone did not induce any tumors or any remarkable histologic changes in the kidney by week 32. β-C is a nephrotoxin that induces polyuria and decreases the activities of some enzymes in the proximal convoluted tubules (*30, 31*). β-C induces degeneration and necrosis of the epithelium in the proximal convoluted tubules (30). In the present study these histologic changes induced in the kidneys by daily sc injections of 45 mg β-C/100 g body weight for 7 days had almost disappeared by week 32, but this treatment enhanced the development of renal tubular cell tumors but not of tumors in other organs in rats treated with 1,000 ppm EHEN. Thus the histologic changes induced by β-C in the kidneys may enhance the development of renal tubular cell tumors in rats treated with 1,000 ppm EHEN.

Renal tubular cell tumors were induced by week 32 in 6 of 20 rats fed diets containing 500 ppm of EHEN for 2 weeks and then given sc injections of 45 mg β-C/100 g body weight daily for 7 days. A dose of 500 ppm EHEN in the diet for 2 weeks was subthreshold for renal tumorigenesis, as reported previously (32). No renal tubular cell tumors were induced by week 32 in rats fed diets containing 500 ppm EHEN alone for 2 weeks, and there were few histologic changes in the kidneys by week 32 among rats treated with 500 ppm EHEN for 2 weeks. Thus the fact that treatment with β-C after this subcarcinogenic dose of EHEN induced tumors in 6 of 20 rats confirms the theory that β-C is a promoter in EHEN-induced renal tubular cell tumorigenesis.

There are a few reports on the effects of various compounds on the development of renal tumors in rats treated with DMN (*25-28, 32*), streptozotocin (*29, 34*), and EHEN (*24*). NDPS (*27, 29*) and citrinin (*28*) enhanced the development of renal tubular cell tumors in rats treated with DMN. NDPS and citrinin induced interstitial nephritis following degeneration of the proximal convoluted tubules (*27-29*). However, β-C is a stronger promoter than NDPS or citrinin in renal tubular cell tumorigenesis, possibly because it directly injures the proximal convoluted tubular epithelium. Lead acetate is also a strong promoter in EHEN-induced tumorigenesis (*24*) and is a weak carcinogen (*35-38*). Lead acetate, like β-C, injures the proximal convoluted tubules (*39, 41*). Thus prolonged or temporary injury of the proximal convoluted tubules may enhance or promote the development of renal tubular cell tumors in rats treated with a chemical carcinogen.

The promoting effect of 12-*O*-tetradecanonylphorbol 13-acetate is reported to be due to changes in the cell membrane (*42*). Changes in the cell membrane of the proximal convoluted tubular cells induced by β-C may explain the promoting effect of this compound on induction of renal tubular cell tumors by EHEN.

Further studies are required on changes induced by β-C in the cell membrane. DMN induced both renal tubular cell tumors and nephroblastomas in rats, the incidence of the nephroblastomas being higher (*33*). Streptozotocin induced renal tubular cell tumors without nephroblastomas in rats, but these renal tubular cell tumors took a long time to develop (*34*). Inasmuch as EHEN, which also induces only renal tubular cell tumors, induces tumors more rapidly than streptozotocin in rats, EHEN is a better initiator for use in tests on promoters of renal tubular cell tumorigenesis.

Some renal tubular cell tumors induced by EHEN are malignant because some had areas of necrosis and hemorrhage and because some were transplantable (Hiasa Y: Unpublished observations). Histologically, there was no difference between the cells in small and large renal tumors induced by EHEN and the cells in small and large renal tumors induced by other chemical carcinogens. Therefore, it was very difficult to distinguish cancers from renal tubular cell tumors, and the term "tumor" is used instead of "cancer" in the present paper.

Secretagogue Response in Rat Pancreatic Acinar Carcinoma [1,2,3]

John R. Warren [4,5]

ABSTRACT—The secretion of protein, like cell proliferation, is an integrated response that reflects structural organization of the cell periphery. Stimulation of protein secretion was thus utilized for comparison of integrated responses of the cell periphery in pancreatic acinar carcinoma of the rat and integrated responses in normal rat pancreas. Results of this comparison include: *a*) The stimulation of protein secretion in acinar carcinoma fragments by carbamylcholine chloride and cholecystokinin octapeptide, pancreatic secretagogues that interact with specific plasma membrane receptors, was only a fraction (one-fifth to one-half) of that observed in normal pancreatic minilobules. *b*) The Ca^{2+} ionophore A23187 and the cyclic nucleotide $N^6,O^{2'}$-dibutyryl cyclic AMP, secretagogues that act independently of specific membrane receptors, did not stimulate secretion in the acinar carcinoma. The observed quantitative and qualitative differences in protein secretion indicate fundamental differences in cell periphery organization between the normal and transformed acinar cells of pancreas.—JNCI 1982; 69:969–974.

Release of protein by pancreatic acinar cells in response to stimulation by secretagogues is an integrated response involving membrane structures of the cell periphery (*1*). For the peptide secretagogue cholecystokinin and muscarinic cholinergic agents such as the agonist carbamylcholine, initial secretagogue binding to specific plasma membrane receptors results in displacement into the cell of Ca^{2+} from membrane-bound stores (*1, 2*). The displacement of intracellular membranous Ca^{2+} stores by carbamylcholine and cholecystokinin activates protein secretion by acinar cells. Another important group of secretagogues, including the Ca^{2+} ionophore A23187 and the cyclic nucleotide derivative db-cAMP, stimulates pancreatic acinar cell secretion in the absence of specific interactions with plasma membrane receptors. The ionophore A23187 forms channels for increased Ca^{2+} flux across cell membranes and thereby stimulates Ca^{2+}-dependent protein secretion by acinar cells (*3*). The cyclic nucleotide db-cAMP activates cAMP-dependent protein kinase, and activation of cAMP-dependent kinase is thought to result in acinar cell secretion (*4, 5*).

For the comparison of properties of the periphery of normal acinar cells and acinar carcinoma cells, the responsiveness of normal pancreas and pancreatic acinar carcinoma to these four secretagogues has been contrasted. The nafenopin-induced pancreatic acinar cell carcinoma of the F344 rat has been utilized for these experiments (*6*). In initial studies, the acinar carcinoma of the rat was observed to secrete protein in response to the cholinergic agonist carbamylcholine chloride, but at a rate less than that observed with normal rat pancreatic minilobules under identical experimental conditions (*7*). For the examination of the significance of diminutive responsiveness of the acinar carcinoma to carbamylcholine, the responsiveness of the carcinoma to additional secretagogues has been investigated. The C-terminal octapeptide of the protein hormone cholecystokinin stimulated protein secretion in the acinar carcinoma. Again, however, the rate of cholecystokinin octapeptide-stimulated protein secretion in the carcinoma was only a fraction of the rate detected in normal pancreatic minilobules. The secretagogues A23187 and db-cAMP were without stimulatory action in the pancreatic carcinoma under conditions stimulatory for normal pancreas. These differences in secretagogue responsiveness between the acinar carcinoma and normal pancreas indicate fundamental alteration in integrated responses involving the acinar carcinoma cell periphery. Directly testable mechanisms (insensitivity to extracellular Ca^{2+}, defective protein kinase) are discussed that could explain the observed differences in secretagogue responsiveness. In addition, implications of secretagogue responsiveness for pathways of cellular differentiation in the pancreatic acinar carcinoma are reviewed. A preliminary report of this work has been presented (*8*).

MATERIALS AND METHODS

Chemicals and incubation medium.—The secretagogues utilized in these experiments were obtained as follows: carbamylcholine chloride (carbachol) and db-cAMP (monosodium salt) from the Sigma Chemical Co., St. Louis, Mo.; the synthetic C-terminal octapeptide of cholecystokinin from E. R. Squibb & Sons, Inc., Princeton, N.J.; and the Ca^{2+} ionophore A23187 from Calbiochem-Behring, La Jolla, Calif. Normal pancreas was dissociated with the use of a commercially purified preparation of collagenase (CLSPA, lot #51 A 599) from Worthington Biochemical Corp., Freehold, N.J. The incubation medium utilized in all experiments contained 123 m*M* NaCl, 6.2 m*M* KCl, 33 m*M* $NaHCO_3$, 1.5 m*M* KH_2PO_4, 3.3 m*M* $CaCl_2$, 0.6 m*M* $MgSO_4$, 18 m*M* glucose, 0.1 mg soybean trypsin inhibitor/ml (Sigma Chemical Co.), 1.0% (vol/vol) complete amino acid mixture (catalog #LM-112; Kansas City Biologicals, Lenexa, Kans.), 2 m*M* glutamine (Kansas City Biologicals), 0.2% (wt/vol) fraction V bovine albumin (Sigma Chemical Co.), and antibiotics (100 U penicillin/ml and 100 μg streptomycin/ml). The osmolality of this incubation medium was 352 mosmol/kg water. The fraction V albumin was extensively dialyzed against distilled water and then

lyophilized before use in the incubation medium. Pulse-chase labeling of carcinoma or pancreas protein for secretion measurements was accomplished with L-[3,4,5-^{3}H]leucine (50 Ci/mmol) from Research Products International Corp., Elk Grove Village, Ill. The 3,5-dinitrosalicylic acid and D-(+)-maltose for the determination of amylase activity were from Eastman Kodak Co., Rochester, N.Y., and the soluble starch substrate was from Schwarz/Mann Div., Becton, Dickinson & Co., Orangeburg, N.Y. Sodium pyruvate, reduced β-nicotinamide adenine dinucleotide, and the 2,4-dinitrophenylhydrazine color reagent for measurement of LDH activity were purchased from Sigma Chemical Co.

Measurement of [^{3}H]leucine-labeled protein release by acinar carcinoma and normal pancreas.—Fragments of the pancreatic acinar carcinoma were mechanically prepared by being sieved through stainless steel screens, and minilobules were obtained by collagenase dissociation of pancreas (200- to 250-g F344 rats fasted for 48 hr) exactly as described previously (*9*, *10*). The acinar carcinoma fragments varied in size, consisted of sheets of neoplastic cells, contained abundant, large, endothelium-lined vascular channels, and in wet preparation completely excluded the vital dye trypan blue. Pancreatic minilobules consisted of groups of acini and occasional small ducts and also completely excluded trypan blue in wet preparation. The carcinoma fragments and normal pancreatic minilobules were pulse-chase labeled at 37°C by L-[3,4,5-^{3}H]leucine (*7*, *9*). Labeling of cell protein was accomplished by incubation for 15 minutes at 37°C with 60 μCi [^{3}H]leucine/ml in incubation medium containing 0.4 m*M* [^{1}H]leucine (*7*, *9*). The fragments or minilobules were then washed once, and the [^{3}H]leucine label was chased by incubation for 60 minutes at 37°C without [^{3}H]leucine in incubation medium containing 4.0 m*M* [^{1}H]leucine. Appearance of radioactive label in zymogen granules has been demonstrated under these conditions of pulse-chase labeling for both acinar carcinoma and normal pancreatic acinar cells (*9*, *11*). For experiments in which protein release was measured at both 37 and 4°C the pulse-chase-labeled carcinoma fragments or pancreatic minilobules were incubated for an additional 30 minutes at 37 or 4°C without secretagogue. The fragments or minilobules were then washed by centrifugation and incubated without or with secretagogue for 3 hours at 37 or 4°C in 12×75-mm polypropylene culture tubes (2.0 ml of a 2.0% vol/vol fragment or minilobule suspension/tube) for measurement of protein release. Tubes and solutions were precooled to 4°C before use with fragments and minilobules at 4°C. Three replicate tubes were prepared at each secretagogue concentration and temperature examined. Ethanol was used as a carrier solvent for A23187 and db-cAMP. Ethanol alone at the concentrations utilized (0.5–1.0% vol/vol) had no effect on protein release. In experiments performed with db-cAMP, 5 m*M* theophylline was also added to the incubation medium. All incubations were performed under a 95% O_2–5% CO_2 gas phase. The pH of the incubation medium as measured by a Beckman model 3550 digital pH meter with the use of a 39501 pH combination electrode was maintained at 7.4 when the medium was supplemented with 2 m*M* HEPES.[6] Incubation tubes were placed at a 5° slant (model ATR-100 Virglass tube rack; VirTis Co., Gardiner, N.Y.) on a rocker platform (Bellco Glass, Inc., Vineland, N.J.). The radioactivity present in acid-precipitable protein (1.0 *N* perchloric acid at 4°C overnight) was measured in fragments or minilobules and in incubation medium by liquid scintillation counting (Beckman LS-9000 liquid scintillation spectrometer) of perchloric acid precipitates digested in 0.6 *N* NaOH at 37°C. The amount of [^{3}H]leucine-labeled protein present in incubation medium was calculated for all experiments as a percent of total labeled protein (incubation medium plus fragments or minilobules). Where indicated, statistical analysis of protein release was accomplished by Student's *t*-test for carcinoma fragments (or pancreatic minilobules) incubated at 37°C as compared to 4°C and for carcinoma fragments as compared to pancreatic minilobules.

Measurement of amylase release.—Acinar carcinoma fragments were incubated without or with carbamylcholine for 3 hours at 37 or 4°C under experimental conditions identical to those utilized to follow [^{3}H]leucine-labeled protein release. After the 3-hour incubation, carcinoma fragments were separated from incubation medium by centrifugation and were frozen-thawed five times in distilled water. Amylase activity in the incubation medium and amylase activity released from frozen-thawed fragments were measured with the use of soluble starch as a substrate (*12*).

Measurement of LDH release.—Possible damage of acinar carcinoma cells by carbamylcholine or A23187 and of normal pancreatic acinar cells by A23187 was assessed by measurement of passive leakage of the cytosolic enzyme LDH into incubation medium. The LDH activity in incubation medium and LDH released from frozen–thawed carcinoma fragments or pancreatic minilobules were determined by colorimetric measurement of pyruvate reduction (Sigma technical bulletin No. 500).

RESULTS

When the amount of [^{3}H]leucine-labeled protein present in the incubation medium was measured as a percent of total labeled protein (incubation medium plus carcinoma fragments), 14.2±1.7% (mean ± SD, *n*=3 experiments) of total labeled protein was released by carcinoma fragments incubated at 37°C without carbamylcholine, and 16.7±3.0, 17.6±3.2, 18.3±3.1, 21.2±2.3, 22.0±3.5, or 21.1±2.6% of total labeled protein was released by carcinoma fragments incubated with 10^{-8}, 10^{-7}, 10^{-6}, 10^{-5}, 10^{-4}, or 10^{-3} *M* carbamylcholine, respectively. The same preparations of carcinoma fragments incubated at 4°C without and with carbamylcholine (10^{-8}–10^{-3} *M*) released 4.9±2.0, 4.7±1.8, 4.4±2.2, 4.6±1.5, 5.4±2.7, 6.0±1.5, and 5.6±1.9% of the total labeled protein. In a separate group of experiments, the amount of [^{3}H]leucine-labeled protein and the cytosolic enzyme LDH present in incubation medium was concomitantly measured as a percent of total labeled protein or LDH activity. Carcinoma fragments incubated at 37°C without or with 10^{-8}, 10^{-7}, 10^{-6}, 10^{-5}, 10^{-4}, and 10^{-3} *M* carbamylcholine released 20.9±1.7, 21.2±0.5, 23.7±1.1, 25.7±1.8, 29.3±1.6, 28.4±1.4, and 27.2±2.8%, respectively, of the total labeled protein, whereas in the same experiments (n=3) the fragments released 14.4±5.9, 13.1±4.2, 14.1±3.7, 15.4±4.7, 14.6±3.1, 16.8±5.0, and 15.5±2.3% of the total LDH activity. These results show that the concentration-dependent increase in the amount of [^{3}H]-leucine-labeled protein in incubation medium stimulated by carbamylcholine at 37°C was not accompanied by an increase in the amount of LDH in the incubation medium. We conclude that the increased release of [^{3}H]leucine-labeled protein by carcinoma fragments induced with carbamylcholine at 37°C was not due to passive membrane leakage of cytosolic protein. When the release of [^{3}H]leucine-labeled protein at 37 and 4°C was calculated at each carbamylcholine concentration as net release (protein release observed with carbamylcholine − protein release observed without carbamylcholine), both dependence of net protein release at 37°C ($\Delta_{t=37°}$) on carbamylcholine concentration and absence of stimulation of net release at 4°C ($\Delta_{t=4°}$) were apparent (text-fig. 1A). Carbamylcholine was also observed to stimulate a concentration-dependent net release of amylase from carcinoma fragments at 37°C (−0.1±0.7, +3.6±0.2, +3.6±2.3, +6.8±0.6, and +4.4±1.5% at 10^{-8}, 10^{-7}, 10^{-6}, 10^{-5}, and 10^{-4} *M* carbamylcholine, respectively) but not at 4°C (−0.5±1.0, +0.1±0.7, +0.9±1.2, +1.1±1.7, and +0.9±1.8% at the same carbamylcholine concentrations) (n=3 experiments). We conclude, therefore, that carbamylcholine induces protein secretion in metabolically active acinar carcinoma fragments.

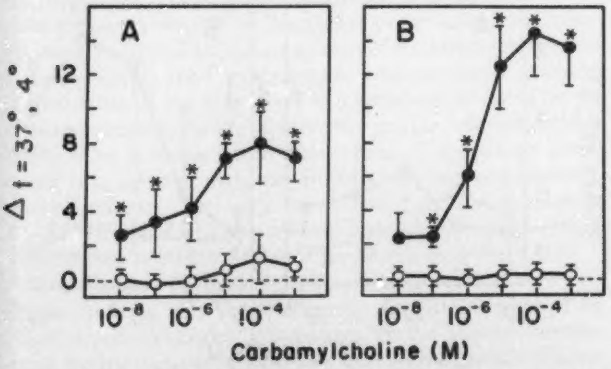
[6] 4-(2-Hydroxyethyl)-1-piperazine ethanesulfonic acid.

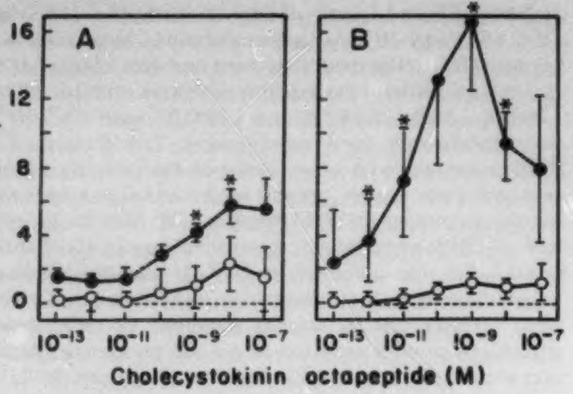
Minilobules were prepared from normal pancreas by collagenase dissociation (*10*) and were incubated under identical conditions without or with carbamylcholine. An increase in the amount of [^{3}H]leucine-labeled protein released into the incubation medium was detected for normal pancreas minilobules incubated with carbamylcholine at 37°C (8.8±2.1% of total labeled protein released without carbamylcholine and 11.1±1.6, 11.2±2.6, 14.7±3.2, 21.3±4.0, 23.2±2.7, and 22.5±3.1% with 10^{-8}, 10^{-7}, 10^{-6}, 10^{-5}, 10^{-4}, and 10^{-3} *M* carbamylcholine, respectively) but not for minilobules incubated with carbamylcholine at 4°C (1.3 ± 0.5% without carbamylcholine and 1.3±0.6, 1.5±0.4, 1.2±0.3, 1.5±0.4, 1.6±0.8, and 1.5±0.5% with 10^{-8}–10^{-3} *M* carbamylcholine) (n=3 experiments). Dependence of net [^{3}H]leucine-labeled protein release on carbamylcholine concentration was clearly present with normal pancreas minilobules incubated at 37°C (text-fig. 1B). Maximal stimulation of [^{3}H]leucine-labeled protein release in the pancreas minilobules was achieved at 10^{-5} *M* carbamylcholine, a value identical to that obtained by other laboratories for in vitro preparations of normal pancreas (*1*). The rate of stimulated protein secretion in normal pancreatic minilobules at maximal carbamylcholine concentrations (≥10^{-5} *M*) (text-fig. 1B) was significantly greater than rates of stimulated protein secretion in acinar carcinoma fragments (text-fig. 1A). At 10^{-5} *M* carbamylcholine, the rate of stimulated protein secretion in pancreatic minilobules was 1.9-fold greater than the rate of secretion in carcinoma fragments (P<0.02), at 10^{-4} *M* carbamylcholine 2.2-fold greater (P<0.05), and at 10^{-3} *M* carbamylcholine 2.2-fold greater (P<0.01).



TEXT-FIGURE 1.— Effect of carbamylcholine on net [^{3}H]leucine-labeled protein release ($\Delta_{t=37°,4°}$) by acinar carcinoma fragments (A) or normal pancreas minilobules (B) at 37 (●) or 4°C (○). Release of [^{3}H]leucine-labeled protein into the incubation medium was measured as the percent of total [^{3}H]leucine-labeled protein present in incubation medium and carcinoma fragments or pancreas minilobules. *Each point* reported for $\Delta_{t=37°,4°}$ is corrected for [^{3}H]leucine-labeled protein release detected in the absence of carbamylcholine and represents the mean ± SD (*vertical bars*, SD) obtained in three experiments. Statistically significant differences (P<0.05) in net [^{3}H]leucine-labeled protein release between 37 and 4°C are denoted by *asterisks.*

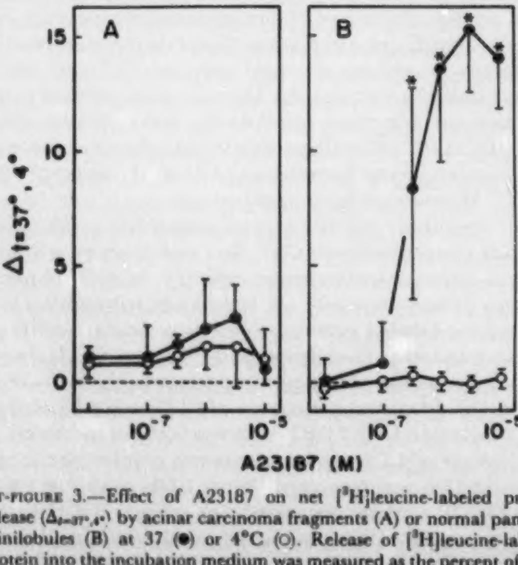
The peptide secretagogue cholecystokinin octapeptide also stimulated net release into buffer of [^{3}H]leucine-labeled protein with normal pancreatic minilobules incubated at 37°C (text-fig. 2B), and rates of stimulated protein secretion in normal pancreatic minilobules demonstrated a biphasic dependence on cholecystokinin octapeptide concentration identical to that reported by other groups (*1*). Compared to the stimulation seen with the normal pancreatic minilobules, less stimulation of net [^{3}H]leucine-labeled protein release occurred with acinar carcinoma fragments incubated at 37°C in the presence of cholecystokinin octapeptide (text-fig. 2A). Significant stimulation of protein secretion in acinar carcinoma fragments occurred only at 10^{-9} and 10^{-8} *M* cholecystokinin octapeptide. The rate of stimulated protein secretion in pancreas minilobules was fivefold greater (P<0.01) at 10^{-9} *M* cholecystokinin than the rate of secretion in acinar carcinoma fragments and 2.5-fold greater (P<0.02) at 10^{-8} *M* cholecystokinin octapeptide.

The ionophore A23187 acts on pancreatic acinar cells to increase transmembrane Ca^{2+} flux and thereby stimulates protein secretion by the acinar cells (*2*). At A23187 concentrations greater than 10^{-7} *M*, significant stimulation of net [^{3}H]leucine-labeled protein release was detected with pancreatic minilobules incubated at 37°C (text-fig. 3B) with a maximal response obtained at approximately 10^{-6}–5×10^{-6} *M* A23187. Maximal net release of [^{3}H]leucine-labeled protein stimulated by A23187 occurred without increased passive leakage of LDH in the pancreatic minilobules (a value of −0.6±2.6% was measured for net LDH release at 5×10^{-6} *M* A23187), without increased net release of [^{3}H]leucine-labeled protein in the pancreatic minilobules incubated at 4°C (text-fig. 3B), and closely resembled the dependence on A23187 concentration reported elsewhere for in vitro preparations of normal pancreas (*11*). Under the same conditions that were stimulatory for pancreatic minilobules, a significant increase of net [^{3}H]leucine-labeled protein release was not detected in acinar carcinoma fragments incubated with



TEXT-FIGURE 2.—Effect of cholecystokinin octapeptide on net [^{3}H]leucine-labeled protein release ($\Delta_{t=37^\circ,4^\circ}$) by acinar carcinoma fragments (A) or normal pancreas minilobules (B) at 37 (●) or 4°C (○). Release of [^{3}H]leucine-labeled protein into the incubation medium was measured as the percent of total [^{3}H]leucine-labeled protein present in incubation medium and carcinoma fragments or pancreas minilobules. *Each point* reported for $\Delta_{t=37^\circ,4^\circ}$ is corrected for [^{3}H]leucine-labeled protein release detected in the absence of cholecystokinin octapeptide and represents the mean ± SD (*vertical bars*, SD) obtained in three experiments. Statistically significant differences ($P<0.05$) in net [^{3}H]leucine-labeled protein release between 37 and 4°C are denoted by *asterisks*.

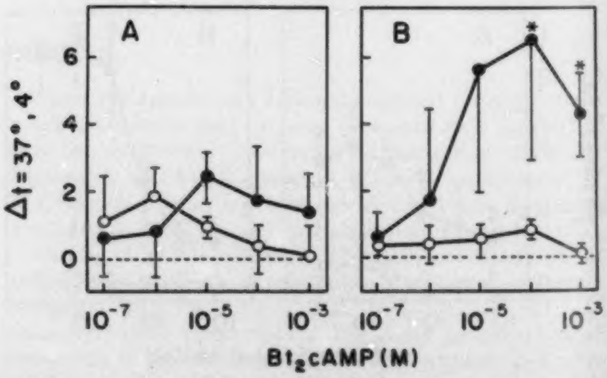
A23187 (text-fig. 3A). The small increase of [^{3}H]leucine-labeled protein release present in carcinoma fragments at 37°C was not significantly different than that observed at 4°C. At A23187 concentrations greater than 10^{-5} *M*, the ionophore induced a concentration-dependent leakage of LDH in carcinoma fragments. (Values of +15.5±6.5, +21.4±2.5, and +37.5±11.8% were measured for net LDH release at 37°C and 5×10^{-5}, 7.5×10^{-5}, and 10^{-4} *M* A23187, respectively.)



TEXT-FIGURE 3.—Effect of A23187 on net [^{3}H]leucine-labeled protein release ($\Delta_{t=37^\circ,4^\circ}$) by acinar carcinoma fragments (A) or normal pancreas minilobules (B) at 37 (●) or 4°C (○). Release of [^{3}H]leucine-labeled protein into the incubation medium was measured as the percent of total [^{3}H]leucine-labeled protein present in incubation medium and carcinoma fragments or pancreas minilobules. *Each point* reported for $\Delta_{t=37^\circ,4^\circ}$ is corrected for [^{3}H]leucine-labeled protein release detected in the absence of A23187 and represents the mean ± SD (*vertical bars*, SD) obtained in three experiments. Statistically significant differences ($P<0.05$) in net [^{3}H]leucine-labeled protein release between 37 and 4°C are denoted by *asterisks*.

The fourth secretagogue included in this study, db-cAMP, is thought to stimulate pancreatic acinar cell secretion by direct activation of cAMP-dependent protein kinase (*4, 5*). Significant stimulation of net [^{3}H]leucine-labeled protein release was observed in pancreatic minilobules incubated at 37°C with 10^{-4} and 10^{-3} *M* db-cAMP (text-fig. 4B). Bauduin et al. (*13*) have previously observed in vitro stimulation of rat pancreas at approximately 10^{-4}–10^{-3} *M* db-cAMP. As was reported by Bauduin et al. for rat pancreas pieces (*13*), maximal stimulation of protein secretion in the pancreatic minilobules by db-cAMP was considerably less than maximal stimulation obtained with carbamylcholine and cholecystokinin. More importantly, no significant stimulation of protein secretion was seen in acinar carcinoma fragments incubated with db-cAMP (text-fig. 4A).

In repeated experiments ($n=12$) the amount of [^{3}H]leucine-labeled protein released into the incubation medium as a percent of total labeled protein was 12.8±3.5% at 37°C and 4.9±2.3% at 4°C when the acinar carcinoma fragments were incubated without secretagogues. Likewise, with pancreatic minilobules incubated in the absence of secretagogue, the amount of labeled protein released into the incubation medium as a percent of total protein was 8.8±2.9% at 37°C and 1.4±0.4% at 4°C ($n=12$ experiments). From these results one may calculate the basal (unstimulated) rate of [^{3}H]-leucine-labeled protein release by metabolically active carcinoma fragments or pancreatic minilobules by subtracting the amount of labeled protein present in incubation medium at 4°C from the amount present in incubation medium at 37°C. A basal rate of protein release in acinar carcinoma fragments of 7.9±3.6% and in normal pancreatic minilobules of 7.5±2.7% was observed. These values for basal rates



TEXT-FIGURE 4.—Effect of db-cAMP (Bt_2cAMP) on net [^{3}H]leucine-labeled protein release ($\Delta_{t=37^\circ,4^\circ}$) by acinar carcinoma fragments (A) or normal pancreas minilobules (B) at 37 (●) or 4°C (○). Release of [^{3}H]-leucine-labeled protein into the incubation medium was measured as the percent of total [^{3}H]leucine-labeled protein present in incubation medium and carcinoma fragments or pancreas minilobules. *Each point* reported for $\Delta_{t=37^\circ,4^\circ}$ is corrected for [^{3}H]leucine-labeled protein release detected in the absence of db-cAMP and represents the mean ± SD (*vertical bars*, SD) obtained in three experiments. Statistically significant differences ($P<0.05$) in net [^{3}H]leucine-labeled protein release between 37 and 4°C are denoted by *asterisks*.

of [^{3}H]leucine-labeled protein release are very similar to in vitro basal rates of secretion reported by other investigators for normal pancreas (*14*). Two conclusions are drawn from the observed rates of protein release in the absence of secretagogue: 1) In contrast to the large differences observed for the secretagogue-stimulated rates of protein secretion by the carcinoma and normal pancreas, no significant difference existed between basal (unstimulated) rates of [^{3}H]leucine-labeled protein release by metabolically active cells in the acinar carcinoma fragments and in the normal pancreatic minilobules. 2) Rates of [^{3}H]leucine-labeled protein release at 4°C indicate that at most only 5% of labeled cells in the carcinoma fragments and 1% of labeled cells in the pancreatic minilobules were sufficiently damaged during preparation of fragments and minilobules to passively leak radioactive protein.

DISCUSSION

Two important differences were observed between the stimulation of protein secretion in the pancreatic acinar carcinoma and the stimulation of protein secretion in normal pancreas: 1) The rate of cholecystokinin octapeptide- and carbamylcholine-stimulated secretion in acinar carcinoma was only a fraction (one-fifth to one-half) of the rate of stimulated secretion in normal pancreas. 2) A23187 and db-cAMP did not stimulate protein secretion in the acinar carcinoma but, under identical experimental conditions, did stimulate secretion in normal pancreas. The major difference between techniques used to prepare the carcinoma fragments and normal pancreatic minilobules was the use of collagenase to obtain minilobules. In previous work we have found that treatment of carcinoma fragments with collagenase under conditions comparable to those used to prepare minilobules diminished carbamylcholine stimulation by the fragments to 50–60% of the rate observed for carcinoma fragments not treated with collagenase (*7*). Thus mechanically prepared carcinoma fragments not treated with collagenase are optimal for measurement of secretagogue responsiveness. Diminished secretagogue responsiveness detected with the use of the fragments is considered by us to be an intrinsic property of the pancreatic acinar cell carcinoma. Diminutive secretagogue responsiveness of the acinar carcinoma is consistent with our electron microscopic analysis, which indicates that, at a maximum, only approximately 30–50% of the carcinoma cells are capable of incorporating protein into zymogen granules for discharge (*15*).

Stimulation of protein secretion by the peptide hormone cholecystokinin and the cholinergic agonists consists of an afferent and an efferent component. In the afferent component, the hormone or agonist interacts with a specific plasma membrane receptor (*1*). Interaction of cholecystokinin or carbamylcholine with their specific receptors is followed by displacement of membrane-bound Ca^{2+} into the cell interior which activates the cell for secretion (*2*). The efferent limb consists of zymogen granule migration to the plasma membrane, fusion of granule and plasma membranes, and discharge of zymogen protein to the cell exterior. The ionophore A23187 activates the efferent component of protein secretion without interacting with specific plasma membrane receptors (*2*). The absence of responsiveness of acinar carcinoma fragments to A23187 indicates that the efferent limb of stimulated protein secretion sensitive to extracellular Ca^{2+} (*16, 17*) is defective in acinar carcinoma cells. Absence of A23187-stimulated protein secretion in acinar carcinoma fragments was an unexpected observation. Both carbamylcholine stimulation and A23187 stimulation of pancreatic acinar cell secretion are Ca^{2+}-dependent processes (*2*). Thus since carbamylcholine had been found in our initial group of experiments to stimulate acinar carcinoma secretion (*7, 9*), it was expected that A23187 would also stimulate secretion in the carcinoma. A possible explanation for this discrepancy is the ability of intracellular Ca^{2+} stores to support stimulation by carbamylcholine of secretory protein discharge in normal pancreas (*2, 17*). It can be proposed that carbamylcholine stimulates protein secretion in the acinar carcinoma by mobilization of intracellular Ca^{2+} stores. However, if secretion in the acinar carcinoma were refractory toward influx of extracellular Ca^{2+} into carcinoma cells, absence of A23187 stimulation of protein secretion in the acinar carcinoma would be explained. In addition, it has been demonstrated that release of Ca^{2+} from intracellular stores is responsible for only a fraction of the secretory protein discharge in normal pancreas stimulated by carbamylcholine in the presence of physiologic extracellular Ca^{2+} concentration (*17*). Stimulation of sustained secretion by carbamylcholine appears to require influx of extracellular Ca^{2+} into the pancreatic acinar cell (*17*). We can speculate, therefore, that the diminutive responses of the acinar carcinoma to carbamylcholine (and to cholecystokinin octapeptide) also reflect insensitivity of carcinoma secretion to extracellular Ca^{2+}. The proposed insensitivity of the acinar carcinoma to extracellular Ca^{2+} will be directly tested by measurement of the dependence of carbamylcholine and cholecystokinin octapeptide stimulation of protein secretion in carcinoma fragments on extracellular Ca^{2+} concentration. The proliferative insensitivity of neoplastically transformed cells to extracellular ionized calcium has recently been observed (*18*). Further examination of Ca^{2+} homeostasis should yield important information on the regulation by Ca^{2+} of integrated cellular responses, including proliferation as well as protein secretion, in the acinar carcinoma. In addition, db-cAMP has been observed to activate protein phosphorylation in normal pancreatic acinar cells (*4*), activation of protein phosphorylation appears to be coupled to stimulation of acinar cell secretion by db-cAMP (*4*), and cAMP-dependent protein kinase has been identified in normal acinar cells (*5*). The inability of db-cAMP to stimulate protein secretion by acinar carcinoma cells indicates a deficiency of the cAMP-dependent protein kinase system. Like Ca^{2+}, cAMP is an important regulator of integrated cell function, and it will be important to elucidate why cAMP-dependent responses are deficient in the carcinoma.

Finally, discussion is required as to whether diminished secretagogue responsiveness of the acinar carcinoma is or is not an expression of maturational arrest in the carcinoma. Rat pancreas during normal embryogenesis becomes highly responsive to the secretagogues A23187 and db-cAMP several days prior to becoming responsive to cholinergic and peptide secretagogues (*19, 20*). It appears, therefore, that maturation of the efferent component occurs prior to maturation of the afferent component in pancreatic embryogenesis. If secretagogue responsiveness in the acinar carcinoma reflects arrest of carcinoma cells at a stage corresponding to immature normal acinar cell development, then responsiveness of the acinar carcinoma to A23187 and db-cAMP should be comparable to or exceed carcinoma responsiveness to carbamylcholine and cholecystokinin octapeptide. This was not the case, and diminished secretagogue responsiveness is, therefore, not adequately explained as immaturity of acinar differentiation in the pancreatic carcinoma. We have recently reported that, unlike normal embryonic pancreas, the presence of plasmalemma receptors for the lectin concanavalin A is not a specific membrane marker for pancreatic acinar carcinoma cells containing mature cytoplasmic zymogen granules (*21*). These lectin binding data also suggest that cellular differentiation in the acinar carcinoma does not mimic stages of acinar cytodifferentiation in normal pancreatic embryogenesis. Morphologic evidence has been obtained in other studies (*22*) that the direction of cellular differentiation in pancreatic carcinoma is from cells with zymogen maturation to ductlike cells lacking such maturation (retrodifferentiation), rather than from undifferentiated cells lacking zymogen maturation to cells with such maturation (stem cell differentiation). Both mitotic activity and DNA synthesis have been observed in the nafenopin-induced acinar carcinoma in cells containing mature zymogen granules (*15*). Therefore, granule-containing carcinoma cells could theoretically serve as a proliferative pool for the generation of carcinoma cells lacking zymogen maturation.

Enhanced Metastatic Potential of Tumor Cells Harvested From Spontaneous Metastases of Heterogeneous Murine Tumors[1,2,3,4]

James E. Talmadge[5] *and* **Isaiah J. Fidler**[5]

ABSTRACT—These studies demonstrated that cells populating spontaneous metastases are, in general, more metastatic than the cells populating the parent neoplasm, thereby providing direct evidence that the process of metastasis is selective and not random. The tumors used in these studies were the UV-2237 fibrosarcoma, an in vitro cloned line (C-40) from the UV-2237 tumor, and the K-1735 melanoma, all of which are syngeneic to the C3H/HeN (mammary tumor virus-negative) mouse strain; the M5076 reticulum cell sarcoma and the Lewis lung carcinoma 3LL, which are syngeneic to the C57BL/6 mouse strain, were also used. All tumors were implanted sc into the footpads of syngeneic mice, and several resulting spontaneous metastases were isolated and established in culture as individual cell lines. For each tumor system, comparison was made of the ability of parent tumor cells and cells isolated from several spontaneous metastases to produce either experimental or spontaneous metastases. Cells populating spontaneous metastases produced by heterogeneous and poorly metastatic tumors were significantly more metastatic than the cells of their respective parent tumors. In contrast, cells populating metastases produced by previously selected tumors did not differ significantly in metastatic potential from cells populating their parent tumors. In such systems, metastasis appeared to be random.—JNCI 1982; 69:975–980.

A growing body of data suggests that malignant, metastatic neoplasms are heterogeneous and that metastases result from the proliferation of a minor subpopulation of cells that preexist within the parent neoplasm (*1–3*). Only a few (<0.1%) tumor cells survive the multistep process to produce metastases (*4–6*), which raises the question of whether the metastatic process is random (*7–9*) or selective (*10, 11*). Selection could only take place under certain conditions. The starting tumor population would have to be unselected and heterogeneous with regard to metastatic potential, and the metastatic process per se would have to exert selective pressures on the participating tumor cells (*2, 11*). We investigated this issue further by determining whether cells populating a spontaneous metastasis are more metastatic than cells populating the parent neoplasm. A finding that the cells of the metastases were more metastatic would constitute direct evidence that the metastatic process is selective. To rule out the possibility that our results were unique to one tumor system or another, we used four different murine tumor systems and found in each system that tumor cells harvested from spontaneous metastases have a greater propensity to metastasize than cells harvested from their respective heterogeneous parent tumors. However, when the starting "parent tumor" consisted of an already selected cell line or a cloned, presumably homogeneous, population, the cells from metastases did not differ significantly in metastatic potential from the parent tumor cells.

MATERIALS AND METHODS

Mice.—Specific-pathogen-free mice of the inbred strains C3H⁻ and C57BL/6N were obtained from the Animal Production Area, NCI-Frederick Cancer Research Facility. Within a single experiment, all mice were matched for age and sex.

Tumors.—Tumors syngeneic to the C57BL/6 mouse were the Lewis lung carcinoma 3LL (obtained from Dr. J. Mayo, NCI-Frederick Cancer Research Facility) and the M5076 reticulum cell sarcoma of histiocytic origin (high metastatic potential) (*12, 13*). Tumors syngeneic to the C3H⁻ mouse were the UV radiation-induced fibrosarcoma UV-2237 (*14*), a metastatic clone (C-40) isolated in vitro from the parent UV-2237 tumor, and the metastatic, UV radiation-induced, croton oil-promoted malignant melanoma K-1735 (obtained from Dr. Margaret Kripke, NCI-Frederick Cancer Research Facility) (*15, 16*).

All adherent tumors were adapted to growth in culture as described previously (*12, 16, 17*). Cell cultures were maintained on tissue culture plastic in Eagle's minimum essential medium supplemented with 5% fetal bovine serum, sodium pyruvate, nonessential amino acids, L-glutamine, and a twofold vitamin solution (Flow Laboratories, Inc., Rockville, Md.). The M5076 cells were grown in RPMI-1640 medium (Grand Island Biological Co., Grand Island, N.Y.) supplemented with 10% heat-inactivated equine serum (Flow Laboratories), L-glutamine, sodium pyruvate, and 50 µg gentamicin/ml. All cell lines were free of mycoplasma and the following murine viruses: reovirus type 3, pneumonia virus of mice, K-virus, Theiler's virus, Sendai virus, minute virus of mice, mouse adenovirus, mouse hepatitis virus, lymphocytic choriomeningitis virus, ectromelia virus, and lactate

ABBREVIATIONS USED: C3H⁻=C3H/HeN mammary tumor virus-negative; HBSS=Hanks' balanced salt solution.

dehydrogenase virus (M.A. Bioproducts, Walkersville, Md.). We avoided using cell lines that had been cultured for long periods of time; to assure that our results would be reproducible, we renewed the cultures from frozen stocks every 2–3 months and maintained them without antibiotics.

Preparation of tumor cells for injection.—We harvested the tumor cells from subconfluent cultures (50–70% confluence) by rinsing the monolayers with 0.25% trypsin and 0.02% Versene. After 1 minute, the flasks were tapped sharply to dislodge the monolayer, and the cells were washed in medium with fetal bovine serum. The suspension cultures of M5076 cells were harvested as previously described (*13*). The cells were resuspended in Ca^{2+}- and Mg^{2+}-free HBSS. Only suspensions containing single cells of greater than 90% viability (determined by the trypan blue exclusion test) were used.

Isolation and culture of spontaneous metastases.—To obtain spontaneous metastases, we injected tumor cells into the posterior footpads of syngeneic mice. The limbs bearing tumors were amputated at the midfemur when the tumors reached 1.2–1.5 cm in diameter. Mice were killed 4–8 weeks thereafter, and single pulmonary or hepatic (M5076) metastases were isolated in an aseptic manner. Individual lines were established in culture from single metastases.

Assay for experimental pulmonary metastasis.—Unanesthetized mice received injections in the lateral tail vein of 0.2 ml HBSS containing tumor cells. The cell inoculum varied among the different tumor systems (*see* "Results"). The mice were killed 21–35 days later, and the lungs or livers were removed, rinsed in water, and fixed in Bouin's solution to facilitate observation of tumor colonies (*17*). After this treatment, tumor colonies were visible as raised opaque foci. They were counted under a dissecting microscope.

Spontaneous metastasis assay.—Viable tumor cells in a volume of 0.05 ml HBSS were injected into the mouse posterior footpad at cell doses previously determined to yield tumors in most recipient mice. When the tumors reached 1.2–1.5 cm in diameter, the legs bearing tumors were amputated at the midfemur. The mice were killed 6–8 weeks later and necropsied; the presence of metastases was determined. In studies of the M5076 tumor, the local tumors were not excised. Because this tumor is very invasive, mice bearing the M5076 sarcoma were necropsied 42 days after intrafootpad injection.

Statistical analyses.—Differences in the number of metastases among test groups were analyzed with the Mann-Whitney *U* test.

RESULTS

K-1735 Melanoma

We compared the metastatic potential (experimental and spontaneous) of cells from the parent K-1735 melanoma and four spontaneous metastases produced by parent tumors growing at a primary site. The data are shown in table 1. The iv injection of 25,000 viable tumor cells from spontaneous metastases into syngeneic $C3H^-$ mice produced significantly more lung tumor colonies than the same input of parent K-1735 cells. However, when the inoculum dose of cells was increased to 100,000/mouse, the lungs became saturated with tumor colonies, thus obscuring differences in the metastatic potential of the cell lines (*17*).

Because of several reports that excision of primary tumors can affect the production of spontaneous metastases (*18–20*), we examined the incidence of spontaneous metastasis in mice in which the primary tumor was excised and in mice in which the primary tumor was left intact. Either 10^5 K-1735 parent cells or cells from spontaneous metastases were injected into the footpads of $C3H^-$ mice. This dose of cells was tumorigenic in 100% of the mice, but the growth rate of the tumors varied: The parent tumor reached 9 mm in diameter in 43 days, whereas the tumors established from metastases reached this size in 22 days. When tumors reached diameters of 12–15 mm, the leg bearing the tumor was amputated at the midfemur (including the popliteal lymph node) from one group of mice. The mice were

[a] Cells injected into syngeneic mice were from in vitro cultures of parent tumors or of tumors established from spontaneous metastases. Met=metastasis.

[b] Mice were given iv injections of the indicated cell inoculum and killed 35 days later ($n=10$).

[c] Probability of no difference compared to the value for the parent tumor as determined by the Mann-Whitney *U* test. NS=not significant.

[d] Mice were given intrafootpad injections of viable cells. When tumors reached 1–1.2 cm in diameter (44 days for the parent tumors and 22 days for the spontaneous metastases), the leg bearing the tumor was amputated at the midfemur. Mice were necropsied 68 days after the implantation of tumor cells.

[e] Mice were given intrafootpad injections of viable cells. Mice were necropsied when moribund (57–84 days after tumor implantation).

necropsied 8–9 weeks later. In the other group, the tumors were allowed to grow progressively. None of the mice inoculated with K-1735 parent tumor cells and in which the tumor was excised developed spontaneous metastases.

In contrast, 1 of 7, 1 of 8, 3 of 7, and 5 of 10 mice inoculated with cells from the four spontaneous metastases and in which primary tumors were excised developed spontaneous metastases. Differences in survival were recorded between mice bearing parent K-1735 tumors and those bearing primary tumors established from metastatic cell lines. The mean survival time of mice bearing the parent K-1735 melanoma was 84 days. Spontaneous metastases developed in only 2 of 10 mice; the other 8 mice died without evidence of systemic disease. In contrast, when the cells from each of four spontaneous metastases were implanted into groups of mice, the 4 groups survived a mean of 57, 64, 68, and 63 days, respectively. Spontaneous metastases were clearly visible in 6 of 10, 9 of 9, 6 of 8, and 7 of 9 mice. In this tumor system, when the primary tumor was excised, the incidence of metastasis was lower than that when the primary neoplasm was not excised. Nonetheless, in the K-1735 tumor system, cells obtained from spontaneous metastases were more metastatic than their parent tumor cells.

Qualitative differences were also noticeable in the gross morphology of the metastases produced by parent cells and cells isolated from the various spontaneous metastases. Whereas parent cells produced experimental metastases of various sizes and pigmentation, cells from individual metastatic lines produced more uniform lung tumor colonies. The gross appearance of spontaneous lung metastases produced from the parent K-1735 melanoma or metastatic lines growing in the footpad is shown in figure 1. Distinct differences in the size and pigmentation of the metastases are visible. Figure 1 also shows the size of the primary tumors at the time of excision, as well as the presence of a secondary tumor mass in the popliteal node.

M5076 Reticulum Cell Sarcoma

In these experiments, we examined the metastatic potential of cells from the highly metastatic M5076 reticulum cell sarcoma (*12, 13*) and five of its hepatic metastases. Following iv or intrafootpad injection into syngeneic C57BL/6 mice, M5076 cells produced peritoneal, but not pulmonary, metastases in all recipients (*13*). Cells harvested from hepatic metastases produced experimental metastases more efficiently than did cells of the parent M5076 (table 2). The mice were necropsied 21 days after the iv injection of 2×10^4 viable cells, at which time the hepatic tumor nodules were visible. Since this highly metastatic tumor produced spontaneous metastases in practically all of the mice, differences between cells of the parent M5076 and the five metastases could not be measured by examination of the incidence of spontaneous metastases; therefore, we assessed differences in metastatic potential by comparing the number of nodules per mouse. By these criteria, mice given intrafootpad injections of cells obtained from spontaneous M5076 metastases developed significantly more hepatic tumor foci (spontaneous) than did mice given injections of cells from the parent tumor ($P<0.01$). As shown in table 2, there is no apparent correlation between the size of the subcutaneous tumor at necropsy and the median number of hepatic metastases. Therefore, the increase in the number of spontaneous metastases could not be attributed to differences in the growth rate or size of the tumor in the footpad.

UV-2237 Fibrosarcoma Parent Tumor

In studies of the heterogeneous parent UV-2237 tumor (*14*) and nine spontaneous pulmonary metastases, we found that cells obtained from metastases produced more experimental metastases than did cells from the parent tumor (table 3). This finding extended and confirmed a previous study on the ability of the parent UV-2237 tumor and its metastases to form experimental metastases (*11*).

Cloned Cell Line of UV-2237 Fibrosarcoma

Studies of an in vitro cloned, presumably homogeneous, line of the UV-2237 fibrosarcoma (C-40) and four spontaneous metastases produced from this clone demonstrated that cells harvested from the spontaneous metastases varied only slightly from the parent tumor; as compared to the parent (cloned) line, they did not show an increased propensity to produce experimental metastases (table 4).

3LL Carcinoma

The variant 3LL carcinoma examined in this study was far less metastatic than were the other 3LL tumor variants

[c] Probability of no difference compared to the value for the parent tumor as determined by the Mann-Whitney *U* test.

reported elsewhere (*20*). Cells from the 3LL tumor were implanted into the footpads of mice, and the tumor-bearing leg of each mouse was amputated when the tumor reached 1.2–1.5 cm in diameter. Five weeks later only 3 of 20 mice had developed lung metastases. These metastases were harvested, pooled, and established in culture as 3LL-Met-1 line. This selection procedure was repeated a second time, with the 3LL-Met-1 tumor, to yield tumor line 3LL-Met-2. Thereafter, the three tumor variants (3LL parent, 3LL-Met-1, and 3LL-Met-2) were examined to determine their potential for production of experimental and spontaneous metastases.

The ability of these lines to form experimental lung colonies was determined in the following manner: Viable tumor cells (100,000/mouse) were injected iv into the lateral tail vein of each C57BL/6 mouse (10/group). The mice were necropsied 3 weeks later and their lung metastases were counted. Mice inoculated with 3LL parent tumor cells had a median of 0 pulmonary colonies (range, 0–1), cells of the 3LL-Met-1 variant produced a median of 1 pulmonary colony (range, 0–4), and cells of the 3LL-Met-2 variant produced a median of 23 pulmonary colonies (range, 12–56). Thus the incidence of metastasis of the 3LL-Met-2 line was significantly higher than that of the 3LL parent and 3LL-Met-1 (P=0.001). Cells from the parent 3LL and the 3LL-Met-2 cell lines were injected im into the thighs of mice. The 3LL-Met-2 tumors grew to an average of 6.8±1.36 cm^3 and produced numerous metastases. Although the parent 3LL tumor also grew to a similar size (6.73±1.23 cm^3), it produced only a few pulmonary foci. The 3LL-Met-1 cell line (data not shown) exhibited a metastatic ability that was intermediate between that of the 3LL parent and 3LL-Met-2 lines.

Table 4.—*Incidence of experimental metastasis of cells from the C-40 cloned line of UV-2237 fibrosarcoma and individual spontaneous pulmonary metastases*

[a] Met=metastasis.

[b] Mice were given iv injections of 5×10^4 viable tumor cells and killed 21 days later (n=10). Incidence of metastasis produced by any of the cell lines was indistinguishable from that of parent UV-2237 C-40 (Mann-Whitney *U* test).

DISCUSSION

Work from our laboratory (*16*) and from other laboratories (*21–26*) has suggested that the process of metastasis is not random but represents the survival and growth of selected subpopulations of cells that preexist in parent neoplasms. Our present results demonstrate that cells harvested from spontaneous metastases are in general more metastatic than their respective heterogeneous parent cells and thus provide further evidence of the selective nature of the metastatic process. Our findings were not affected by the anatomic location of the metastases, i.e., lung for metastases of the K-1735 melanoma, UV-2237 fibrosarcoma, and 3LL carcinoma and liver for metastases of the M5076 reticulum cell sarcoma. Thus the increased metastatic potential associated with cells from spontaneous metastases does not appear to be an organ-specific phenomenon (*11*). The metastatic potential of tumor cells was determined by two different assays. In the first assay, tumor cells were injected iv and the number of experimental metastases was determined. In the second assay, tumor cells were injected into a subcutaneous site and the incidence of spontaneous metastasis was determined. These two assays are well correlated as was demonstrated earlier by Kripke et al.(*14*).

Recent studies have demonstrated that many rodent and human neoplasms consist of subpopulations of cells with different growth rates, antigenicity, immunogenicity, susceptibility to cytotoxic drugs, and potential for invasion and metastasis (*1–3*). Moreover, in some rodent and human tumors, cells from various metastases have been shown to differ from cells residing within the primary neoplasm in their antigenicity (*27, 28*), biochemical properties (*29*), and response to cytotoxic drugs (*30–34*). Our data confirm these observations of tumor heterogeneity and show that the successful selection of cells with enhanced metastatic properties could occur, in a one-step procedure, during the process of metastasis. Thus spontaneous metastases of a primary tumor contain cells with enhanced metastatic properties. However, multiple selection procedures may be needed to obtain tumor variants with extremely high metastatic properties (*24–26, 35*), as evidenced in our study of the 3LL carcinoma. The parent tumor variant was poorly metastatic; although pooled metastases produced by the parent tumor (3LL-Met-1) exhibited increased metastatic potential, a second cycle of selection was needed to obtain a line with a highly metastatic phenotype. Although the process of metastasis selects for metastatic variants, spontaneous metastases per se may vary in their metastatic ability. Therefore, some spontaneous metastases from a poorly metastatic parent tumor population such as the 3LL carcinoma used here or the B16 melanoma (*25*) may not be as highly metastatic as cell populations enriched by multiple selection cycles (*25, 35*).

Evidence that a heterogeneous starting population is required for the selection of metastatic variants is provided by the finding that the cloned, presumably homogeneous, tumor failed to produce metastases with increased metastatic potential (table 4). This observation reemphasizes that growth per se in a metastatic site (lungs) does not confer metastatic properties on tumor cells; i.e., adaptive processes do not play a major role in the development of metastases (*11, 35*).

Several factors can influence the outcome of studies on experimental and spontaneous metastasis (*17*). To obtain reproducible results in assays of metastasis, one must take great care to ascertain that the procedures used to prepare tumor cells for injection do not extensively modify cell membrane characteristics because such modifications may reduce the metastatic capabilities of the injected cells (*17, 35–37*). This situation may partially explain why, in some recent studies, tumor cells obtained after extensive trypsinization of neoplasms produced few metastases when they were implanted iv; these results suggested that metastasis was not a selective process (*7, 8*).

Furthermore, as already stated, to demonstrate a selection process in metastasis, the starting parent tumor must be heterogeneous. Trope (*38*) recently hypothesized [subsequently confirmed by Fidler and Hart (*39*)] that the repeated passage of tumors by trocar implantation of fragments produces tumors that are no longer populated by diverse subpopulations but rather exhibit cellular uniformity. Because the methods of transplantation and culture can profoundly influence the composition of a tumor population, a tumor in one laboratory may not have the same characteristics as the presumably identical tumor in another laboratory. A case in point is the 3LL carcinoma. This tumor has been reported by most investigators to be highly malignant and metastatic (*9, 20*). Yet the 3LL carcinoma variant that we recently obtained was neither. Nonetheless, when metastases produced by this parent tumor were isolated and repeatedly passaged, an increasingly metastatic cell population was produced that may well approximate the variant population used in other laboratories. Because the 3LL carcinoma variant that we obtained was poorly metastatic, we succeeded in demonstrating that the process of metastasis selects for cells with increased metastatic potential (table 4). However, if we had used an already highly metastatic 3LL variant (*9, 20*) as a starting population, further selection for metastasis would have been difficult (*7*).

In conclusion, we have demonstrated that, compared to parent tumor cells, tumor cells from spontaneous metastases, obtained from unselected tumors that are heterogeneous with regard to a metastatic phenotype, have an increased potential to develop experimental and spontaneous metastases. In contrast, metastases from homogeneous (cloned) or already selected tumors vary only slightly from the parent tumor in their ability to form lung colonies. These findings provide direct evidence that the process of metastasis is selective.

Meeting Highlights

Adult T-Cell Leukemia–Lymphoma: Role of a Human Retrovirus[1]

A brief overview was given by Dr. Essex about viruses as potential causes for leukemia and lymphoma in humans, about retroviruses that cause leukemia or lymphoma in animals under natural conditions, and about the general biology of retroviruses. Thus far the only virus that has been clearly shown to be reproducibly associated with any form of human leukemia or lymphoma is the Epstein-Barr herpesvirus (EBV), an agent that has been associated with Burkitt's lymphoma (BL). BL is a monoclonal cancer of B-cells that occurs at elevated rates in children in certain regions of Africa. As with other B-cell tumors, the involved cells of BL have chromosomal abnormalities, usually in the form of a chromosome 8 to chromosome 14 translocation. EBV genome can usually be found in tumor cells taken from African BL patients, but its DNA is primarily in an episomal form rather than in an integrated form.

Several viruses have been shown to cause leukemia or lymphoma in animals. In chickens, mice, cats, cattle, and gibbon apes, retroviruses have been shown to cause one or more forms of lymphoproliferative cancers under natural conditions. In chickens and cattle the lymphoid tumors are primarily of B-lymphocyte origin, whereas in cats and mice they are primarily cancers of T-lymphocytes. In most, and perhaps all, of these cancers the tumors are monoclonal, and analysis by Southern blotting hybridization shows integration of the retrovirus proviral genome at a single site in all cells from the same tumor but at different sites in tumor cells from different individuals whose tumors were caused by the same virus. In all of these species the retroviruses that cause the diseases in question are acquired by horizontal or contagious transmission rather than by genetic inheritance. In selected cases, such as in lymphoid tumors of chickens, the viruses are congenitally transmitted, and in most species it appears that acquisition of the virus very early in life is most likely to result in the establishment of persistent infection.

Most retroviruses have a distinctive "C-type" appearance by electron microscopic evaluation, and they bud from the cytoplasmic membrane of productively infected cells. Their genome containing two complete copies of single-stranded RNA is about 70S, and the buoyant density of the virions is 1.14–1.16 g/ml in sucrose. The RNA replicates through a DNA proviral stage in which virus-encoded reverse transcriptase is used, and integration of proviral DNA into the DNA of the infected cell routinely occurs. The typical retroviral genome is 8–10 kilobases in length, and each end has a "long terminal repeat" sequence which can act as an efficient promoter. Retroviruses have a structure that is characteristic of transposons, and they apparently represent one of the most efficient ways for the natural activation and/or transduction of genes in animal cells. The typical genome has three genes: *a*) *gag*, which is at the 5′ end of the RNA and encodes for a polyprotein that undergoes post-translational cleavage to make the four peptides composing the core of the virion, *b*) *pol*, which encodes for the reverse transcriptase, and *c*) *env*, which encodes for the major virion envelope glycoprotein that protrudes at the surface of the virus, allows adsorption to receptor-containing cells, and serves as a target for virus-neutralizing antibodies.

Little is known about how retroviruses cause leukemia at the molecular level. Replication-defective forms of many retroviruses have been isolated and characterized. Such recombinants have usually acquired or transduced one of a series of highly conserved cell "*onc*" (*c-onc*) genes, which usually allow the virus to transform cultured fibroblasts and cause polyclonal tumors in vivo after very brief latent periods. One possible mechanism by which retroviruses might cause cancer under natural conditions is by the de novo generation of recombinants by replicating competent "helper" viruses. Another possible mechanism, for which some evidence is available in the avian system, is "promoter insertion." In this case, the promoter of the replicating helper virus integrates adjacent to a *c-onc* gene, transcriptionally activates that gene, and the presumed product (demonstrated to be a tyrosine-specific protein kinase in some instances) causes the phenotypic alteration characteristic for the given type of cancer.

Development and Characterization of Human T-Cell Lines

Recognition and characterization of the new human retrovirus, which apparently causes a cancer of mature T-lymphocytes, were made possible by the identification of human T-cell growth factor (TCGF) by Dr. Gallo and his colleagues. TCGF, which was also subsequently isolated in mice (and is referred to as interleukin-2 by some investigators) will allow the continuous proliferation of mature T-cells. This molecule, as purified by Mier and Gallo, is a 13,000-dalton protein that binds to receptors on mature terminal transferase (Tdt)-negative T-cells of the erythrocyte rosette-positive and OKT 4 (helper) positive lineage. TCGF can be used to maintain cultures from tumors of the mature T-cell type, including some cases diagnosed as mycosis fungoides (MF) or Sézary syndrome (SS) and many cases that are classified as adult T-cell leukemia (ATL). Some of the cultures from such tumors subsequently become constitutive producers of TCGF, and in such cell cultures the molecule is present both in the media and on the cytoplasmic membrane. Receptors for TCGF are preferentially expressed after stimulation of the target cells by antigen and/or lectins. The first isolation of the human T-cell leukemia virus (HTLV) was made in Dr. Gallo's laboratory in two lymphoblastoid cell lines established from a patient with a tumor composed of mature T-cells of the characteristic type (*see* below). With the use of TCGF, many lines have now been established in the Gallo laboratory, and at least three established lines are constitutive producers of TCGF.

---

[1] Proceedings of a workshop held at Fred Hutchinson Cancer Center, Seattle, Washington, March 10, 11, 1982.

Dr. Miyoshi described his work on the derivation and characterization of human T-cell lines that contain a type C virus, which is apparently the same virus as or is in the same virus family as is HTLV.[2] Several cell lines were established, usually by the procedure of cocultivating patient's cells with normal cord blood leukocytes. Some cell lines, such as MT-1, are of patient origin, while other lines, such as MT-2, are apparently derived from the infected cord blood cells. Four such lines were described (MT-1 through MT-4). Most grew efficiently as tumors when transplanted into immunosuppressed hamsters. One line that was clearly patient derived had a 14q+ chromosome aberration, whereas another that was clearly of cord blood origin (MT-2) had a normal karyotype. These observations are compatible with a situation in which only the tumor-derived lines have distinct karyotype abnormalities, whereas cultures derived from in vitro immortalization by HTLV would not be expected to have analogous chromosome translocations, at least not until after long-term in vitro cultivation. Although neither TCGF nor mitogens were added to these cultures, it appears likely that most cultures that were maintained on a long-term basis became constitutive producers of TCGF. Such cultures regularly contain virus-related antigens such as the ATL antigen (ATLA), the cytoplasmic antigen (or antigen complex) initially described by Dr. Hinuma using acetone-fixed cell immunofluorescence.

Isolation and Characterization of HTLV

The isolation and identification of HTLV was then discussed in further detail by Dr. Gallo. It appears that, although the virus is T-cell tropic, only a subpopulation of T-cells can be infected and/or transformed by this agent. Thus the types of tumors associated with HTLV are invariably of the mature Tdt-negative, T-cell type, and many cases of tumors diagnosed as MF or SS are not typical of the tumor type that is related to HTLV. Those cases of MF or SS that are related to HTLV appear to be very similar to ATL, are highly malignant, and characteristically involve the skin. Hypercalcemia may also be present, presumably because of osteoclastic factors that are released by the tumor cells.

Features that are characteristic of HTLV include "budding" from the cell surface, a typical 70S RNA, a reverse transcriptase that prefers Mg^{2+} over Mn^{2+}, and characteristic virus structural proteins of about 10,000, 13,000, 19,000, 24,000, 42,000, and 52,000 daltons. The proteins that have been best characterized are the 19,000-dalton proteins, designated p19, for which a monoclonal antibody is available, and the major core protein designated p24. It has apparently been quite difficult to characterize the major envelope glycoprotein of the virion; presumably, the difficulty is because of its extreme instability. This observation may be associated with observations of low infectivity observed for typical virus activity when the preparations are from cell culture supernatants.

By serologic analysis of the virion structural proteins and reverse transcriptase activity as well as by nucleic acid hybridization, HTLV is clearly distinct from other known retroviruses, both ecotropic and xenotropic. This list includes various other primate retroviruses, such as the gibbon ape leukemia viruses and the endogenous retroviruses of baboons. Clearly, p24 and p19 are viral proteins in that they co-purify with viral cores and have characteristics similar to those of other retroviral *gag* proteins, such as the distinctive primary amino acid sequence that begins with proline and ends with isoleucine, as is true for p24. Antisera to p19 and/or p24 react efficiently with HTLV-infected lines, including the MT-1 line of Miyoshi, but such antibodies do not react with other noninfected human cells.

The retrovirus that is apparently the closest known relative to HTLV is the bovine leukemia virus (BLV), which causes enzootic leukosis, a B-cell tumor that occurs in cattle throughout the world. Although BLV and HTLV are clearly only related in a very distant sense, common characteristics include *a*) a *gag* protein (i.e., p24) that is comparable in size for BLV and HTLV but is somewhat different in size from most other retroviruses, *b*) a reverse transcriptase that prefers Mg^{2+} over Mn^{2+}, and c) a relative inefficiency for production as extracellular virus, at least in relation to other ecotropic (as compared to xenotropic) retroviruses. Finally, recent studies by Oroszlan, Gallo, and their coworkers indicate distant relatedness between the primary amino acid sequences of the major core protein (p24) of HTLV and BLV.

One of the most important features of HTLV, as stressed by Dr. Gallo, is the fact that it is not genetically inherited because normal human cells (including uninfected tissues from infected patients) do not contain any recognizable sequences related to the virus. This implies that the virus must be acquired horizontally, i.e., as a contagion. The presence of antibodies to HTLV both in patients and in healthy controls that are known either to have been exposed to cases of ATL or to have been exposed to endemic ATL regions and the absence of antibodies in people from nonendemic regions are also compatible with this observation.

Dr. Yoshida then described his studies on the isolation and identification of the HTLV-related virus found in the two cell cultures designated MT-1 and MT-2. As indicated above, these viruses all appear to be either closely related or identical. Dr. Yoshida presented comparable data on the biochemical and biophysical characteristics of the Japanese isolate from MT-2, as well as presented preliminary data on the preparation of a molecular clone of a provirus from the MT-1 cell in the Charon 4a vector. An exciting observation made by Dr. Yoshida was that provirus is apparently found integrated in a single site for all the cells in a given tumor, but provirus is integrated in different sites in tumors taken from different individuals. Those experiments, done by Southern blotting hybridization, yielded results similar to those seen when avian or bovine retroviruses caused long latent-period lymphomas or leukemias that also appeared to arise as a clone of a single altered cell. Using a DNA probe made from virion RNA, Dr. Yoshida found single-copy integration in T-tumor cells from 5 cases of ATL. Although only one DNA band was seen in each tumor, the bands varied in size from one tumor or patient to the next, indicating that the site of integration was different in each case. In some cases, cells from both parents of the patient were also examined and found to be negative, which is compatible with the observation that the virus is not even genetically transmitted in restricted families. In most instances, control (non-T) cells from the same patients did not reveal evidence of provirus, but in one patient the granulocytes also appeared to be infected. The virus was found in multiple sites in the MT-1 and MT-2 cell cultures. The observation that HTLV is integrated in a single site in all the cells of a given tumor implies that the virus was present before the tumorous process began, and the observation contributes substantially to the argument that this virus may be the causative agent of ATL.

---

[2] For simplification, the term HTLV will be used in this report for the designation of all the different human retrovirus isolates found in tumors of the mature T-cell type. Although it is recognized that all of these isolates have not been cross-checked by serologic and/or molecular hybridization, those that have been checked appear to be closely related to the original isolate which was designated HTLV. It is also recognized that some investigators may prefer a different designation for some of the agents subsequently identified by the Japanese investigators, but it appears that such wording would introduce unnecessary confusion in this report, which is *not* intended as a policy statement on issues of nomenclature.

Dr. Reitz then presented nucleic acid hybridization data on various human preparations. Using HTLV–cDNA to explore HUT-102 cells, Dr. Reitz described the first T-cell tumor line of this type as having 2 or 3 copies of proviral DNA per cell. No comparable sequences were found in B-cells or in other tissues from either the patient or other healthy people, indicating a horizontal infection. High levels of mRNA are also found to be expressed in the tumor cells. Using hybridization kinetics, Dr. Reitz found that the HTLV sequences present in HUT-102 were very similar or identical to those in the MT-1 cell culture derived by Dr. Miyoshi from a Japanese ATL patient. The patient that yielded HUT-102 was a 28-year-old black from the Southeastern United States. Using nucleic acid hybridization, Dr. Reitz and his colleagues found comparable closely related viral sequences in tissues from several other non-Japanese patients with the same tumor type including a black male from the Caribbean and a white male from Boston. Using both serologic procedures and nucleic acid hybridization, members of Dr. Gallo's group have now identified tumor cases from various areas of the world in which infection with HTLV has occurred. These include, in addition to Japan, the Eastern United States and the Caribbean, the Western United States, the Middle East, and South America. Dr. Reitz also briefly presented preliminary information from Dr. Manzari and Dr. Wong-Staal in Dr. Gallo's laboratory about the molecular cloning of the 5′ proximal viral sequences, representative of the U5, R, and *gag* gene regions, in the PBR-322 plasmid.

In Vitro Immortalization

Dr. Miyoshi then reviewed his studies on "transformation" or "immortalization" of human cord blood lymphocytes with HTLV. His results were that both adult and cord blood lymphocytes could be immortalized with a very high rate of success if they were cocultivated with MT-2 cells that had been lethally irradiated. The infected target cells subsequently became immortalized but did not show karyotypic changes, at least not soon after establishment of the new cultures. Most of the newly infected cells were positive for the ATLA; the proportion of cells positive for this antigen increased from between only 2 and 3% soon after cocultivation to nearly 100% after a month of cultivation. Whether this was because of a selective growth advantage of the cells that were initially infected or because of subsequent infection of uninfected cells is unclear. It was clear, however, that high efficiency of infection or immortalization could only be achieved by cocultivation as opposed to inoculation with "cell-free" virus and that the MT-2 culture appeared to be the best donor cell for these experiments. Some of the newly established cultures revealed "hairy cell" processes, suggesting that alterations in phenotype had also occurred.

Dr. Hinuma then presented related studies on in vitro immortalization of peripheral blood lymphocytes in which he also found that a high degree of successful immortalization could be effected with MT-2 as the donor. More than 90% of the cells were positive for HTLV antigens 2–4 weeks after cocultivation with lethally irradiated donor cells. The infected recipient cells had a phenotype of positivity for Leu 1, Leu 3a, and Leu 4 and of negativity for Leu 2a. About 50% of the cells were positive for Ia antigens, and cell fusions could be observed in the cultures, which is compatible with the possibility that transmission of this virus might only occur with high efficiency during cell-to-cell contact. This manner of infection with HTLV might also be analogous to that seen with BLV because BLV is known to be poorly infectious when in the cell-free form but is efficient at inducing a syncitial-type effect in sensitive target cells. It seemed likely that two key elements of the successful infection and immortalization of cord blood cells was the virus of MT-2 origin and the cocultivation procedure. Dr. Gallo also mentioned that some of the more recent isolates in his laboratory have a greater potential for infectivity than has the original HUT-102 isolate.

Clinical Pathologic and Cytogenetic Aspects

The syndrome called ATL was initially recognized as a distinct clinical entity and was described as such by Dr. Takatsuki. He briefly described the syndrome at this meeting. It is characterized by mature T-cells but is distinct from many cases of SS. ATL occurs in adults whose mean age is about 50 years. Cutaneous infiltration is frequent, the rate of disease progression is rapid, and the survival rate is low. The disease clearly occurs most frequently in Kyushu, and many Japanese cases that occur outside this area can be traced back to an origin (i.e., of virus exposure) in Kyushu. Most but not all cases are characterized by hepatomegaly, splenomegaly, and lymphadenopathy. Anemia is not a characteristic feature of this disease, and immunoglobulins are usually within normal limits. Although the rates of ATL are not high (perhaps 100 cases/year in all of Japan), the proportion of adult leukemias that are T-cell is higher in Japan than in most other areas of the world.

Cytogenetic abnormalities are seen in many cases of ATL. These abnormalities were described by Dr. Takatsuki and Dr. Miyoshi and include nonrandom occurrences of trisomy 7 and of translocations producing a 14q+. Dr. Nowell pointed out that trisomy 7 does not appear to occur nonrandomly in other human tumors, including cutaneous T-cell lymphomas in the United States. Translocations involving chromosome 14, producing a 14q+ anomaly, however, are common in B-cell neoplasms and are present in some cases of T-cell chronic lymphocytic leukemia. They apparently involve the immunoglobulin heavy chain gene. Detailed chromosome data are not available on non-Japanese T-cell tumors that are HTLV-positive.

The most consistent surface phenotype is OKT $1^+3^+4^+$-$10^+11^+5^-6^-8^-$ and Ia^+ or Ia^-. Although this antigenic phenotype is normally associated with helper–inducer T-cells, in vitro some ATL cells show a suppression of immunoglobulin synthesis by normal B-cells.

Histopathologic and cytologic criteria for the recognition of ATL were discussed by Dr. Hanaoka, Dr. Jaffe, and Dr. Kadin. The presence of at least 10% multiply lobate or pleomorphic cells in the peripheral blood is characteristic, but a leukemic component may be absent in as many as 40% of the cases. The histopathology in lymph nodes is varied, but a similar spectrum was encountered in cases from Southwestern Japan, the Caribbean, and the United States. Histologic forms of ATL documented as occurring in association with positive serology for HTLV include *a*) the pleomorphic type, which is most frequent; *b*) the large cell type; *c*) the mixed cell type; and *d*) the medium-sized cell type. At this time, however, no cytologic or histologic features pathognomonic of viral association have been demonstrated.

In nearly all instances, ATL can be distinguished clinically and pathologically from the cutaneous T-cell lymphomas (CTCL), i.e., MF and SS. Still cases are unquestionably positive for HTLV, both by serology and viral isolation, in which, clinically and pathologically, the disease is more compatible with CTCL. Further studies correlating virology, histopathology, immunology, and clinical features will be necessary for further definition of the spectrum of HTLV-associated T-cell cancers.

Epidemiology

Dr. Blattner discussed seroepidemiologic studies with patients and controls from various areas of the world. He described about 10 cases of ATL from the West Indies from a study conducted with Dr. Catovsky and his co-workers. In most if not all cases, antibodies that reacted with HTLV antigens were found in sera from such patients. In most cases antibody titers were determined by radioimmunoassay to the p24 and p19 gag antigens and to cell-surface antigens by immunofluorescence. In essentially all cases there was agreement among the different procedures, and, if antibodies were present at all, they were usually present for all the antigens.

Dr. Gallo and Dr. Blattner subsequently presented serologic data for a large series of ATL and other tumor cases as well as for numerous controls. More than 90% (32/35) of the cases of typical ATL appeared to have antibodies to HTLV. Individuals with other forms of lyphoreticular neoplasms were sometimes positive for such antibodies, with various forms of T-cell cancers of a similar type having the next most frequent rate of positivity. Samples from 86 U.S. individuals with other types of neoplasms were negative. Natural antibodies to p24 were found in about 30% of the healthy relatives of ATL patients and in about 12% of the healthy donors from endemic ATL regions of Japan. About 3–5% of the healthy donors from the Caribbean area had such antibodies. Sera from approximately 180 healthy U.S. donors and approximately 800 healthy European donors were negative for such antibodies. The geometric mean antibody titers to the HTLV p24 were about the same for the antibody-positive ATL patients when compared to the antibody-positive healthy people, whether these antibody-positive people were ATL-exposed relatives of patients or were people from the endemic ATL regions.

Dr. Hinuma also presented data on the serologic screening of ATL patients and healthy controls for antibodies to ATLA, the cytoplasmic antigen that is specific for HTLV as expressed on MT-1 cells. Dr. Hinuma found that sera from 140 of 142 patients with ATL had antibodies to ATLA and that most cases of other T-cell cancers from the endemic ATL area also had such antibodies. When sera from healthy controls older than 40 years and from various areas of Japan were checked, a close association was found geographically for the Kyushu area and the presence of ATLA antibodies. Although very few of the healthy people were antibody-positive in most areas distant from Kyushu (i.e., 0/74 in Sendai, 0/60 in Yamagata, 0/74 in Kyoto, and 1/56 in Sapporo), about 25% of the healthy people from the Kyushu region had such antibodies. These results indicate a close correlation between ATL in Japan and the presence of antibodies to ATLA. A limited number of samples from healthy adults of several other countries were also screened. With the exception of Taiwan, where 2 of 40 healthy people were ATLA antibody-positive, individuals from most other areas in the Orient appeared to be negative for such antibody activity.

Finally, results presented by Dr. Miyoshi and Dr. Hinuma suggested that HTLV antigen-positive cells and/or that active virus was present in the small number of antibody-positive people who were analyzed for ATLA and/or for the ability of their cells to infect cord blood lymphocytes by cocultivation. Although these results are preliminary, they obviously raise the possibility that most antibody-positive healthy people may be virus carriers.

Summary and Conclusions

Clearly, HTLV is highly associated with the development of an extremely malignant leukemia of mature T-lymphocytes, which has been classified as ATL in Japan but has not been as clearly and consistently classified as a distinct clinical entity by other reporting countries. HTLV, the agent initially discovered by Dr. Gallo and his colleagues, appears likely to be the cause of this disease. On the basis of both epidemiologic and molecular considerations, the association between HTLV and this particular clinical entity appears at least as strong as, and probably stronger than, the association between any other human cancer and a particular viral agent (including the association between EBV and BL or the association between hepatitis B-virus and primary liver cancer). Although the disease associated with HTLV is clustered in southern Japan and in the Caribbean, both the disease and the agent have been found in various areas of the world. The virus is clearly contagious, even though it has a low degree of infectivity by cell culture analysis. The exact mechanism of infection and the source of virus are unknown. The possibility of transmission by blood transfusion has been suggested, but the frequency of exposure in the population of endemic areas (≤25% of the adults) is obviously too high to be explained solely as a transfusion-related event. The possibility that an animal reservoir may exist has also been suggested. If, however, a significant number of the antibody-positive healthy people are indeed carriers with latent infections, this carrier population would be an adequate reservoir for the maintenance of HTLV in the human population, and no vector or outside animal reservoir would be needed.

In "Enhancement of Experimental Pancreatic Cancer in Syrian Golden Hamsters by Dietary Fat," by Diane F. Birt, Shahrokh Salmasi, and Parviz M. Pour, page 1328, footnote *b* in table 2 should read: Teklad vitamin mix (catalog #40060) at 1.5 g/385 kcal supplies in the final diet in mg/385 kcal: 16 *p*-aminobenzoic acid; 149 ascorbic acid; 0.07 biotin; 0.0045 vitamin B_{12}; 10 calcium pantothenate; 214 choline; 0.3 folic acid; 16 inositol; 7.4 menadione; 15 niacin; 3 pyridoxine HCl; 3 riboflavin; 8 thiamine HCl; and in units/385 kcal: 2,974 vitamin A palmitate; 330 vitamin D_2; 18 vitamin E acetate.

April 1982, vol 68, No. 4

In "Mechanisms of Immunologic Eradication of a Syngeneic Guinea Pig Tumor. I. Quantitative Analysis of Adoptive Immunity," by Suyu Shu, James T. Hunter, Herbert J. Rapp, and Leila S. Fonseca, page 678, second column, the period should be deleted at the end of line 6 and lines 7–11 should read, ". . . rejected. These data suggest that suppression of id line-10 tumor challenges by the transferred immunity in guinea pigs was independent of development of systemic immunity in the recipients. However, ..." Also, near the end of line 16 in the second column, "py" should read "by."

Announcements

The Journal *will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.*

Formaldehyde Toxicology Meeting

Washington, D. C., will be the site of this meeting to be held at the Washington Hilton Hotel on November 3, 1982. The meeting will enable scientists to present work on formaldehyde toxicology research that has been carried out since the 1980 CIIT conference. Scheduled speakers will present recent research in the areas of mechanisms of toxicity, protective mechanisms, epidemiology, classical toxicology, and risk assessment.

For additional information, complete program, and registration materials please contact the Formaldehyde Institute, 1075 Central Park Avenue, Scarsdale, New York 10583 (telephone: 914-725-1492).

Symposium on Application of Biological Markers to Carcinogen Testing

The U. S. Environmental Protection Agency will sponsor this symposium to be held at the Holiday Inn, Bethesda, Maryland, on November 15–19, 1982. This symposium will discuss the current status of biochemical and immunological markers to carcinogenicity with three main objectives: to review and update specific markers, to identify data gaps, and to recommend research goals. Sessions will encompass in vivo and in vitro antibodies, viruses, and DNA-adducts. Abstracts for poster sessions will be accepted until October 15, 1982.

For additional details please contact Ms. Claire M. Wilson, Associated Universities, Inc., Suite 603, 1717 Massachusetts Avenue, N. W., Washington, D. C. 20036 (telephone: 202-462-4475).

Eighth Annual Postgraduate Course

"Ultrasound for Clinicians" is the title of this course being offered by the Department of Radiology, Brigham and Women's Hospital, and the Department of Continuing Education, Harvard Medical School, on February 28–March 2, 1983. AMA Category I Credit is for 22.5 hours; Dr. David C. Grant is Program Director.

For additional information please contact the Department of Continuing Education, Harvard Medical School, 25 Shattuck Street, Boston, Massachusetts 02115 (telephone: 617-732-1525).

Seventh Annual Meeting of the Cell Kinetics Society

The Hilton Hotel in Baltimore, Maryland, will be the site of this meeting to be held on March 16–19, 1983. The Cell Kinetics Society has an international membership of approximately 300 experimentalists, clinicians, and mathematical modelers who share an interest in the cell proliferation patterns of normal and abnormal tissues.

Inquiries concerning this meeting or membership should be directed to Dr. Bruce F. Kimler, Secretary, Cell Kinetics Society, Department of Radiation Therapy, University of Kansas Medical Center, Rainbow Boulevard at 39th Street, Kansas City, Kansas 66103.

First International Meeting on Cell Biochemistry and Function

The new journal entitled *Cell Biochemistry and Function* (first issue April 1983) will sponsor this meeting to be held at the University of Surrey, Guildford, England, on March 23–25, 1983. The scientific program will include lectures by invited speakers and poster papers covering the following topics: enzymes and receptors in context; cellular transport; special techniques for the investigation of materials and activities within functioning whole cells; diagnostic procedures involving whole cell preparations; carcinogenesis; and pharmacology and toxicology.

For further details please write to Ms. Stella A. Dutton, Butterworth Scientific Limited—Journals Division, P.O. Box 63, Westbury House, Bury Street, Guildford, Surrey GU25BH, England.

The Fourth Annual Meeting of the Society for Clinical Trials

The organization of the Society for Clinical Trials will sponsor this scientific session to be held in St. Louis, Missouri, on May 8–11, 1983. The sessions will focus on the design, organization, management, and analyses of clinical trials. Abstracts for contributed papers must be received by January 1, 1983.

For additional information please write to Dr. Christian R. Klimt, Secretary, Society for Clinical Trials, Inc., 600 Wyndhurst Avenue, Baltimore, Maryland 21210.

Thirteenth International Congress of Chemotherapy

Vienna, Austria, will be the site of this meeting to be held at the Kongresszentrum-Hofburg on August 28–September 2, 1983. The scientific program will consist of lectures, symposia, round table sessions, and free papers with posters focusing on antimicrobial and anticancer topics.

December 31, 1982, is the deadline for registration. The deadline for submitting manuscripts for final publication is April 30, 1983. For further information please contact Professor K. Karrer, Institute for Cancer Research, University of Vienna, Borschkegasse 8a, A-1090 Vienna, Austria, or Secretariat of the Thirteenth International Congress of Chemotherapy, % Wiener Medizinische Akademie, Alser Strasse 4, A-1090 Vienna, Austria.

Journal of the National Cancer Institute

November 1982
Volume 69
Number 5

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department. Use of funds for printing this periodical has been approved by the Director of the Office of Management and Budget through August 30, 1985.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price per copy, $7.00. Subscription price for two volumes per year in the United States, $70.00; foreign, $87.50. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20816.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20816.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAPS facilities should indicate in a footnote how their additional data may be obtained.

Approximately one-half of all manuscripts submitted to the Journal are accepted for publication. Publication of manuscripts is contingent on transfer of copyright to the Journal. Forms for this purpose will be sent to authors when a manuscript has been approved for publication. All material published in the Journal is in the public domain; therefore, permission to reproduce any portions is not necessary. As a matter of courtesy, communication should be made to the author(s) concerned.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, noninbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols; *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Biochemical Nomenclature and Related Documents* (IUB, 1978) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1978) of the IUB for recommended names of enzymes and information on nomenclature of isozymes; *The Merck Index* (9th ed) for chemical compounds; "Standard Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40: 2083–2128) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221–245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends, and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs.* Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Medicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3–10/Ann Intern Med 1979;90:95–99/Br Med J 1979;1:532–535/ or Lancet 1979;1:428–430).

The Serum Cholesterol–Cancer Relationship: An Analysis of Time Trends in the Framingham Study[1]

Paul D. Sorlie, *M.S.*,[2] *and* **Manning Feinleib**, *M.D., Dr. P.H.*[2,3,4]

ABSTRACT—Time trends in serum cholesterol were analyzed in the Framingham Study data to determine whether low serum cholesterol, which appears to be associated with increased cancer risk, can truly be called a precursor to the development of the disease. Serum cholesterol measured at base line was found to be associated with the risk of both fatal cancer and all cancers occurring in the subsequent 18 years in men ($P<0.05$). This inverse association seems particularly strong for colon cancer in men. Analysis of time trends in the Framingham data did not yield consistent results for all ages. Men 50–59 years old had a statistically significant lower serum cholesterol measured 16–18 years before cancer diagnosis. For men 60–65 years old, a statistically significant trend toward lower serum cholesterol was apparent as measurement was made closer to the time of cancer diagnosis. Although the Framingham data are not conclusive, they do suggest that in some cancer cases where the serum cholesterol level was lower than that expected at as much as 16–18 years before cancer diagnosis, the depressed level was likely to be a precursor to the tumor growth. However, consistent with the metabolic consequences of tumor growth, the data show that in some cancer cases, serum cholesterol had decreased at measurements made close to the time of cancer diagnosis.—JNCI 1982; 69:989–996.

Of the many analytical complexities encountered in the study of the relationship between serum cholesterol and cancer, one of the most difficult is the ascertainment of the temporal relationship between the presence of low serum cholesterol and the onset of the clinical manifestations of cancer. The relationship between the level of base-line serum cholesterol and subsequent cancer death has been described in recent publications (*1–10*). Two of them present evidence suggesting that low serum cholesterol is caused by metabolic disturbances resulting from the cancer process, inasmuch as the relationship seemed strongest when death occurred shortly after the measurement of cholesterol (*1, 2*). To accurately understand the changes in serum cholesterol that precede cancer, we would need to know the time and course of cancer from its beginning as abnormal cell division to its discovery as a malignant tumor. Because this early process is largely unknown, the interpretation of the observed cholesterol changes with time is largely subjective. Does the low serum cholesterol "precede" the cancer if the cholesterol level is found to be lower 2 years, 5 years, or 10 years before clinical onset of disease? Perhaps a lower level for 20 years is required before it can be reasonably determined to be a precursor.

In one respect, the Framingham data are quite well suited for analysis of serum cholesterol in the preclinical stage of cancer. Data are available for nine repeat measurements of serum cholesterol up to 18 years before cancer diagnosis. In another respect, however, the Framingham data are lacking. Inasmuch as the Framingham Study was designed to collect data on coronary heart disease cases, the number of subjects who developed cancer was generally small, particularly when analysis by specific site is required.

MATERIALS AND METHODS

The Framingham Study examined a cohort of 5,209 men and women at biennial intervals, with the first examination covering the period 1948–52 (*11*). Serum cholesterol was routinely measured by the method of Abell-Kendall for examinations 2–10. At examination 1 a colorimetric method was used, at examination 11 the analysis was made on plasma and not serum, and at examination 12 blood was not drawn. For analysis of time trends in serum cholesterol, the cholesterol values determined at examinations 2–10 were used. At examination 4, alcohol usage and smoking histories were recorded in addition to the routine data collection. Thus some of the analyses in this paper use examination 4 records as the base-line data.

To determine which subjects developed cancer in the course of our study, a detailed review of all 5,209 records was undertaken, and any record that contained mention of a tumor or cancer was reviewed extensively by a physician. Information was then abstracted on cancer site, histologic type, date of diagnosis, method of diagnosis, and other relevant information. Pathology data were requested by mail, telephone calls, or personal visits. As reported earlier (*5*), histologic confirmation was available for 94% of the cancer cases. The distribution by cancer site was similar to that found in the Third National Cancer Survey (*12*). A total of 691 cancer cases were detected up to the 13th cycle of examinations, 629 by histologic confirmation, 39 by nonhistologic confirmation, and 23 with uncertain confirmation. (The 23 cases were not included in the analysis.) The number of cancer cases in each table varies depending on which base line and follow-up was required for the analysis. Cancer incidence cases consist of fatal and nonfatal cases, and cancer mortality was determined from the number of cases in which the underlying cause of death was ascribed to cancer.

Incidence rates of cancer in 18 years were calculated by five levels of serum cholesterol (not quintiles) and by sex and age groups [35–44, 45–54, 55–64, and 65–69 yr (tables 1, 2)]. These rates were age adjusted by the indirect method,

[4] We are grateful to Dr. Roger Williams, Ms. Patricia McNamara, and Ms. Adele Rosenthal for their thorough collection and review of the Framingham records for cancer.

with the total Framingham cohort used as the standard population. Trends in these rates were estimated according to the maximum likelihood estimates of the logistic function regression (*13*). To examine time trends in serum cholesterol in relation to the onset of cancer, mean differences between cancer cases and noncases were calculated for each examination. The mean difference by time before cancer diagnosis was estimated by a crude pooling of the separate mean differences and by a maximum likelihood method to combine differences, as described by Truett and Sorlie (*14*). With the Truett method, statistical testing of overall differences and time trends in the differences can be made.

RESULTS

The age-adjusted relationship between serum cholesterol and cancer morbidity and mortality is shown in table 1. From values for base-line serum cholesterol at examination 4 and from data on 18 years of subsequent cancer incidence (through examination 13), a significant inverse relationship is seen in cancer mortality for men in particular and for all cancer cases in general. The population at risk in tables 1 and 2 was free of any clinical evidence of cancer at examination 4. The principal elevation in risk occurs in those men with serum cholesterol below 190 mg/dl. Although this trend is not statistically significant in women, they, too, show an elevation in risk when the cholesterol level goes below 190 mg/dl. The trends are similar for fatal cancer and for all cancer in the 18-year follow-up from examination 4.

The difficulties in using a cardiovascular study to analyze cancer incidence become obvious when specific cancer sites are investigated. Only cancers of the three major sites (breast, lung, and colon) approached the number required for meaningful analysis. The age-adjusted cancer incidence rates by site are presented in table 2. Only colon cancer in men shows a statistically significant inverse gradient of risk. Again, the data for women do not show this relationship.

TABLE 1.—*Cancer mortality and morbidity rates,*[a] *by serum cholesterol level, age adjusted for men and women aged 35–69 years: Framingham Study*

Serum cholesterol, mg/dl	Men			Women

[a] Age-specific incidence rates 18 yr after examination 4; adjusted by indirect method.

[b] Trend tested by means of logistic function coefficients; serum cholesterol level and age were the independent variables. NS=not significant.

In an earlier publication on cancer in Framingham (*5*), multiple logistic function coefficients were presented to show that the relationship between serum cholesterol and cancer persisted even after multivariate adjustment for age, alcohol, cigarette consumption, education, systolic blood pressure, and relative weight.

In the preceding analysis, several factors could be presented to refute the hypothesis that low serum cholesterol merely reflects existing disease: 1) The analyses were all performed on data for a population free of any clinically recognizable cancer. Furthermore, cancer cases diagnosed within 3 months after the routine examination were excluded as prevalence cases because the initial suspicion of cancer may have originated at the examination. 2) The analysis used incidence cases that occurred up to 18 years after base-line measurements of cholesterol. Very few cases occurred in the first 4 years of the follow-up. 3) The lack of a relationship between cholesterol level and cancer incidence in women would argue against the above hypothesis, because the assumption reasonably can be made that once the cancer process begins, the metabolic consequences for men and women would be similar, particularly for the same cancer site, e.g., colon cancer.

To describe the time at which cancer subjects began to show lower than average serum cholesterol values, mean values of cholesterol were tabulated for subjects with and without cancer at all examinations between 2 and 10. Detailed tables for all age and sex groups are presented in tables 3–10. The data are presented in detail so that the reader can evaluate the unadjusted as well as the adjusted results.

Tables 3–10 have the following format: The mean value and standard deviation of serum cholesterol (first row) are shown for measurements made at examinations 2–10 for those subjects who were free of cancer throughout the time period. All subsequent rows show the difference in mean serum cholesterol between subjects with and without cancer. The second row shows the mean difference for those subjects who developed cancer at examination 3 (i.e., between ex-

aminations 2 and 3) and for these subjects only the difference in cholesterol at examination 2 is tabulated. The third row gives data for those who developed cancer at examination 4, and their differences at examinations 2 and 3 are tabulated. This sequence proceeds to the last row, which shows the differences (cases minus noncases) at examinations 2–10 for those individuals who developed cancer between examinations 10 and 11. All of these subjects had to have known serum cholesterol levels at all examinations prior to evidence of cancer. Thus a row, from left to right, will show the change in cholesterol in exactly the same cohort of individuals as it was measured closer to the time of the cancer diagnosis. A column, from top to bottom, will show the variation in a measurement at a single examination for individuals in whom cancer became evident at a time more distant from the examination.

Because the largest cohort of cases is only 14 cases (table 5) and because there is considerable inter- and intra-individual variability, the mean differences need to be combined to make more stable estimates. Those mean differences on the diagonal, from upper left to lower right, form those measurements that were made just before the discovery of cancer, i.e., within 0–2 years. On the next diagonal are those differences in measurements made 2–4 years before diagnosis

of cancer. Finally, the last mean difference is shown in the lower left hand corner—the difference determined 16–18 years before the cancer event.

In a crude sense, an overall mean difference can be determined by combining the mean differences along the diagonal, multiplying the number of cases by the mean value, adding these products, and then dividing by the total number of cases. This yields a rough estimate of the differences between cases and noncases by distance from the event. These differences are shown in tables 11 and 12 under the heading "crude estimates." Another method for combining these differences was described by Truett and Sorlie (*14*) and derives maximum likelihood estimates by means of a more elaborate weighting by the variance-covariance matrix. These estimates are also presented in tables 11 and 12 and were computed from mean differences when at least 2 cancer cases were among the cohorts (indicated by the rows in tables 3–10).

The Truett method also includes statistical tests of the estimated differences and also tests whether a trend exists in the differences as a function of time to the event (tables 11, 12). Differences at each interval before diagnosis were tested for statistical significance from zero and are indicated in tables 11 and 12 by asterisks. The statistic for heterogeneity indicates whether significant variation occurs in the differences by interval of diagnosis, and the trend statistic tests indicate whether a linear trend is present in the differences by time interval to diagnosis.

For younger men aged 30–39 years, there appears to be a trend from positive differences to negative differences as the measurement was made closer to the time of cancer diagnosis. This trend is not statistically significant ($P<0.10$). For men aged 50–59 years, a statistically significant difference is seen between those with and without cancer at as much as 16–18 years before cancer diagnosis. No evidence of a trend is apparent in the difference as these men were measured closer to the time of cancer diagnosis. For older men aged 60–65 years, there is a significant trend for differences that change from a large positive difference 18 years before cancer diagnosis to a slightly negative difference just before the event.

For women the results are quite mixed. Women 30–39 years old had significantly lower cholesterol levels when measured 14–16 years before cancer diagnosis. In the age group 40–49 years a significant trend from large differences to small differences was apparent. In the older women, 60–65 years old, 2 subjects showed markedly reduced cholesterol levels.

The Truett method of analysis has a fairly stringent requirement that all measurements before cancer diagnosis be known. A bias could be caused if the measurements for cancer subjects who missed examinations were different from the measurements for those who took the examinations. The mean differences were compared for those subjects with known cholesterol values for all measurements before the disease and for all subjects without these requirements. However, aside from variation due to the small number of cases, no evidence exists that exclusion of those cancer cases with missing values would bias the results in any appreciable way.

The analyses by Cambien et al. (*1*) and Rose and Shipley (*2*), which show that the relationship disappears after removing cancer cases that occurred soon after measurement, are investigating the effect of the first vertical column of tables 3–10. In the Framingham data, removal of the cancer cases that became evident at examinations 3 and 4 in any of the age–sex groups would have no real effect on the overall difference computed from the vertical column. One difficulty in analyzing the columns is that they are composed of single individuals, thus emphasizing the inter-individual variability. The rows, however, contain only the variability from intra-individual and examination sources.

DISCUSSION

The data from the Framingham Study presented in this paper show elevations in cancer incidence primarily at low levels of serum cholesterol (<190 mg/dl) (table 1). There appears to be a gradient in incidence above that level, but it is very slight. Women also show an elevation in incidence at these low levels, but the gradient is not statistically significant. The evidence of a threshold effect and its precise location in other studies are difficult to quantify inasmuch as the methods for cholesterol measurement are so variable. However, a strong impression is conveyed that the largest elevation in risk appears for those with serum cholesterol below 190 mg/dl in the Paris study (*1*), those below 193 mg/dl in the Maoris–New Zealand study (*3*), those below 195 mg/dl in the Puerto Rico study (*7*), and those below 180 mg/dl in the Hawaii study (*8*). The studies from Sweden (*6*) and Whitehall, England, (*2*) show a more steady gradient of risk. All of these studies used the determination of cholesterol in the serum, with the exception of the Whitehall study which used plasma cholesterol.

As stated earlier, the findings of two of those studies show that the gradient of risk is largely attenuated when adjustment is made for mortality occurring soon after the baseline cholesterol measurement (*1, 2*). However, several other studies have analyzed the data by time between measurement and cancer death and found that the relationship still exists (*3, 4, 7, 8*). The Framingham data provide evidence that both hypotheses are true to some extent. Low cholesterol is likely to be both a precursor and a response to the cancer process. In some age–sex groups, the Framingham data show clear evidence that cholesterol levels are depressed in cancer cases at as much as 18 years before cancer diagnosis. In other age groups, a trend is apparent for the cholesterol level to become more depressed as the subjects were measured closer to time of cancer diagnosis. Whether these age differences represent real age effects or sampling variability is difficult to say.

Although the lack of consistent results between studies is disconcerting, it should not be too surprising. These studies were not designed in size to study cancer. Obviously, this will result in greater variability of the estimated relationships and less consistent results. Variations in the nature of the studies may also explain the differences. Some of the studies used the cause of death coding of the death certificate, others reviewed all available information to determine cause of deaths, and in others ascertainment of nonfatal cancer was also made. Some of the studies used a fairly representative population sample, but others used occupational cohorts that would have been selected more likely according to healthy status.

There are several possible explanations for the cancer–cholesterol relationship. The first is that low serum cholesterol is a result of existing cancer in the preclinical stages. In the Framingham Study and in several other studies there is evidence that cholesterol levels *in part* are related to the time course of the disease, and this evidence is consistent with the alteration of the cholesterol level by cancer. This consistency is contingent, however, on a model of cancer pathogenesis that describes cancer as a long-term insidious process that may linger in a preclinical state for many years. In that event, low serum cholesterol might serve as a "marker" for preclinical malignant tumor growth. However, most oncologists would be reluctant to accept that a metabolically active lesion would remain preclinical for 10 or more years.

A second possible explanation is that serum cholesterol is a covariate to some other factor that plays a more primary role in cancer development. If there is such a factor, it apparently would not be any of the variables analyzed in the studies listed above. The factors of smoking, alcohol consumption, relative weight, or socioeconomic status do not explain the cholesterol relationship. Possibly, the one consistency in these studies is that the results are still strong after multivariate adjustment. Other important covariates have been postulated, including the relationship between vitamin A, cholesterol, and cancer (*15*).

A third possible explanation is that low cholesterol has a direct etiologic relationship with cancer. At present, however, the biologic plausibility of the cholesterol relationship is moot. A sound hypothesis implicating low serum cholesterol as an initiator or promoter of carcinogenesis has yet to be found. However, the population studies described above present sufficient positive evidence to encourage researchers to evaluate the role that cholesterol may play, if any, in the genesis or promotion of malignant tumor growth.

Reactivity in Neoplasia, Preneoplasia, and Pregnancy of Lymphocytes Against Fetal Extracts: Cross-Reactions Between Man and Mouse[1, 2]

Günter Pasternak,[3] Bernhard Schlott,[3] Jürgen Reinhöfer,[3] Günter Gryschek,[3] Bodo von Broen,[3] *and* **Sybille Albrecht[3, 4]**

ABSTRACT—KCl extracts (3 *M*) from human fetuses were tested by macrophage electrophoretic mobility (MEMB), leukocyte migration inhibition, and/or leukocyte adherence inhibition techniques against lymphocytes-leukocytes from tumor-bearing humans and control persons. A positive MEMB test was found in 209 of 284 (73%) patients with various types of clinically manifest tumors. Only 15 of 134 (11%) controls gave a positive reaction by the MEMB test. Leukocyte migration was significantly inhibited in 48 of 64 (75%) tumor patients, and leukocyte adherence was significantly inhibited in 40 of 50 (80%) tumor patients versus 7 of 50 (14%) and 10 of 54 (19%) in the corresponding controls. Lymphocyte reactivity to fetal extracts is also detectable in inbred XVII/Bln, CBA/Bln, and C3H/Bln mice bearing spontaneous or transplanted tumors of different etiology. Human and mouse fetal extracts gave cross-reactions. Lymphocytes from tumor-bearing mice were reactive against fetal extracts from the cow, pig, sheep, guinea pig, cat, and chicken. Mice bearing benign skin warts induced by 7,12-dimethylbenz[*a*]anthracene (DMBA) as well as DMBA-treated mice without visible skin lesions gave a positive MEMB test. Likewise, pregnancy is associated with lymphocyte reactivity to fetal extracts.—JNCI 1982; 69: 997–1004.

Malignant transformation is associated with changes in gene expression that result in the production of antigens characteristic of those of fetal origin. These TAFA have been found in various tumor-host systems and species including humans (*1–4*). There are TAFA such as AFP or CEA that may appear in the sera of tumor bearers in high concentration. Their detection is dependent on xenogeneic antibodies (*5–7*). Conversely, there are TAFA not detectable in the serum that induce an immune response in the autochthonous tumor host. In this case antibodies and/or cellular reactivity to fetal and tumor cells are the indicators of fetal antigen production in the tumor bearer (*8–15*). TAFA specific for certain types of tumor (*10, 16*) and those shared by many, if not all, of the tumors (*17–19*) may be distinguished. Apparently, TAFA include a variety of molecular structures (*20*).

The existence of cross-reacting TAFA in experimental tumors is indicated by the fact that, under certain conditions, fetal tissue immunizes against syngeneically transplanted tumors of different etiology and histology. Thus transplantation resistance was shown against simian virus 40- (*21*), adenovirus- (*17*), and polyomavirus-induced sarcomas of hamsters (*22*) as well as against chemically induced sarcomas (*23, 24*) and adenocarcinomas (*25*). Likewise, lymphoid cells or sera from multiparous or fetal tissue-immunized donors can be cytotoxic for tumor cells in vitro (*10, 18, 26–29*). At least one or a few of the antigenic determinants involved seem to be expressed in various species, since mouse and human fetal tissue may immunize against hamster tumors (*22, 30*) and antibodies occur against human and mouse fetal liver cells in the sera from patients with carcinomas of the breast, colon, and lung and with malignant melanoma (*13*).

The role played by the antifetal reactivity developing in pregnancy and malignant tumors is still debatable (*3, 31*). Expression of fetal antigens is associated with cell-mediated immunity in pregnancy (*26, 32–34*). Apparently, due to sensitization against fetal antigens, tumor-bearing women with previous pregnancies had a significantly improved survival over women with no history of pregnancy (*35, 36*). Furthermore, melanoma patients with elevated IgM antibody to an oncofetal antigen showed a prolonged disease-free interval and survival (*37*). Conversely, tumors may develop and grow progressively in the presence of antifetal reactivity. T-suppressor cells have been considered a causative factor (*38–40*).

If antifetal reactivity in pregnancy and neoplasia to a species-independent antigen is a widely distributed phenomenon, then techniques other than graft rejection and antibody- or cell-mediated cytotoxicity might also allow reactivity detection and characterization.

There are a number of indirect immunologic assays, mainly based on lymphokines, that are released from lymphoid cells in the process of a specific reaction with antigen. Among these assays, the LMI and LAI tests are now generally used in tumor immunology. In addition, MEMB test may show the same degree of sensitivity and specificity, depending on the test conditions chosen. However, controversial experiences have been reported with the MEMB test, particularly with respect to its diagnostic value in cancer

(*41, 42*). In our hands, the three assays were likewise applicable to the measurement in tumor patients and tumor-bearing mice of leukocyte sensitization to 3-*M* KCl extracts from fetal organs. The results were closely correlated (*14*).

In the present investigation, we completed our data on the interspecies cross-reactivity of fetal extracts and tested the lymphocyte reactivity in mice and humans during pregnancy and under preneoplastic conditions.

MATERIALS AND METHODS

Extracts.—Liver, spleen, kidney, lung, and heart from human fetuses obtained from therapeutic or spontaneous abortion were pooled and stored at −20°C. The ages of the fetuses ranged from 2 to 7 months of gestation. Extracts were prepared by the 3-*M* KCl method of Meltzer et al. (*43*) modified according to Pellis et al. (*44*). Fetal organs were minced with scissors and mixed for 2 minutes in a 3-*M* KCl solution (1;10 wt/vol) containing 0.01 *M* Tris buffer at pH 7.3–7.4 in an Ultraturrax homogenizer (Janke and Kunkel Co., Staufen im Breisgau, FRG). After being further stirred (16 hr at 4°C), the suspension was centrifuged at 100,000×*g* for 1 hour. The clear supernatant was dialyzed against distilled water or 10 m*M* Tris in 0.15 *M* NaCl at pH 7.4. Then the material was again centrifuged at 100,000×*g* for 15 minutes and concentrated to about one-tenth of the original volume by an Amicon filter RM 10, dextran 75,000 (VEB Serumwerk, Bernburg, GDR), or the hollow fiber system DC-2a (Amicon Corp., Lexington, Mass.). The concentrated material was then precipitated with 1 volume of a cold 4-*M* $(NH_4)_2SO_4$ solution. After centrifugation (100,000×*g* for 30 min), the precipitate was solubilized in Tris-buffered saline and dialyzed until sulfate ions were no longer detectable. Finally, the protein content of the extract was determined by the method of Lowry et al. (*45*). Samples of the fetal extract were stored in liquid nitrogen until used.

In the same manner extracts were prepared from the liver, spleen, kidney, lung, and heart of adult tumor-free persons who died by accident and of fetuses from the cow, sheep, cat, and guinea pig. For the preparation of mouse and chicken fetal extracts, whole fetuses were used. In general, fetuses were derived at various times during the final third of the pregnancy period. Donors of mouse fetuses were XVII/Bln mice. Fetuses were of primiparous as well as multiparous origin.

Blood samples.—Blood was obtained from patients with clinically manifest tumors of different histology, organ localization, and stage. In one of the test groups, gynecologic patients particularly were studied. This group included patients with dysplasia of the cervical squamous epithelium and carcinoma in situ.

Blood from tumor patients was taken before surgical, radiologic, or cytostatic therapy. Control blood was obtained from normal blood bank donors, voluntary persons of the laboratory and clinical staff, and patients with nonmalignant diseases.

Heparinized whole blood (30 ml with 3,500 U heparin; Spofa, Prague, Czechoslovakia) was used as a source of leukocytes or lymphocytes. All blood samples were coded.

Leukocyte and lymphocyte preparation.—The techniques described below have been published previously (*46*). For leukocyte isolation the heparinized human blood was mixed 4:1 (vol/vol) with a 6% dextran solution (Infukoll; VEB Serumwerk) and incubated for 30 minutes at 37°C. Cells in the supernatant were repeatedly washed by centrifugation (10 min each at 250×*g*). After the red blood cells were lysed by distilled water, the leukocytes were suspended in EMEM (Staatliches Institut für Immunpräparate und Nährmedien, Berlin, GDR).

Lymphocytes were isolated according to the method of Bøyum (*47*). After spontaneous sedimentation of red blood cells (30 min at room temperature), the supernatant leukocyte-containing plasma layer was pipetted off and put on a 5-ml sample of Lymphoprep (Nyegaard & Co., Oslo, Norway) in a tube. After centrifugation for 20 minutes at 580×*g*, the lymphocyte-containing layer between the supernatant and Lymphoprep was isolated and washed three times in EMEM.

Mouse lymphocytes were obtained from axillary, inguinal, and lumbar lymph nodes. Alternatively, spleen cells were used. Cell suspensions were prepared by means of a Potter glass homogenizer. Cell aggregates were removed by filtration of the suspension through gauze. After the suspension was washed three times in EMEM, the cell concentration was adjusted to 10^7 cells/ml. According to the trypan blue dye exclusion test, lymphocytes of human and mouse origins contained more than 90% viable cells.

Peritoneal macrophages.—Guinea pigs received ip injections of 20 ml paraffin oil each. After 7–21 days, the peritoneal cavities of the animals were washed with a 150- to 200-ml isotonic NaCl solution. As controlled by cell smears, this solution contained mainly macrophages (60–80%), which were repeatedly washed, and the solution was finally suspended in EMEM at a dose of 7×10^6 cells/ml.

Mouse strains and tumors.—Lymphocyte donors were inbred mice of the following strains: XVII/Bln, CBA/Bln, and C3H/Bln. UV 15264 is a UV light-induced sarcoma, and Gr 101 is a Graffi virus-induced leukemia. Both tumors originate from XVII mice and have a long transplantation history. They are generally transferred by im inoculation of cells, and they grow as solid tumors. MCa 21224 is a transplanted mammary carcinoma, which recently developed spontaneously in a CBA mouse. Furthermore, C3H mice with spontaneous mammary cancer served as spleen or lymph node donors.

MEMB test.—Incubation of lymphocytes with fetal extracts was done according to the split method of Pritchard et al. (*48*). In the first step of incubation, 10^6 lymphocytes in 2 ml EMEM were mixed with an aliquot of fetal extract generally containing 300 µg protein. After 70 minutes at 37°C, the lymphocytes were removed by centrifugation (5 min at 1,300×*g*). The supernatants were stored at −20°C until used. Controls were supernatants after lymphocyte incubation in the absence of antigen ("lymphocyte blank").

We assumed that sensitized lymphocytes when in contact in vitro with the corresponding antigens release the MSF.

In the second step, 7×10^6 macrophages were added to each supernatant, and the mixture was incubated for 90 minutes at 23°C. MEMB and its reduction after MSF were then measured by the cytopherometric test. Controls included macrophage samples in EMEM alone ("macrophage blank") and samples with supernatant from lymphocyte blank. At the concentration used, the fetal extracts did not influence the MEMB.

For measurements, two Opton cytopherometers (Zeiss, Oberkochen, FRG) and the Parmoquant 2 cytopherometer (Zeiss, Jena, GDR) were used. The Opton instruments were equipped with television monitors, electronic timing, data processing by computer, and an alphanumeric display. In the Parmoquant 2, which is based on the same principle of cell electrophoresis, the additional elements are a presumptive part of the instrument (*49, 50*). Both types of equipment allow the manual and automatic modes of operation. Data analyses by the computer include estimation of mean mobility, standard deviation, and significance of results in comparison with those of control samples. Irregularities of the measurement, i.e., excessive drifting and exceeding of expected values and tolerance limits, are signalized. An experiment was considered positive when the difference of the electrophoretic mobility between control and test cells was statistically significant according to Student's *t*-test ($P \leq 0.05$).

LMI test.—The assay corresponded with that of Clausen (*51*). Leukocytes at a dose of 9×10^6 were incubated with 60 μg fetal extract in a volume of 60 μl for 30 minutes at 37°C. Then four 10-μl samples of this suspension and corresponding control samples were put into holes of an agarose layer on Partigen plates (Behringwerke, Marburg, FRG). After incubation for 18 hours at 37°C in a humidified CO_2 incubator, the agarose plates were fixed with methanol and Formalin and the migration areas were measured by planimetry. An MI was calculated as follows: MI=average area of migration in the presence of antigen/average area of migration in the absence of antigen. An MI of ≤ 0.7 was arbitrarily considered positive (*46*).

LAI test.—The tube LAI assay was done according to the technique of Holáň et al. (*52*). Leukocytes at a dose of 10^6 in 0.5 ml were placed in a glass tube that had a plane area of 1.5×3.0 cm at the bottom. Test samples also containing the fetal extract (≈250 μg protein) and controls (without extract) were incubated for 2 hours at 37°C. During this time the tubes were held in a horizontal position to allow the cells to adhere to the plane area. Nonadherent cells were finally counted in a hemacytometer. Adherence inhibition was expressed in percent. A value of more than 30% was arbitrarily considered positive (*46*).

Statistical analysis.—Individuals were grouped according to the clinical diagnosis. After the test samples were decoded, the results were listed in the corresponding group. Groups were compared by the chi-square test with Yates' correction ($P \leq 0.01$).

RESULTS

Fetal extracts prepared by the 3-*M* KCl method from the liver, spleen, kidney, lung, and heart of 2- to 7-month-old human fetuses induce effects on peripheral blood leukocytes and lymphocytes of human tumor patients that imply an immunologic sensitization to fetal antigens in this particular group. Supernatants obtained after incubation of the lymphocytes with fetal extract inhibit the electrophoretic mobility of guinea pig macrophages and thus show the presence of MSF, characteristic of a positive MEMB test. Altogether, the positive MEMB test was found in 209 of 284 (73%) cases with various types of tumor (table 1).

Fetal extracts were likewise active when tested by LMI and LAI. Leukocyte migration was significantly inhibited in 48 of 64 (75%) tumor patients investigated, and leukocyte adherence was significantly inhibited in 40 of 50 (80%) tumor patients investigated. The data represent a summary of different series of experiments. In general, the proportion of positive cases ranged from 70 to 80% (table 1).

In most cases leukocytes or lymphocytes from clinically healthy persons did not react with the fetal extracts. Only 15 of 134 (11%) persons were positive by MEMB, 7 of 50 (14%) by LMI, and 10 of 54 (19%) by LAI. The differences between the groups of tumor patients and clinically healthy persons are statistically significant ($P \leq 0.01$) for each test (table 1). Extracts from normal, adult human organs were active in 8 of 28 (29%) tumor patients when tested by MEMB (not in the table). However, 22 of these 28 (79%) patients reacted positively against fetal extract.

Preparations of fetal extract were of different qualitites. Some of them had to be eliminated because of total absence of activity. A discrimination by the MEMB test between tumor and control groups was possible with 9 of 18 extracts prepared.

Fetal extracts suitable for discrimination between tumor and control groups were tested by MEMB against lymphocytes from patients with various types of tumor. Table 2 presents the data obtained from these experiments. Obviously, reactivity to fetal extracts is independent of tumor localization and histology. However, certain groups might differ with respect to the rate of positivity. While 16 of 17 patients with lung cancers were positive, only 12 of 22 cases with melanomas reacted by MEMB. When comparing the data of the control group with those of each one of the tumor groups, we obtained statistically significant differences ($P < 0.01$).

Preliminary results indicate no correlation between tumor stage and MEMB result. However, positive reactions seem to be less frequent in tumor patients over 70 years of age. The same pattern of reactivity was found when 3-*M* KCl extracts from the fetal brain or gut were tested against a panel of lymphocytes from patients with various tumors.

Lymphocyte reactivity to fetal extracts is comparably detectable in mice bearing spontaneous or transplanted tumors (table 3). For example, C3H mice with spontaneous mammary cancers were positive against mouse fetal extract

TABLE 1.—*Reactivity of lymphocytes-leukocytes from tumor patients and controls to human fetal extract: Summary of experiments*

Normal XVII mice	0/16	2/25
CBA mice bearing transplanted mammary cancer MCa 21224	15/16	NT
Normal CBA mice	2/21	
XVII mice bearing transplanted Graffi virus-induced leukemia Gr 101	12/12	NT
Normal XVII mice	4/34	

[a] Significant difference between tumor and control groups ($P<0.01$).

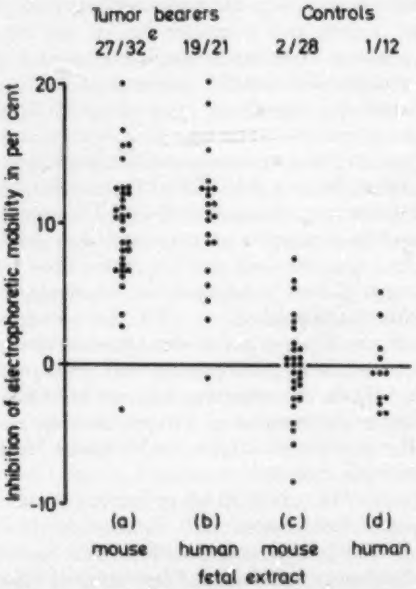
[b] NT=not tested.

(27 of 32 cases) and human fetal extract (19 of 21 cases). Only 2 of 28 and 1 of 12, respectively, normal C3H mice showed a positive reaction when tested by MEMB. Mice bearing the transplantable tumors sarcoma UV 15264, mammary cancer MCa 21224, or Graffi virus-induced leukemia Gr 101 were likewise reactive. At the time of the tests, the tumors had diameters of 10–20 mm.

Text-figure 1 shows the data obtained with lymphocytes from each mouse. This experiment is already summarized in table 3. In text-figure 1, the results are expressed as average inhibition of macrophage electrophoretic mobility in percent as compared with that of controls. A wide range of test results can be stated. However, a clear distinction is possible between the groups of tumor bearers and controls. Macrophages exposed to extract-containing supernatants from control lymphocytes frequently had increased electrophoretic mobility.

Extracts from normal adult mouse tissue were ineffective. Only 1 of 15 tumor-bearing mice gave a positive MEMB test.

Lymphocytes from human tumor patients were reactive against mouse fetal extract (text-fig. 2). As indicated by the proportion of positive cases, there was no difference between the groups of lymphocytes that were exposed to human or mouse fetal extract. Apparently, human and mouse fetal extracts share common components.



TEXT-FIGURE 1.—Lymphocyte reactivity as measured by MEMB to mouse and human fetal extracts in C3H mice bearing spontaneous mammary cancers and in C3H control mice: a and b represent the tumor-bearing groups, c and d are controls, and e is number of positive cases/total number tested.

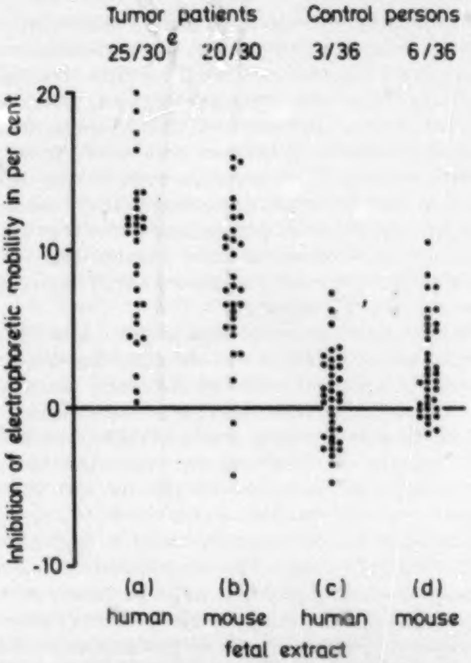
According to the MEMB test, this common component seems to be present in fetal extracts of various species. Fetal extracts from the cow, pig, sheep, guinea pig, cat, and chicken may distinguish between groups of tumor-bearing and control mice (table 4). The clear-cut difference between the groups is striking.

Reactivity to fetal extracts is not limited to cancer. Mice bearing benign skin warts induced by DMBA as well as mice from the same DMBA-treated group having no visible skin lesions were reactive against mouse and human fetal extracts (text-fig. 3). Although the number of animals included in this experiment is relatively low, the results allow a clear distinction between the experimental groups and the controls.

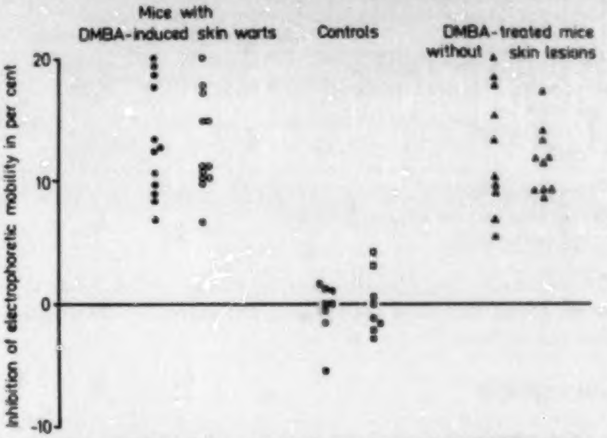
Preliminary results of studies on preneoplastic conditions in humans indicate a similar situation. Gynecologic patients with dysplasia of the cervical squamous epithelium were reactive against human fetal extract in 20 of 40 (50%) cases. When patients with carcinomas in situ were tested, 10 of 21 (38%) showed a positive reaction. In the control group, 6 of 26 (23%) women were reactive (our unpublished results).

Pregnancy is also associated with lymphocyte reactivity to fetal extracts. However, the proportion of positive cases is lower in comparison with that of the tumor group. Furthermore, it is striking that the difference between the groups of pregnant women and controls is detectable only during the first and second trimesters of pregnancy. After delivery (within 2-13 wk) all 22 women tested were unreactive (table 5). Mouse and human fetal extracts gave identical results.

Finally, lymphocytes from pregnant multiparous mice were tested by MEMB against mouse fetal extract at two



Text-figure 2.—Lymphocyte reactivity as measured by MEMB to human and mouse fetal extracts in tumor patients and controls: a and b include 21 patients with gastrointestinal tumors, 2 with mammary cancer, and 7 with tumors of other sites; c and d are blood donors, and e is number of positive cases/total number tested.



Text-figure 3.—Lymphocyte reactivity as measured by MEMB to mouse and human fetal extracts in XVII mice given a total dose of 120 μg DMBA to the dorsal skin. Each animal received 20 doses of 6 μg DMBA in acetone within 10 wk. DMBA-treated mice without skin lesions were studied at the same time and after the same dose of DMBA as were the animals with skin warts. ●, ■, ▲: tests with mouse fetal extract. ○, □, △: tests with human fetal extract. *Each dot* represents the mean value in percent of the inhibition of electrophoretic mobility of macrophages from one single test sample as compared with the control. The lymphocytes of each animal were doubly tested against the mouse as well as the human fetal extracts.

Table 5.—*Lymphocyte reactivity as measured by MEMB to human and mouse fetal extracts in women during and after pregnancy*

Peripheral blood lymphocytes from:	No. of positive cases/total No. tested

[b] NT=not tested.

different doses. The results are presented in table 6. Most of the pregnant mice were reactive and the reactivity decreased after parturition.

DISCUSSION

That neoplasia, preneoplasia, and pregnancy are associated with lymphocyte sensitization to fetal antigens is the conclusion deduced from the present investigation, provided that MEMB, LMI, and LAI measure cellular immunity. LMI and LAI are widely accepted as cellular immunologic tests. In our hands all three techniques gave corresponding results so that there is no reason to doubt the immunologic background of the MEMB technique too. Moreover, data of Zöller et al. (*15*) support the concept that cancer patients are sensitized against fetal antigens and that sensitization is detectable by indirect cellular immune methods such as LMI. In these studies, similarly, 3-*M* KCl extracts from human fetuses of about the same age of gestation were used.

Information on the antigens involved in the lymphocyte reaction is poor. AFP was excluded as an active component. After its complete removal by immunoadsorption the fetal extract was still active when tested with lymphocytes from tumor patients as has been shown by MEMB. The purified AFP did not react (*14, 53*).

CEA was also inactive by MEMB (our unpublished results) and LMI (*54*). Our experiments on the concentration and isolation of the antigenic material by Sephadex G-200, DEAE-cellulose chromatography, or immunoadsorption techniques have been unsuccessful so far. Thus it is still an open question whether one or several antigenic components are responsible for the cross-reactions obtained when the lymphocytes of patients suffering from tumors of different organ localization were exposed to fetal extract.

Zöller et al. (*15*) assumed that 3-*M* KCl extracts of whole human fetuses contain a complex mixture of specificities that may have represented counterparts to most of the tumor-associated specificities. The same group (*55*) attempted to support this hypothesis experimentally by using organ-related fetal extracts. Although some of their data are in favor of this hypothesis, i.e., extracts from fetal gut preferentially reacted with leukocytes from patients who had colorectal cancer, there was still extensive cross-reactivity among the organ-related fetal antigens. Our extract from fetal gut was active in cases with different types of tumor (our unpublished result).

In previous studies by using LMI we have also shown such organ-related or tumor type-specific antigens (*56*). There was extensive immunologic cross-reactivity among mammary cancers when the leukocytes of the patients were exposed to mammary cancer extract. Generally, extracts from other tumors did not react. The same tumor type-specific pattern or reactivity was obtained by MEMB (*57*). This finding does not exclude the existence of a specific cross-reacting fetal component common to all tumors in addition to the type-specific antigen. It has been shown that chemically induced rat tumors possess individually distinct tumor antigens as well as fetal cross-reacting antigens (*58*). That a common fetal antigen that immunizes against tumors of different origin does exist has been shown by Coggin and Ambrose (*22*). Whether MEMB, LMI, or LAI measures such a cross-reacting antigen of the rejection type is not known.

Surprisingly, fetal extracts from various species including the cow, pig, sheep, cat, guinea pig, rat, and chicken share a common fetal component. A complete cross-combination of experiments that was arranged between human and mouse tumor systems demonstrated that lymphocytes from tumor-bearing individuals reacted both with human and mouse fetal extracts. The presence even in the chicken indicates that the component is phylogenetically conserved. A similar pattern of species distribution is also true for AFP (*59*). It would be of interest to know whether fetal extracts from the species mentioned also induce a rejection response against transplanted tumors.

Lymphocyte sensitization to fetal extracts is not limited to cancer. Clear-cut evidence was obtained that mice bearing benign skin warts after DMBA treatment are reactive. Their counterparts, i.e., mice showing no visible skin lesions after treatment with the same dose of DMBA, are likewise reactive. However, it is well known that there are early histologic changes in the mouse skin painted with chemical carcinogen even in the absence of skin warts (*60*). Lymphocyte sensitization is also frequently seen in patients with dysplasia of the cervix uteri. This observation raises a number of questions which, however, cannot be answered as yet. In the first place it is important to know whether reactivity to fetal extracts is characteristic of preneoplastic changes after certain carcinogens or is associated with cell proliferation in general. We have tested patients with inflammatory diseases and found that these patients as compared with a group of clinically healthy persons had a higher proportion of reactivity (our unpublished results). However, results of these experiments are not yet decisive. Furthermore, the time of appearance of this reactivity after carcinogen treatment would be interesting to know.

In mice transplanted with tumor cells, reactivity is detectable about 5–7 days after grafting (*14*). Apparently, lymphocyte sensitization occurs rapidly.

Another question is whether reactivity may develop after oncogenic or nononcogenic viruses. Several conditions such as partial hepatectomy and inflammatory lesions in experimental animals would help to resolve the question of whether differentiation and/or cell proliferation in certain organs are causally related to lymphocyte sensitization.

Another problem is lymphocyte reactivity after surgery. If reactivity is no longer detectable in women after delivery, does the tumor patient who has been successfully treated also show a loss of reactivity? Studies on patients with mammary cancers are in progress to answer this question.

That lymphocyte sensitization to fetal antigens develops under normal conditions is shown in pregnant women. However, the proportion of reactive persons is lower as compared with the proportion in tumor patients. Sensitization seems to be independent of the number of pregnancies. There were positive cases among women with first pregnancies as well as negative ones among multipara. The reason for this is not yet known. Quantitative rather than qualitative aspects have to be considered. The conclusion can be drawn from mouse experiments that the reactive cells not only disappear from the blood circulation but also are absent from the lymph nodes. Cells from the nodes of a high proportion of mice in the postnatal period did not react with fetal extracts. If memory cells are present, they are obviously inactive with respect to lymphokine release.

It has been shown recently by LMI (*61*) that persons in close contact with lung cancer patients or lung cancer materials are sensitized to lung tumor-associated antigen. We have repeatedly tested persons of our laboratory staff who are in permanent contact with the fetal materials and did not find any lymphocyte sensitization.

Detection of lymphocyte sensitization to fetal extracts as a tumor-diagnostic test appears to be problematic for two reasons: 1) The accuracy of the test is not high enough and, therefore, it allows only a grouping of individuals, and 2) neoplasia and preneoplasia cannot be distinguished on the basis of lymphocyte reactivity. Stability of fetal antigen expression on fetal cells was found to be an important factor (*3, 31*). In hamsters and rats immunogenicity of fetal tissue was limited to certain phases during embryogenesis. In our studies fetal extracts were prepared from organs of human fetuses at an age between the 4th and 7th months of pregnancy. Extracts from 2- to 3-month whole fetuses were likewise active (our unpublished results). However, it cannot be excluded that the active components in the materials from fetuses and embryos are different.

At present a classification of the fetal antigen(s) in the extract is almost impossible. Besides AFP and CEA, the human encephalitogenic protein (or myelin basic protein) (*62*) can also be excluded as a reactive component. The isolation procedure for the encephalitogenic protein differs considerably from the 3-*M* KCl method. Furthermore, comparative studies have shown that the number of "false-positives" in the control group is higher if the encephalitogenic protein is used as antigen in place of the fetal extract (*14*).

A similar cross-reactivity of fetal and tumor antigens has been reported by Salinas et al. (*13*). Cross-reactivity was demonstrated by antibodies that appear in sera from patients with tumors of various histologies. Moreover, antibodies of human and mouse origins had the same specificity. There seems to be a close correlation between these findings and our studies on lymphocyte reactivity. Antigen isolation is necessary for direct comparison of the humoral and cellular immune methods.

Cancers of the Gallbladder and Biliary Tract in Alaskan Natives: 1970–79[1,2]

Leslie P. Boss, *M.P.H., Ph.D.*,[3] **Anne P. Lanier**, *M.D., M.P.H.*,[3,4] **Peter H. Dohan**, *M.D.*,[3] *and* **Thomas R. Bender**, *M.D., M.P.H.*[3]

ABSTRACT—The records of Alaskan Native patients with gallbladder and extrahepatic bile duct cancers diagnosed during 1970–79 were reviewed. Of 34 cases identified, the primary cancer was in the gallbladder in 29, resulting in age-adjusted incidence rates for gallbladder cancer of 4.4 for males and 17.6 for females. On the basis of calculations applying cancer incidence rates for U.S. whites to the Alaska Native population, a greater than expected number of both Eskimo and Indian patients were diagnosed. A 5-year review of cholecystectomies indicated that nonmalignant gallbladder disease was also elevated in both Indians and Eskimos.—JNCI 1982; 69:1005–1007.

The incidence rates for GBC vary worldwide (*1*). The variation of GBC rates among ethnic groups in the United States is almost as great as the variation reported worldwide. In the United States, the highest rates are reported for American Indians, followed by Spanish Americans (New Mexico), Mexican Americans (Los Angeles, Calif.), whites, and blacks (*2–5*). Among most U.S. ethnic groups, the rates for GBC are higher among females than males. The female-to-male ratio, roughly twofold in both whites and blacks (*2, 6*), is even higher in American Indians and Spanish Americans (*3–5*).

The etiology of GBC is not known; however, cholelithiasis and cholecystitis are thought to be important factors in its development. Gallstones are found in approximately 80% of patients with GBC, and populations at high risk for gallbladder disease also have high rates of GBC (*2, 7–10*).

The etiology of BDC may differ from that of GBC, since the sex ratio is reversed (males predominate) and fewer patients have gallstones (*2, 8*). Studies of the epidemiology of GBC and BDC have been complicated by the fact that these cancers as well as cancer of the ampulla of Vater have been grouped under a single three-digit code (156) in the ICDA (*11*).

A 5-year survey revealed high incidence rates for cancers of the gallbladder and other biliary passages among the major groups of Alaskan Natives: Eskimo-Aleuts and Indians (*12, 13*). Although American Indians are known to be at increased risk for GBC, Eskimos living outside Alaska have not been reported to be at increased risk. This paper describes the results of a review of records of Alaskan Natives with GBC and extrahepatic BDC diagnosed in a recent 10-year period, 1970–79. Because of the putative association of GBC with gallstones, these results are compared with those from a separate review of patients from this population who had undergone cholecystectomy.

METHODS

Study population.—The Alaskan Native population was estimated to be 65,000 in 1977. All 3 subgroups, Eskimo, Aleut, and Indian, are thought to have originated in Asia (*14*). On the basis of linguistic studies, two types of Eskimos are recognized: Yupik-speaking Eskimos, who live in southwestern Alaska, and Inupiat-speaking Eskimos, who live in northwestern Alaska and across the Canadian Arctic as far east as Greenland (*15*). Linguistic studies also indicate that Aleuts and Eskimos are related and that Aleuts are most like Yupik-speaking Eskimos. Most Aleuts live on the Alaskan peninsula and the Aleutian Island chain. The Eskimos and Aleuts represent 69% of the total Alaskan Native population. Seventeen percent of Alaskan Natives are Tlingit, Haida, and Tsimshian Indians of southeastern Alaska. These Indians are members of the Northwest Coast Indian tribes also found in Canada and the northwestern United States. Athapaskan Indians, who live mainly in the interior of Alaska, make up 14% of the total Alaskan Native population and appear to be linguistically related to the Navajo and Apache Indians of the southwestern United States (*15*).

Total Native population figures used were the IHS projections for fiscal year 1977. We calculated estimates of population by ethnic group by imposing the age, sex, and ethnic distributions determined by Kraus and Buffler (*16*) on the IHS projected population figures.

Identification of cases.—All Alaskan Native patients with a diagnosis of GBC or cancer of related structures (ICDA No. 156) during the 10-year period 1970–79 were identified from death certificates and records of discharge diagnoses, surgical pathology files, and the tumor registries of the referral hospital of the Alaska Area Native Health Service and other hospitals in the state. In addition, a separate review of cholecystectomies performed on Alaskan Natives during 1975–79 provided data on gallbladder disease.

Verification of cases.—To verify the diagnosis in each cancer patient, we reviewed pathology slides, pathology and autopsy reports, and clinical data. The classifications of cancer were similar to those of the ICDA: GBC, cancer in the extrahepatic bile ducts, cancer of the ampulla of Vater, and cancer of the biliary tract, unspecified. Patients assigned to the GBC category were those with early disease confined to

the gallbladder and those with more extensive disease in which the center of the tumor mass appeared to be the gallbladder and in which there was direct liver invasion, minimal ductal dilation, and late onset of clinical jaundice. Patients were assigned to the extrahepatic BDC category if the cancer obviously arose in the hepatic, cystic, or common bile ducts. Cancer in the ampulla of Vater was categorized separately. Patients included in the category of cancer of the biliary tract, unspecified, were those with such extensive disease or atypical histology as to render precise classification impossible.

Calculation of rates.—Cancer incidence rates were standardized to the U.S. population of 1970. The number of observed patients with cancer was compared as a ratio to the number expected. We calculated the number of expected cases by using the Third National Cancer Survey incidence rates for U.S. whites and applying them to estimates of the Alaskan Native population derived from the 1970 U.S. census. The statistical significance of the deviation of the ratios from one was tested by the method of Bailar and Ederer (*17*).

RESULTS

Thirty-four patients with biliary tract cancer were identified. For 31 of these patients, both slides and medical records were available for review. Original pathology and surgery reports were available on the remaining 3. All but 5 of the 34 patients had GBC; 1 male had BDC, another male had cancer of the ampulla of Vater, and 1 male and 2 females had cancer of the biliary tract, unspecified.

Among the 29 patients with GBC, 23 were female and 6 were male, for a female-to-male ratio of 3.8:1 (table 1). Patients ranged in age from 53 to 82 years, with a mean age of 71 years. Half the female patients were diagnosed under the age of 70 years, whereas all male patients were over 70 years of age at diagnosis.

There was no obvious geographic clustering of GBC patients by birthplace or residence at diagnosis. Two members of one family, a sister and a brother, diagnosed in 1977 and 1979 at ages 77 and 72, respectively, were among the 29 patients. The rest of the patients were not known to be related.

Annual crude and adjusted rates per 100,000 for GBC were, respectively, 1.8 and 4.4 for males and 7.1 and 17.6 for females. Corresponding rates for total GBC and bile duct cancer based on all 34 cases were 2.7 and 6.2 in males and 7.7 and 18.6 in females. When standardized rates for GBC were compared with those of other U.S. ethnic groups, Alaskan Natives were found to have high rates, exceeded only by the incidence in American Indians living in New Mexico (table 2).

TABLE 1.—*Number of cases and annual age- and sex-specific incidence rates of GBC per 100,000, Alaskan Natives, 1970–79*

Age at diagnosis, yr	Males		Females	
	No.	Rate	No.	Rate
50–59	0	—	3	13.7
60–69	0	—	8	63.6
≥70	6	68.0	12	171.9
Total	6	1.8	23	7.1

TABLE 2.—*Annual incidence rates of GBC per 100,000 population*[a]

Racial and ethnic groups	Male	Female
United States (1969–71)		
All races	1.1	2.1
White	1.1	2.2
Black	0.7	1.6
New Mexico (1969–75)		
Spanish American	2.0	10.5
American Indian	5.1	21.1
Alaskan Natives (1970–79)	4.4	17.6

[a] Age adjusted to the 1970 U.S. population.

TABLE 3.—*Number of patients observed (O) with GBC and ratios of observed-to-expected cases (O/E) by sex and ethnic group, Alaskan Natives, 1970–79*

Ethnic group	Males		Females	
	O	O/E	O	O/E
Indian				
Athapaskan	0	—	3	7.5[a]
Southeastern	3	10.0[b]	5	10.0[b]
Eskimo				
Inupiat	2	6.7	6	10.0[b]
Yupik-Aleut	1	1.2	9	6.4[b]
Total	6	3.5[a]	23	8.2[b]

[a] $P < 0.05$.
[b] $P < 0.01$.

Table 3 shows the ethnic distribution of the GBC patients and the ratio of observed-to-expected cases. Twenty-two of the GBC patients were full Native, 5 were probably full Native, and only 2 were known to be of mixed ancestry. Although the number of cases are small, the ratios indicate that females of all 4 ethnic groups (Inupiat- and Yupik-speaking Eskimo, as well as Athapaskan and southeastern Alaskan Indian) are at significantly increased risk. The ratio was significantly increased in males only for Alaska's southeastern Indians, although Inupiat Eskimo males also had a high ratio. Inclusion of the 3 patients categorized as having unspecified cancer of the biliary tract does not change the conclusions regarding ethnic distribution.

The type of cancer in all 29 patients with GBC was adenocarcinoma, classified as well differentiated in 17 patients, poorly differentiated in 11 patients, and adenosquamous in 1 patient. Gallstones were present in 23 patients (79%), and all but 3 of these patients had stones of cholesterol or mixed composition.

During the 5-year period 1975–79, 607 cholecystectomies or cholecystostomies were performed on Alaskan Natives. Sixteen patients were diagnosed with GBC during the same period: 13 during cholecystectomy for symptoms of cholelithiasis, 2 during laparotomy for suspected cancer, and 1 at autopsy. Therefore, GBC was diagnosed in 13 of 607 patients (2.1%) who had gallbladder surgery. In women who had gallbladder surgery, 14% of those 60 years of age or older and 26% of those 70 years or older were found to have GBC.

Only 3 of the 29 patients were alive as of January 1981: 2 patients diagnosed in 1979 and 1 patient diagnosed in 1970. The median postsurgical survival for the other 26 patients was 3 months.

DISCUSSION

GBC is the fifth most frequently diagnosed invasive cancer among Alaskan Native females and accounts for 4% of all cancers in Native females and 1.2% of all cancers in Native males. The female-to-male ratio (3.8:1) of GBC in this population is higher than the 2:1 ratio reported among U.S. whites and blacks but similar to that reported for American Indians of the southwestern United States (*3, 6, 18*).

Incidence rates of GBC based on this report indicate that GBC develops in Alaskan Native males and females nearly as often as in Indians in New Mexico. Because of the reported high rates of GBC among American Indians, elevated rates among Alaskan Indians were expected. Indeed, rates were significantly high in females both among Athapaskans, who are thought to be related to the Navajo and Apache of the southwestern United States, and among southeastern Alaskan Indian females, members of the Northwest Coast Indian tribes. Among males, rates were high for southeastern Alaskan Indians.

Of some surprise, however, was the finding of elevated rates of GBC among Alaskan Eskimos. Rates were elevated in both Inupiat- and Yupik-speaking female Eskimo subgroups. Among males, rates were elevated, although not significantly, in Inupiat-speaking Eskimos.

High rates of GBC have not been reported among Eskimos living outside Alaska. In a report of cancer in 180 Canadian Eskimos, 7 patients with biliary tract cancer were identified; 5 of these had cancer originating in the ampulla of Vater, and only 2 had cancer that had localized in the gallbladder (*19*). Among Greenland Eskimos, 5.5% of all types of cancer arose in the liver or biliary tract, in contrast to 2% in Danish cancer patients (*20*). However, no data on GBC alone have been reported.

Alaskan Indians and Eskimos differ genetically, and there has been little intermarriage. These groups also differ in diet, life-style, and area of residence. Both Alaskan Indians and Eskimos differ in many ways from other Native American groups.

Gallbladder disease (cholelithiasis and cholecystitis) appears to be an important risk factor for the development of GBC. Our investigation of gallbladder surgery among Alaskan Natives for 1975–79 suggested that gallbladder disease was increased in both Eskimo and Indian females when compared with the incidence in the U.S. white population. Rates of gallbladder disease for Native males were not higher than those for U.S. white males, although within Alaska rates for Indian males were higher than those for Eskimo males (*21*).

Therefore, among females in this population, rates for both gallbladder disease and GBC appear to be increased, which supports the reported association of the two. Among males, the numbers of cancers are too small to be conclusive, but southeastern Alaskan Indian males had the highest rates of both gallbladder disease and GBC.

This review provides additional data to support the earlier report of elevated rates of GBC among Eskimo–Aleuts. Although rates of gallbladder disease are also high, the association of gallbladder disease and GBC among Alaskan ethnic groups deserves further study. In view of the marked differences in life-style of Alaskan Natives and other ethnic groups, additional studies should be done to identify common risk factors for gallbladder disease and GBC among the various populations with increased rates.

Collagen Polymorphism in Extracellular Matrix of Human Osteosarcoma[1,2,3]

Frederic D. Shapiro[4] *and* **David R. Eyre**[4,5,6]

ABSTRACT—The collagenous matrix of human osteosarcoma was characterized biochemically and ultrastructurally. The highly cellular regions of the tumors contained many osteoblast-like cells filled with dilated rough endoplasmic reticulum. The extracellular matrix displayed a random weave of banded collagen fibrils (30–90 nm in diameter) interspersed with thinner, unbanded fibrils (15 nm in diameter). Tumors from 9 patients were analyzed for collagen composition. All gave a similar collagen profile. Three main molecular species of collagen were abundant: type I, type III, and type V, which occurred in the approximate proportions of 65:25:10. A high ratio of $\alpha1$(I) to $\alpha2$(I) chains suggested that one-third of the type I collagen was present as a type I trimer molecule. In contrast, normal bone matrix consisted almost exclusively of type I collagen. The fibrillar collagens in the soft tumor seemed unusually rich in hydroxylysine and hydroxylysine glycosides; type I collagen had two to three times the hydroxylysine content of normal bone collagen.—JNCI 1982; 69:1009–1016.

By light microscopy, the extracellular matrix of human osteosarcomas resembles the woven osteoid laid down by osteoblasts during early bone development or in fracture healing (*1–3*). Although collagen is the most prominent component of the tumor matrix, its chemical characteristics have not been defined. Chemical definition of the collagen seemed an important task because collagen typing may be of value in assessing the clinical prognosis of osteosarcomas.

Five genetically distinct types of collagen molecule have been firmly identified and can be grouped into two families: fibrillar collagens (I, II, III) and basement membrane or pericellular collagens (IV, V) (*4, 5*). Type I is the commonest collagen; it is abundant in skin, tendon, bone, and other coarsely fibered connective tissues. Type II is found mainly in cartilage, and type III seems to be the collagen constituent of reticulin fibers. Within each type of collagen, further chemical heterogeneity is also evident because of variations in the degree of certain post-translational modifications that include hydroxylation of lysine residues, glycosylation of hydroxylysine residues, and the quantity and quality of intermolecular cross-links. Type I collagen, for example, is two to three times richer in hydroxylysine in young developing bone than in the mature tissue (*6, 7*). In this paper we report the biochemical characteristics and ultrastructure of collagen in the matrix of human osteosarcoma.

MATERIALS AND METHODS

Tissue selection.—Specimens of osteosarcoma tissue were sampled immediately after surgical resection or amputation. The patients ranged in age from 10 to 19 years. The lesions studied came from the distal femur, proximal tibia, proximal humerus, and ilium. Tissues from parosteal, periosteal, or secondary osteosarcomas were excluded. None of the patients had been subjected to chemotherapy or radiation therapy before surgery. Because osteosarcoma lesions are usually heterogeneous in cell and matrix composition, care was taken to dissect for analysis subregions that appeared uniform. The subregions assessed were 1) soft tumor tissue which was highly cellular and included early tumor osteoid, 2) tumorous bone (i.e., the hard, mineralized tissue within the tumor mass itself), and 3) normal cortical bone. Care was taken to exclude cartilaginous areas from the specimens taken for analysis. Tissue samples from each of the regions were subjected to light microscopy and biochemical analysis, and soft tumor samples were examined by electron microscopy. Collagen analyses were performed on those specimens that appeared grossly and histologically most uniform. In all, tumors from 9 patients were analyzed separately.

Histologic examination.—Tissue for light microscopy was fixed in neutral buffered Formalin, decalcified when necessary in 25% formic acid, embedded in paraffin, cut at 6 μm, and stained with either hematoxylin and eosin or safranin O and fast green (*8*). Tissue for electron microscopy was dissected into 1-mm cubes, fixed in a mixture of one part 2.5% glutaraldehyde and two parts 1% osmium tetroxide, and embedded in Epon (*8*). Sections of 1 μm were stained with toluidine blue for light microscopic assessment and, if satisfactory, 60-nm sections were then stained with lead citrate and uranyl acetate for examination on a JEOL 100C electron microscope operated at 60 kV.

Collagen analyses.—Calcified samples of normal bone and tumorous bone were decalcified in 0.5 M EDTA (pH 7.4) for 4–8 days at 4°C, washed with water, and freeze dried. Soft tumor tissue was analyzed without decalcification.

Amino acid analyses.—Tissue samples were hydrolyzed in 6 M HCl under N_2 for 24 hours at 108°C. Amino acids were quantified by a single column procedure (Beckman 121MB amino acid analyzer) that resolved hydroxyproline and hydroxylysine.

Hydroxylysine glycoside analysis.—Tissue samples were hydrolyzed in 2 M NaOH for 24 hours at 108°C. Glucosylga-

lactosylhydroxylysine, galactosylhydroxylysine, and nonglycosylated hydroxylysine were quantified on the Beckman 121MB analyzer, as previously described (*9*).

CNBr Digestion.—Whole tissue samples and salt-fractionated collagens from pepsin digests were reacted with equal weights of CNBr in 70% formic acid for 16 hours at room temperature. The principal type of collagen in the sample was assessed by electrophoresis of the collagen CNBr–peptides in 10% polyacrylamide slab gels (*10*).

Pepsin digestion.—Samples of soft tumor tissue were homogenized in 0.5 *M* acetic acid (100 mg wet wt tissue/5 ml) and stirred with pepsin (3 mg/5 ml; Boehringer Mannheim Biochemicals) for 20 hours at 4°C. Insoluble material was removed by centrifugation. The supernatant was neutralized with solid Na_2HPO_4 and dialyzed overnight at 4°C against 0.02 *M* Na_2HPO_4. The collagen precipitate was collected by centrifugation. For each tumor, a portion of this material was analyzed directly by gel electrophoresis in 5% polyacrylamide. From selected large tumors, the collagen was fractionated by salt precipitation as follows: The pellet was redissolved in 1 *M* NaCl containing 0.05 *M* Tris (pH 7.5) by stirring at 4°C overnight. Successive precipitates were then collected by centrifugation at NaCl concentrations of 1.7, 2.5, and 4.0 *M*, stirring for 1 hour after each increase in salt concentration. Each precipitate was dissolved in 0.1 *M* acetic acid and was then freeze dried.

SDS-polyacrylamide gel electrophoresis.—We applied the method of Neville and Glossman (*11*) and used 1.5-mm thick slabs. Protein bands were stained overnight with 0.4% Coomassie blue R250 in 10% acetic acid, 20% isopropanol, and 70% water; the gels were destained in 7% acetic acid. Tracks of pepsin-digested collagen were scanned densitometrically (E-C Apparatus Corporation densitometer), and the relative amounts of $\alpha 1(I)$, $\alpha 2$, αA, and αB chains were quantified. Because the $\alpha 1(III)$ chain was partially resolved from $\alpha 1(I)$ but overlapped αA, the amount of type III collagen in a pepsin digest was estimated from the weight of collagen recovered in the 1.7-*M* NaCl precipitate and the proportion of $\alpha 1(III)$ in this fraction, as determined by gel electrophoresis.

RESULTS

Electron Microscopy

The cell and matrix ultrastructure of tumors from all patients showed a similar spectrum. The cell nuclei varied markedly in size and shape, and the chromatin was usually marginated. The nucleoli were prominent in number, size, and density. The most impressive ultrastructural features of the cellular, early osteoid region of the tumors were malignant osteoblasts rich in dilated RER frequently present in confluent lakes. The RER was intact and filled with a moderately dense homogeneous material (fig. 1). Intracellular filaments 5–7 nm in diameter were often present in the malignant osteoblast-like cells, although they were rarely packed densely. Glycogen granules were uncommon; lipid inclusions were seen on occasion. Most of the tumors contained other less well-differentiated cells with sparse flattened RER arrayed as circumferential or stacked lamellae. Multinucleated cells were frequent, some having cytoplasm similar to that of mononuclear tumor cells and others having abundant mitochondria characteristic of giant cells.

The extracellular matrix (figs. 2A–2D) was composed of crossbanded collagen in a relatively random weave. In some areas, the fibrils were parallel. Fibrils ranged from 30 to 90 nm in width, with the crossbanding periodicity from 58 to 62 nm. Parallel clusters of thin (≈15 nm in diameter), unbanded fibrils were also seen intermixed with the larger crossbanded fibrils. Further ultrastructural assessments have been made (*12*).

Collagen Chemistry

Light microscopy was used as the basis for selecting uniform specimens for biochemical analysis.

Hydroxylysine content.—The hydroxylysine content of total collagen in the soft tumor was twofold to threefold greater than that of normal bone collagen (table 1). A higher proportion of the hydroxylysine residues of the soft tumor collagen was glycosylated and the glucosylgalactosylhydroxylysine:galactosylhydroxylysine ratio was much higher than the ratio in normal bone (table 1). Intermediate levels of hydroxylysine and hydroxylysine glycosides were found in the tumorous bone. It may be significant that of the 7 tumors analyzed, 5 had closely grouped glucosylgalactosylhydroxylysine:galactosylhydroxylysine ratios at 3.3, whereas the other 2 both had low ratios around 1.0 (table 1).

Collagen types.—Electrophoresis of pepsin-solubilized tumor collagen (fig. 3) and derived CNBr peptides (fig. 4) showed that type I collagen was the prominent collagen in all specimens of osteosarcoma. However, all specimens of soft tumor tissue were relatively rich in type III (25% of total) and type V collagens (10% of total). In normal bone, less than 2% of the collagen is type V, and no type III has been detected. Type I trimer collagen also seemed abundant as judged by the high ratio of $\alpha 1(I)$ to $\alpha 2(I)$ (table 2). The identification of type I trimer collagen must remain tentative, however, because most of the $\alpha 1(I)$-rich material was precipitated in the 1.7-*M* NaCl fraction rather than in the 4.0-*M* NaCl fraction, as others have found (*19, 20*). One possible explanation is that the pepsin-extracted collagen studied here has different solubility properties than those of the type I trimer collagen studied elsewhere in which lathyritic tissue was used, thereby avoiding pepsin. Alternatively, the high ratio of $\alpha 1(I)$ to $\alpha 2(I)$ chains in the 1.7-*M* NaCl fraction may be due to selective breakdown of the

Type V	<2	10

$\alpha 2(\mathrm{I})$ chain by overdigestion with pepsin, though normal bone type I showed little evidence for similar destruction under the same conditions. Gel electrophoresis of the 1.7-*M* NaCl fraction after CNBr digestion (fig. 5) confirmed that about one-half of the material was type III collagen, the remainder consisting of $\alpha 1(\mathrm{I})$ and $\alpha 2(\mathrm{I})$ chains. The apparent content of type I trimer collagen was quantified from the ratio of $\alpha 1(\mathrm{I})$ to $\alpha 2(\mathrm{I})$ in the total pepsin digests.

Another apparent anomaly should be commented on. In figure 5, the chain identified as $\alpha 1(\mathrm{III})$ runs as a monomer both with and without disulfide-bond cleavage. The disulfide-bonded trimer (γ-chain), a species usually prominent in many preparations of type III collagen before reduction of cystine disulfides, was virtually absent. This behavior seems peculiar to the gel electrophoresis system we use; purified preparations of type III collagen from fetal skin, for example, behave in the same way. We established the identity of the slow α-chain as $\alpha 1(\mathrm{III})$ by CNBr–peptide mapping (fig. 5).

This profile of collagen types was shown by 2 individual tumors for which the pepsin-solubilized collagen was fractionated by salt precipitation. For 9 tumors, the gel electrophoresis profiles of the total pepsin-solubilized collagen all gave essentially the same distribution, with similarly high ratios of αB to $\alpha 1(\mathrm{I})$ and $\alpha 1(\mathrm{I})$ to $\alpha 2(\mathrm{I})$. Type III CNBr peptides were always evident as components of whole CNBr digests of soft tumor (fig. 5).

The high content of hydroxylysine in the tumor collagen as a whole was not due solely to the abundance of type V collagen, which is known to be particularly rich in hydroxylysine. The individual salt-precipitated fractions that contained types I and III (and perhaps type I trimer) collagens all had unusually high contents of hydroxylysine (table 3). No type II collagen was detected in any specimen, confirming the absence of cartilaginous tissue. Although small amounts of type IV collagen from basal laminae would be difficult to detect by the present methods, the electrophoretic analyses of pepsin digests ruled out significant quantities.

Analysis of pepsin digests of tumorous bone showed more type I collagen and less type III, type I trimer, and type V collagens (data not shown), suggesting that the latter three collagen types are primarily associated with the neoplasm itself.

TABLE 3.—*Hydroxylysine content of salt-precipitated collagen fractions from soft tumor tissue*

Fraction	Collagen type, electrophoretic analysis	Hydroxylysine content,[a] residues/α-chain
1.7 *M* NaCl	Type III, type I, type I trimer	10.2
2.5 *M* NaCl	Type I	11.6
3.0 *M* NaCl	Type I, type V	14.7
4.0 *M* NaCl	Type V	23.1

[a] Calculated from amino acid analyses on the basis of 333 glycines/α-chain.

DISCUSSION

The ultrastructural studies of the highly cellular, early osteoid regions demonstrated malignant osteoblasts with abundant dilated RER. Similar findings on osteosarcoma ultrastructure have been reported by others (*1–3*). The primary matrix component was collagen, seen both in parallel and more frequently in woven conformations. In general the collagen was ultrastructurally unremarkable in comparison to collagen seen in developing or repairing bone. Our ultrastructural findings of osteosarcoma tissue have been detailed elsewhere (*12*).

Biochemically, an unusual mix of collagen types has been identified in the soft tumor matrix of osteosarcoma. Three main collagens are abundant—type I, type III, and type V—which is in contrast to the distribution in normal bone matrix, which consists almost exclusively of type I collagen. The evidence suggests that a type I trimer molecule—$[\alpha 1(\mathrm{I})]_3$—may also be abundant. Type II collagen was not detected, although it will be recalled that regions demonstrating cartilage either as seen by gross examination or by light microscopy were specifically avoided. In sarcomas, the type I collagen contained two to three times more hydroxylysine and more hydroxylysine glycosides than did type I collagen of normal adult bone. All 9 tumors showed this characteristic collagen composition. The only property that showed any evidence for subgrouping was the degree of glycosylation of hydroxylysine. However, the 2 patients distinguished by having the lower ratio of glucosylgalactosylhydroxylysine to galactosylhydroxylysine did not stand out in any other way, either in clinical course of the disease or in morphology or chemistry of the tumor.

Type I trimer collagen is still a poorly characterized molecule whose polymeric form and function are unknown. It seems most prominent in young, developing tissues, e.g., embryonic bone and tendon (*13*). It was also found in a virus-induced mouse tumor, originating from epithelial cells of the salivary glands, that produces bone and cartilage (*14*). This mouse tumor produced type I collagen—$[\alpha 1(\mathrm{I})]_2\alpha 2(\mathrm{I})$—and type I trimer collagen—$[\alpha 1(\mathrm{I})]_3$. An abundance of type I trimer collagen in the osteosarcoma matrix may, therefore, be another example of a neoplasm expressing a protein that is prominent normally only during development. Fetal proteins, such as carcinoembryonic antigen and α-fetoprotein, are synthesized actively by various human neoplasms (*15*).

Although blood vessels might be a source of some of these collagens, particularly of type III, light microscopy showed that vessel walls could contribute only a minor portion of the total matrix collagen. Type III collagen seems to be the collagen component of reticulin fibers found in many tissues (*16*), though it is not yet clear whether type III collagen is restricted in distribution to reticulin. Type III is prominent in human leiomyomas (*17*), and a rhabdomyosarcoma cell line (*18*) has been shown to produce predominantly type III and much smaller amounts of type IV collagens.

Type V collagen seems to be present in most connective tissues in small amounts and is synthesized together with types I and III collagens by fibroblasts in culture (*19*). It is believed to be concentrated pericellularly, so its relative abundance in the soft tumor specimens may be directly related to the high cellularity of the tissue.

Other matrix-rich tumors have been shown to make predominantly a single collagen product. A transplantable chondrosarcoma in the rat produced type II collagen exclusively (*20*), cartilaginous portions of a human osteosarcoma synthesized procollagen type II in organ culture (*21*), and a poorly differentiated murine chondrosarcoma produced type IV collagen (*22*).

At present, the histologically defined subtype of osteosarcoma appears to be of no value in predicting clinical outcome (*23*). Osteoblastic, chondroblastic, fibroblastic, and telangiectatic (*24*) variants show no predictable differences in prognosis, and the choice between chemotherapy and surgery is not based on the dominant tissue component. Thus at present, collagen typing would appear to be of limited clinical value although more specific therapies might eventually make such information useful. Collagen typing has potential value in differentiating between highly anaplastic osteosarcomas that show no distinct osteoid histologically and that often require the implementation of varying therapies. Of potential value is the observation that Ewing's sarcoma may be rich in type IV collagen (*25*).

Questions on the properties of osteosarcoma extracellular matrix remain. Is all the collagen made by the malignant osteoblast-like cells, those cells most obviously active in protein synthesis, or is the bone formed partially or even exclusively as a secondary, reactive phenomenon of nonmalignant host cells? Undifferentiated mesenchymal cells can be induced to form bone, for example, in response to implants of decalcified bone matrix (*26, 27*). Irrespective of the origin of osteosarcoma bone, special properties of the early tumor matrix seem indicated.

Exogenous Estrogens and Other Risk Factors for Breast Cancer in Women With Benign Breast Diseases[1,2,3]

David B. Thomas,[4] **Joyce P. Persing,**[5] *and* **William B. Hutchinson**[6,7]

ABSTRACT—A group of 1,439 white women who were initially treated for biopsy-proved benign breast diseases from 1942 to 1975 in a single private surgery practice were followed through 1976 for development of breast cancer. Information on age, parity, and use of noncontraceptive estrogens was collected on all women at the time of their initial benign lesion. At follow-up, ages at menarche, menopause, and birth of first child were obtained, as was information on use of estrogens after the initial lesion. Slides from the initial lesion were reinterpreted and classified by a panel of pathologists. The influence of gross and microscopic features of the initial benign conditions on subsequent risk of breast cancer was ascertained and reported previously. This paper presents results of additional analyses based largely on Cox's proportional hazards model. Risk of breast cancer was related to nulliparity and ages at menarche and birth of first child and to a lesser extent to age at artificial menopause. Exogenous estrogen taken prior to the initial benign lesion did not alter risk of breast cancer. Subsequent use, primarily of conjugated estrogens, eliminated the protective effect of an artificial menopause and appeared to act synergistically with epithelial hyperplasia or papillomatosis in the initial lesion and calcification of that lesion to increase the risk of breast cancer. A marked increase in risk of breast cancer in succeeding birth cohorts was unexpectedly found that could not be explained by temporal changes in any of the other risk factors considered.—JNCI 1982; 69:1017–1025.

Risk of breast cancer is approximately doubled in women with benign breast diseases (*1–5*). The present study was initially conducted to identify specific histologic features of benign breast lesions that distinguish women at increased risk of breast cancer. Results of that aspect of the study have been published (*5*). They, along with those of Page et al. (*4*), showed risk of breast cancer to be particularly related to proliferative lesions of the ductal epithelium.

A number of case-control (*6–13*) and prospective (*14–18*) studies have been conducted to determine whether exogenous, noncontraceptive estrogens alter the risk of breast cancer. The results are generally inconsistent. Some studies showed risk of breast cancer to be increased long after initial use of estrogens (*13, 15, 16, 18*) in women exposed to high doses (*12, 13, 16, 18*), in women with an artificial menopause (*13, 15*), and in women with such risk factors for breast cancer as nulliparity (*13*) and family history of breast cancer (*13*); but other studies showed no such results. A consistent finding among one prospective (*15*) and two case-control (*12, 13*) studies is an increased risk of breast cancer in relation to use of exogenous estrogens in women with benign breast lesions; no results contradicting these have been published.

The results of additional analyses of data from our follow-up study of women with benign breast disease (*5*) are presented in this paper. These analyses were performed primarily to investigate further the influence of exogenous estrogens on risk of breast cancer in women with benign breast lesions. Risk associated with estrogen use in women with various histologic types of benign lesions is considered for the first time. Analyses were also performed to ascertain whether menstrual and reproductive risk factors for breast cancer are operative in women with benign mammary conditions and to investigate temporal trends in breast cancer incidence in such women.

METHODS

Details of the study design and data collection have been reported previously (*5*). White women (1,439) initially seen in a private surgery practice from 1942 to 1975 for benign breast lesions were followed through 1976 to ascertain whether they had developed breast cancer. Methods of follow-up included letters and phone calls to the study subjects, review of office records, and the obtaining of death certificates for women who had died.

When the patient made her initial visit for a benign lesion, information was obtained and recorded on age, parity, and prior use of noncontraceptive estrogens. Information on prior use of noncontraceptive estrogens was limited to yes–no responses. Additional data on age at menarche, age at birth of first child, type of and age at menopause, and use of exogenous estrogens since the initial episode of benign breast disease were ascertained at follow-up for development of breast cancer. Information on the use of estrogens included the type of estrogen (recorded as oral contraceptives, Premarin, other estrogens, and hormones of an unidentified type), date and age at first use, and duration of use. mation was not obtained on treatment schedules, strength of preparation, or reasons for use. Of the 504 women who used estrogens after their initial benign breast lesion, 419 used Premarin or other estrogens, 47 used only oral contraceptives, and 38 used only hormones of an unidentified type. Most users of Premarin, other estrogens, and hormones of an unidentified type used them during and after the perimenopausal period. Thus use of all these hormones probably largely represents use of estrogens for menopausal symptoms, and these users were grouped together in the analyses. Oral contraceptives tended to be used at earlier ages but by too few women to analyze as a separate group. In the analysis presented, the oral contraceptive users are grouped with the menopausal estrogen users because results of one previous study have suggested that oral contraceptives (*19*), like menopausal estrogens, may increase the risk of breast cancer in women with prior benign breast lesions.

Slides from the initial benign lesions and any subsequent breast cancers were reread and classified according to a standard protocol. Five major types of benign breast diseases were distinguished (inflammatory disease, fibrocystic disease, fibroadenoma, nipple adenoma, and intraductal papilloma). Women with fibrocystic disease were further classified with respect to the components present (apocrine metaplasia, adenosis, sclerosing adenosis, epithelial hyperplasia or papillomatosis, calcifications, inflammation, and atypia).

The data were analyzed by means of Cox's proportional hazards model (*20*), which specifies that the instantaneous incidence of breast cancer at age t for a woman with covariables $z(t)$ is given by $\lambda[t,z(t)] = \lambda_0(t) \cdot e^{\beta' z(t)}$. In this expression, $\lambda_0(t)$ represents the unknown age-specific incidence function for a base-line individual $[z(t)=0]$. A consequence of the model is that the breast cancer age incidence functions for individuals characterized by explanatory variables $z_1=z_1(t)$ and $z_0=z_0(t)$ at age t are proportional: $e^{\beta'(z_1-z_0)}$ is the ratio of their disease incidence rates and defines an RR function measured relative to that of individuals characterized by z_0.

The model is partially nonparametric in that no assumptions are made regarding the functional form of the breast cancer incidence function for base-line individuals. Statistical inference is based on asymptotic likelihood theory.

The proportional hazards model was used because of the flexibility it permits in handling large numbers of variables whose values may change over the course of the study (time-dependent covariates). Factors in this study that were time-dependent include estrogen use, parity, and menopausal status. This technique was also used to measure exposures that accumulated over time (e.g., duration of estrogen use) and latency effects (i.e., effects that depend on the elapsed time since some event).

The proportional hazards model assumes that the covariates act multiplicatively on the underlying base-line incidence (hazard) of breast cancer. The consistency of our data with this specification was examined in several ways. Marked departures from the proportional hazards assumption were assessed by the inclusion of additional time-dependent covariates in the model and tests of their statistical significance. Such factors allow the RR to be a time-dependent, rather than a constant, multiple of the base-line incidence of breast cancer (*20*). For example, this technique enabled us to determine whether the effect of an early menarche on breast cancer risk is greater during the premenopausal and perimenopausal years than in the years following menopause. Graphical methods provided additional means for assessment of the goodness of fit of the proportional hazards model to the data (*21*).

RESULTS

The total study group consists of 1,439 women with biopsy-proved benign breast disease who contributed a total of 18,542 person-years of observation for an average of 12.9 years per person. Forty-one percent of the women were followed for 15 years or more and 25% for 20 years or more. Table 1 characterizes the study group according to follow-up status. Fifteen percent of the women were not contacted at the time of follow-up. These women are included in the study until the date of their last visit for benign breast disease and contribute an average of 3.8 person-years of observation per person. The only follow-up data available from them are a small amount of information abstracted from the physician's records. The remaining 1,221 women were followed through 1976. Of these, 66 were found to have developed breast cancer, 37 had bilateral mastectomies for benign lesions, and 87 had died of causes unrelated to breast cancer. Cardiovascular diseases were the most common causes of death. The women with bilateral mastectomies were considered at risk of breast cancer until the time of their second mastectomy. The remaining 1,031 women were contacted at follow-up, as were 53 of the 66 women who developed breast cancer. Of the 13 deceased women with breast cancer, some follow-up information was obtained on 7 of them from next-of-kin.

In the analyses that follow, 86 of the breast cancer-free women (6.3%) have been eliminated: 84 because they were less than 30 years of age at the time of their last contact or at follow-up and 2 because they were older than 82 years of age at their initial diagnosis of benign breast disease. Since the youngest breast cancer case occurred at age 30 and the oldest at age 82, person-years of observation on these 86 women contribute no useful information. The analyses are, therefore, based on a maximum of 1,353 women, 66 of whom developed breast cancer. Women with no information

TABLE 1.—*Distribution of study population by status at follow-up*

Subgroups of women	Distribution of women		Average person-years of observation per person
	Number	Percent	
Complete follow-up	1,221	84.9	14.5
No breast cancer by 1976	1,031	71.7	15.0
Bilateral mastectomy for benign lesion before 1976	37	2.6	3.8
Died prior to 1976	87	6.0	14.2
Developed breast cancer by 1976	66	4.6	13.0
Incomplete follow-up	218	15.1	3.8
Total	1,439	100.0	12.9

regarding particular variables were excluded from analyses involving those variables.

Women who developed breast cancer did not differ from the others by age at diagnosis of initial benign lesion, duration of follow-up, or age at follow-up (equivalent to age at diagnosis of breast cancer for women who developed breast cancer).

Results of detailed analyses regarding specific histologic types of benign breast disease and breast cancer risk have been published (*5*). Excess risk of breast cancer was related to the presence of fibrocystic disease and particularly so if there was evidence of epithelial hyperplasia or papillomatosis and calcification. Fibroadenoma was not associated with any increased risk except in women with concomitant fibrocystic disease.

The influence of four reproductive and menstral factors on risk of breast cancer is shown in table 2. For each factor, estimates of the RR were obtained by division of the relevant data into appropriate categories (age at event) and estimation of separate, age-adjusted RR for each category. This was done with the use of the proportional hazards model with dummy variables. This technique makes no apriori assumptions regarding the direction of the relationship between risk of breast cancer and these factors. Virtually identical results were obtained by means of the Mantel-Haenszel approach (*22*) and a person-years analysis. Age at menarche and age at birth of first child showed relationships to breast cancer risk similar to those from previous studies (*23*).

As expected, the age-adjusted RR of breast cancer was lowest in women with a surgical menopause before age 45, slightly higher in premenopausal women and women with a natural menopause before age 45, and higher yet in women with a surgical menopause after age 45. However, the RR in women with a natural menopause after age 45 was unexpectedly low. There was no evidence that the apparent protective effect of a surgical menopause increased with advancing age. In these analyses, women with surgical menopause included both oophorectomized and nonoophorectomized women. In addition, this analyses does not take account of the possible influence of menopausal estrogen use.

The estimated RR of breast cancer in relation to each of the four factors shown in table 2 were also estimated by modeling the associated factors as linear functions of the log-breast cancer incidence function—i.e., $\log\lambda[t;z(t)] = \log\lambda_0(t) + \beta' z(t)$. The linear modeling was found to explain the variation in risk as well as the nonrestrictive models. Moreover, these estimates were not appreciably altered by simultaneous adjustment for each of the other variables in the table and for various features of the benign lesions. Therefore, the linear models were used to adjust for these four variables in subsequent analyses.

In the analyses of estrogen use following benign breast disease, women using estrogens contributed person-years of observation to the users category for each year subsequent to their initial use. Prior to then, they were considered nonusers. Using the proportional hazards model and not adjusting for any other factors, we estimated the RR associated with such use to be 1.80 (95% CI = 1.04–3.10; χ_1^2 = 4.51).

The RR associated with estrogen use was also estimated by the construction of a series of 2×2 tables based on the ages t_k at which breast cancer was diagnosed. Among women whose use or nonuse of estrogens was ascertained, breast cancer occurred at 23 ages between 30 and 76, so there were 23 possible 2×2 tables. The data in each of these tables are shown on a separate line in table 3. Women are only considered at risk of breast cancer subsequent to their initial benign breast lesion. The number of women at risk thus changes with age, not only due to the loss of individuals from further observation but also due to the addition of women at their age of initial benign breast disease (*24*). Within each line of the table, individuals are classified with respect to their breast cancer status at age t_k and according to whether or not they had used estrogens by that age. Individuals may be reclassified in different groups at different ages. These data were analyzed by means of technique of Mantel and Haenszel (*22*) and gave an estimated RR of 1.84, with a corresponding chi-square statistic (without con-

[a] Based on 1,036 women, 56 of whom developed breast cancer. Mantel-Haenszel estimate of the RR is 1.84 (95% CI=1.05–3.23).

tinuity correction) of 4.53 (P=0.03). Using Miettinen's test-based procedure (*25*), we estimated the 95% CI of the RR to be from 1.05 to 3.23.

When a single dichotomous variable is considered, the proportional hazards model is mathematically equivalent to the Mantel-Haenszel procedure (*26*). The similarity of the above results demonstrates this common conceptual framework. The advantage of the model is that it permits extensions to multiple continuous variables which are not easily handled by the Mantel-Haenszel stratification procedure.

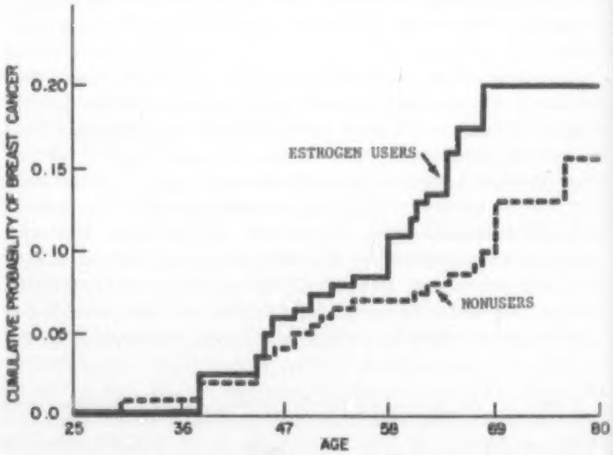
Text-figure 1 shows Kaplan-Meier (*27*) estimates of the cumulative lifetime probability of developing breast cancer for estrogen users and nonusers. As in table 3 the compositions of the 2 groups are time-dependent since the factor defining them (estrogen use) is itself time-dependent. For example, a woman who enters the study at age 35 and begins using etrogens at age 50 would be in the nonusers category from ages 30 to 49 and in the users category from age 50 on. The text-figure illustrates that the effect of exogenous estrogens does not become apparent until after the usual age of menopause. Moreover, the estrogen effect appears to become more pronounced with the passage of time, although this tendency is not statistically significant.

The use of estrogens *prior* to diagnosis of benign breast disease did not affect subsequent breast cancer risk, and the RR associated with use of estrogens after the initial benign breast lesion was not altered by any earlier use.

The RR associated with use of exogenous estrogens after benign breast disease did not vary significantly with age or year of first use or interval of time from the initial benign breast lesion to first use. There was also no evidence of an increase in RR with increases in duration of use. The RR for users of less than 5 years was 1.87 (95% CI = 0.98–3.53), whereas that for users of 5 or more was 1.91 (95% CI = 0.90–4.03). When duration of use was dichotomized at 3 and 4 years of use, RR of breast cancer were actually slightly greater for those in the shorter duration category.

Because follow-up occurred over 34 years, we were able to investigate temporal trends in the incidence of breast cancer by including a linear term for year of birth in the regression equation. As table 4 demonstrates, there appears to have been large increases in breast cancer risk in successive birth cohorts. This trend is the strongest of any in these data ($P < 0.001$) and represents over a fourfold increase in risk between the 1905 and the 1925 cohorts.

We attempted to validate this observation using two other techniques. First, we plotted separate age incidence curves for various birth cohorts. This method was of limited utility because the curves for different cohorts were based on small numbers of cases and did not cover common ages sufficiently to allow one to draw conclusions on inspection. Second, we constructed risk sets at each age at which breast cancer occurred, in the same manner as was shown in table 3 for estrogen use, and compared the average year of birth for women who developed breast cancer with that for those who did not. As shown in table 5, on the average, compared to women of the same age who did not develop breast



TEXT-FIGURE 1.—Cumulative lifetime probability of breast cancer for 2 time-dependent groups representing estrogen users and nonusers. Estrogen users are counted as nonusers until the age at which they first began to use estrogens.

TABLE 4.—*RR of breast cancer in relation to year of birth: Results of proportional hazards analysis*[a]

Year of birth	RR[b] (95% CI)
1905	1.00

1920–1929	1.48	1.68
≥1930	2.54	2.84

[a] Based on 1,353 women.

[b] The linear model was fit to the midpoints of the intervals defining cohorts. The years 1905 and 1935 were used for the two open-ended intervals. Score test for linear trend: $\chi_1^2=6.3$, $P=0.01$.

cancer, those who did tended to be born in more recent cohorts.

To determine whether the assumption of a linear year of birth trend used in the model to obtain the estimates in table 4 was reasonable, we divided the data into four approximate 10-year birth cohorts. Separate estimates of the RR were made independently from each cohort rather than with the asumption of a linear trend. These RR estimates are shown in column 2 of table 6. The 1910–19 cohort was used as the base line. Column 3 shows estimates of the RR obtained by our assigning a year of birth to all women in each interval equal to the midpoint of the interval and assuming a linear model. The departure of the RR in column 2 from the linear trend in column 3 was minor ($\chi_2^2=0.25$; $P=0.88$) whereas the trend itself was highly significant ($\chi_1^2=6.3$; $P=0.01$).

Most of the women in this study were at risk of breast cancer at ages over 45. This fact makes it difficult to compare the shape of the breast cancer age incidence curves with those of other studies. Nonetheless, by including an interaction term between age and year of birth in the model, we were able to test for differences in the shape of the age incidence curves for the various birth cohorts. There was no evidence that the increase in risk with age varied with year of birth ($\chi_1^2=1.20$; $P=0.27$). Although age at diagnosis of initial benign breast lesion was related to year of birth, adjusting for it did not influence the effect of birth cohort on breast cancer risk.

Table 7 shows that temporal changes in the ages at menarche, birth of first child, natural menopause, or surgical menopause cannot account for the large cohort effect, nor can changes in the histologic characteristics of benign lesions. Estrogen use in both women with natural and surgical menopause, on the other hand, was strongly related to year of birth (table 7). The proportion of users by age 48 in more recent cohorts was more than three times that in earlier cohorts. This finding is not surprising because use of estrogens in our area (*28*), as well as in the United States (*29*), has increased severalfold since the mid-1960's.

To determine whether this change in estrogen use could explain the cohort effect, we adjusted for estrogen use when evaluating the year of birth trend. Women with no information regarding estrogen use were excluded from this analysis. The sample size is, therefore, different from that of table 4. To compare the adjusted and unadjusted results, we also performed the same analysis as represented in table 4 on the reduced data set. These two sets of RR estimates are presented in table 8. The cohort effect was only slightly reduced after we controlled for differences in breast cancer risk due to estrogen use.

Table 9 shows estimated RR of breast cancer in estrogen users adjusted for various combinations of reproductive factors and features of the initial benign breast lesion, with and without adjustment for the cohort effect. Estimates of the RR associated with estrogen use were not appreciably altered by adjustment for reproductive factors or features of the benign lesions and are generally significantly larger than

TABLE 7.—*Known and potential risk factors for breast cancer in women in succeeding birth cohorts*

Risk factor	Year of birth			
	≤1909	1910–1919	1920–1929	≥1930
Average age at menarche	13.3	13.0	13.0	12.7
Average age at birth of first child	25.3	25.8	24.5	24.0
Average age at natural menopause	49.3	50.3	48.3	—
Percent with surgical menopause by age 46	22.9	25.4	25.1	22.2
Percent with fibrocystic disease characterized by epithelial hyperplasia or papillomatosis (age adjusted)	28.2	37.1	34.0	35.6
Percent who used estrogens by age 48				
Total women	11.3	15.7	39.8	—
With natural menopause	11.1	12.3	32.2	—
With surgical menopause	20.8	28.6	58.7	—

TABLE 8.—*RR of breast cancer in relation to year of birth, unadjusted and adjusted for estrogen use: Results of proportional hazards analyses*[a]

Year of birth	RR (95% CI)	
	Unadjusted for estrogen use[b]	Adjusted for estrogen use[c]
1905	1.00	1.00
1910	1.34 (1.06–1.69)	1.28 (1.00–1.63)
1915	1.79 (1.13–2.86)	1.63 (1.00–2.65)
1920	2.40 (1.19–4.84)	2.08 (1.01–4.32)
1925	3.22 (1.27–8.18)	2.66 (1.01–7.04)

[a] No.=1,036.

[b] RR per year=1.06 (1.01–1.11); $\beta \pm SE=0.0585 \pm 0.0238$; score test for linear trend: $\chi_1^2=6.2$, $P=0.01$.

[c] RR per year=1.05 (1.00–1.10); $\beta \pm SE=0.0490 \pm 0.0248$; score test for linear trend: $\chi_1^2=3.9$, $P=0.05$.

1.0 (column 3). However, after taking account of the cohort effect, we reduced the magnitude of the RR associated with estrogen use to a nonsignificant level irrespective of adjustments for any other factors (column 4). Thus it appears that at least part of the apparent association of breast cancer risk with estrogen use may be due to the confounding influence of birth cohort.

No interactions were observed between estrogen use and parity or ages at first birth, menarche, or natural menopause. The RR of breast cancer associated with estrogen use also did not vary with year of birth: RR were 1.70 in women born prior to 1910, 1.38 in women born between 1910 and 1919, and 1.45 in women born after 1919.

The possible interaction of exogenous estrogen use and surgical menopause is shown in table 10. Estimates of the RR shown are adjusted for year of birth. Estrogens did not increase the risk of breast cancer in women with intact ovaries (RR=1.02). The expected protective effect of a surgical menopause is evident in women who did not receive estrogens (RR=0.85), and estrogens appear to have eliminated that protection. It is uncertain whether the RR of breast cancer in estrogen users with an artificial menopause was greater than that of nonusers with intact ovaries.

Table 11 shows estimated RR of breast cancer in relation to estrogen use and characteristics of fibrocystic disease that were found to alter risk of breast cancer (*5*). This analysis is restricted to women who had fibrocystic disease and no other type of benign lesion and is thus based on only 524 individuals. Although none of the RR differ significantly from unity, noteworthy trends are evident. For each of the four categories shown, estrogen use appears to have increased breast cancer risk. Except in women with epithelial hyperplasia or papillomatosis with calcification, this effect was limited to women with a surgical menopause (not shown). In women with epithelial hyperplasia or papillomatosis, but not in women without these conditions, the presence of calcifications in the benign lesion and subsequent use of estrogen appear to act synergistically (on a multiplicative scale) to increase risk. This synergism was most apparent in women with a surgical menopause, but it was also observed to a lesser extent in women with intact ovaries.

TABLE 9.—*RR of breast cancer in relation to estrogen use, unadjusted and adjusted for year of birth and various other potential confounders: Results of proportional hazards analyses*

Potential confounders	No. of women	RR (95% CI)	
		Unadjusted for year of birth	Adjusted for year of birth
None	1,036	1.80 (1.04–3.10)	1.49 (0.84–2.63)
Fibrocystic disease	977	1.80 (1.03–3.15)	1.48 (0.83–2.65)
Age at menarche, birth of first child, and menopause[a]	857	1.80 (0.96–3.38)	1.38 (0.72–2.65)

[a] Includes both natural and surgical menopause.

DISCUSSION

The subjects of this study were largely middle and upper class white women who received care for their benign breast conditions in a single private practice. Actual rates of breast cancer in this population may, therefore, not accurately represent rates in all women with benign breast lesions. However, the RR that have been estimated are based on comparisons of subgroups within the study population and, as previously discussed (*5*), are not likely to have been affected by the self-selected nature of women in the study. For example, for differential selection to have caused a spuriously elevated RR of breast cancer in users of estrogens, women with benign lesions who later used estrogens and then went on to develop breast cancer would have to have been more likely to seek care for their initial lesion than future users who did not develop breast cancer. This seems an unlikely possibility.

The incompleteness of follow-up is also not likely to have resulted in spurious findings. For this to have erroneously resulted in an elevated RR of breast cancer in estrogen users, those users lost to follow-up would have had to have been at a lower risk of subsequent breast cancer than users who were completely followed. Furthermore, because those lost to follow-up were a small proportion of the total study population, the difference in their risks would have to have been large. This is unlikely because the differences in the completely and incompletely followed women with respect to parity and type of benign breast lesion were small (*5*), and although more of those lost to follow-up were younger and had fibroadenomas (lower risk), more of them also were nulliparous (higher risk).

The incomplete nature of the information on estrogen use is a true limitation of this study. The only formation on use prior to the initial benign lesion was a yes or no response to a query at the time the woman was initially evaluated for her benign condition. Use subsequent to the initial lesion was largely ascertained from the study subject at the time of follow-up, when detailed questions regarding use after her most recent office visit for a benign lesion were asked. For the 184 women with more than one benign lesion who used estrogens, use between the first and most recent lesion was obtained only from medical records, and like use subsequent to the first benign lesion was limited to a yes or no response. Fortunately, these women constituted only 13% of the study population, and risk of subsequent breast cancer was not related to number of episodes of benign breast disease. This incomplete information is thus not likely to have resulted in a spurious association between estrogen use and breast cancer. It could, however, have reduced the probability of finding a true increase in risk associated with exogenous estrogens.

The well-documented (*23*) adverse effects of early menarche, late first birth, and nulliparity, and the protective effect of a premenopausal oophorectomy were all found operative in this study population. This suggests that the increased risk of breast cancer associated with benign breast lesions is not due to women with such lesions simply having these risk factors; i.e., these risk factors and benign breast lesions independently alter risk of breast cancer. Results of case-control studies of breast cancer (*23*) are consistent with this conclusion as are findings from case-control studies of benign breast disease that show that risk factors for breast cancer do not consistently distinguish women with benign lesions (*30*). Women with benign breast lesions who have the menstrual and reproductive risk factors for breast cancer are thus at particularly high risk.

Two case-control studies (*12, 13*) have shown use of menopausal estrogens to enhance risk of breast cancer to a greater extent in women with than without a history of benign breast disease, and, consistent with our findings, in one study (*13*) this was only observed in women with a bilateral oophorectomy. The effect on breast cancer risk of estrogen use before versus after the benign lesion was not addressed in either of these studies, but it was in a prospective study by Hoover et al. (*15*). These investigators found the RR of breast cancer to be 4.0 in women who received estrogens prior to their benign lesions, as opposed to 2.1 in women who took estrogen after their lesion was diagnosed. The latter value is close to the RR of 1.8 observed for women in the present study who used estrogens after their initial benign lesion. However, we did not find estrogen use prior to a benign lesion to alter risk of breast cancer. A partial explanation for this discrepancy may be the rudimentary nature of our information on such usage. On the other hand, this information was ascertained at the time of the benign lesion and not years later at follow-up; and it is unlikely that the misclassification of usage could have been of sufficient magnitude to have totally obscured a true fourfold increase in risk.

The risk of breast cancer in women who used estrogens after their initial benign breast lesion was not significantly increased prior to menopause. Risk was elevated after menopause and showed a slight tendency to increase with age. The premenopausal estrogen users include a small number of women who took oral contraceptives plus others whose estrogen use was for unknown reasons. The postmenopausal increase in risk with age is compatible with the latent period between exposure to estrogens and increased risk of breast cancer observed by others (*15, 16, 18*) and not supportive of the results of Jick et al. (*11*), who reported an increased risk of breast cancer in current and recent users of estrogens.

Fibrocystic disease characterized by epithelial hyperplasia or papillomatosis was found to distinguish women in this study who were at particularly high risk of breast cancer, and their risk was elevated even more if their lesions had histologic evidence of calcification (*5*). The influence of estrogens on risk of breast cancer was not related to the presence of epithelial hyperplasia or papillomatosis. However, in women whose lesions had these features, the RR of breast cancer in estrogen users was greatest in women whose lesions had calcifications. Thus in women with fibrocystic disease, the presence of proliferative lesions of the ductal epithelium, calcification of these lesions, and exogenous estrogens all appear to interact to increase the risk of breast cancer. Women with all three of these factors were observed to have a risk of breast cancer that was 7.85 times greater than that of women with none of them. This effect was greatest in women with a surgical menopause. However, these observations are based on small numbers of cases, and the 95% confidence limits of the RR estimates include one. Independent confirmation of these findings is thus needed.

Many previous studies have shown premenopausal oophorectomy to reduce the risk of breast cancer (*22*). This result was noted in the present study, but not in women who had used estrogens. Elimination of the protective effect of an oophorectomy by exogenous estrogens is also evident from the reports of Hoover et al. (*15*) and Brinton et al. (*13*) and is probably a real phenomenon, although it was not demonstrated in the study by Ross et al. (*12*).

In the present study group the influence of estrogens on risk of breast cancer was largely confined to women with an artificial menopause. Compatible with our observations, Brinton et al. (*13*) found the risk associated with estrogens to be greater in women with an artificial menopause than in women with intact ovaries, but unlike us, they also observed some increase in risk in women with a natural menopause. Hoover et al. (*15*) found the increment in risk associated with estrogen use to be unrelated to ovarian status, whereas Ross et al. (*12*) found it to be confined to women with intact ovaries. These discrepant results indicate the need for additional studies of breast cancer in relation to oophorectomy and exogenous estrogen.

Evidence that the observed association between breast cancer and exogenous estrogens is causal would be strengthened if risk was found to increase with the amount of estrogen received. Ross et al. (*12*) found risk to be directly related to total cumulative dose, and Brinton et al. (*13*) found a weak (but statistically significant) increase in risk with duration of use. Hoover et al. (*15*) observed risk to increase with the strength of the preparation, but, paradoxically, to be lower in women who took estrogens daily than in women who took them less frequently. Women in these studies, like those in the present one, were largely users of conjugated estrogens for treatment of menopausal symptoms. Additional evidence for a dose response comes from three studies of women treated with diethylstilbestrol during pregnancy for threatened abortion (*16–18*). The excess risk was greatest in the study in which the mean dose of diethylstilbestrol was 16.3 g (*18*) and smaller in the study in which the mean dose was 11 g (*16*); no excess risk was observed in the study in which women received an average of 1.5 g (*17*). In the present study, risk of breast cancer did not increase with duration of estrogen use. A possible explanation for this finding is the limited accuracy of our information on dosage, which was based solely on responses to questions at the time of follow-up.

As discussed below, an unexpected finding in this study was the marked increase in risk of breast cancer in women in succeeding birth cohorts. Use of estrogens was also more common among women in later than earlier years. Year of birth was thus related to both breast cancer risk and estrogen use. However, it is unclear whether this factor should be considered a possible confounding variable which should be controlled when one is estimating the RR of breast cancer in estrogen users. This depends on the mechanisms responsible for the observed associations.

If some factor other than estrogen use is responsible for the year of birth effect on breast cancer risk, then year of birth can be considered a surrogate for this unknown factor and should be adjusted for as a confounding variable (*31*). However, if year of birth only influences estrogen use, and estrogen use in turn increases the risk of breast cancer, then year of birth is not a confounder and should not be controlled for in the analysis. Because we have no way of knowing which of the above possibilities is correct, we chose to present estimators of RR of breast cancer in estrogen users both adjusted and unadjusted for year of birth (table 9).

Forty-seven women whose only source of exogenous estrogens was oral contraceptives were considered estrogen users in the above analyses. Estimated values of RR in estrogen users were slightly lower when these women were treated as nonusers, but they were not changed sufficiently to alter any conclusions regarding the effects of exogenous estrogens on breast cancer risk.

There was approximately a fourfold increase in risk of breast cancer in birth cohorts spanning a 20-year period. Cohort-specific increases in breast cancer incidence and mortality rates have been reported in the general female populations of Iceland (*32*), Israel (*33*), Japan (*34*), Canada (*35*), England and Wales (*36, 37*), and the United States (*36*), as well as among Japanese immigrants to the United States (*38, 39*). Rather small cohort-specific increases have been related to change in fertility in such high-risk countries as Canada (*35, 40*), the United States (*36*), and England and Wales (*36*), although another study in England and Wales did not confirm this relationship (*37*). The larger cohort-specific increases in incidence in the initially low-risk country of Iceland (*41*) and in Japan (*42*), where rates are still low, have been found not to be related to changes in child-bearing practices. In Japan, they have been correlated with changes in dietary intake of fats and other nutrients (*42*). Rates of breast cancer among various countries have been correlated with these same dietary factors (*43, 44*). The cohort-specific increase in breast cancer risk observed in this study was of the same high order of magnitude as that in Iceland and, like the increases in Iceland and Japan, was not related to changes in child-bearing practices or to changes in ages at menarche or menopause. Also, the shape of the age-incidence curve in the present study did not vary with year of birth, which is consistent with similar observations in succeeding birth cohorts in Iceland and Japan, as well as in Denmark, Slovenia, Connecticut, and Finland (*45*).

In this study, there was a threefold greater use of estrogens in earlier than later birth cohorts, and a relationship between estrogen use and breast cancer was found. However, adjustment for estrogen use only reduced the cohort effect by a small amount. There are two possible explanations for this: 1) Either the cohort effect is largely due to factors unrelated to estrogen use or 2) the information on estrogen use was inadequate, and if it had been more complete, more of the cohort effect would have been explained by the temporal changes in estrogen use. There is no way of determining from analyses of the existing data which of these explanations is correct. If it is the second, then this would, of course, be additional evidence that exogenous estrogens can increase the risk of breast cancer.

Our interpretation of the available evidence is that estrogens may be responsible for a portion of the observed cohort effect but not all of it. The cohort effect *was* reduced by controlling for estrogen use and perhaps would have been reduced more if we had had more precise information on estrogen use. However, it is unlikely that all of the fourfold increase in breast cancer risk with succeeding birth cohorts could be explained on this basis. Other explanations would be conjectural. Dietary factors such those considered in national and international investigations were not studied. If the mechanisms for the large cohort difference observed in this population of women with benign breast lesions are the same as those in countries undergoing "westernization," then detailed studies of breast cancer in women with such lesions may help provide an explanation for large temporal changes in national rates and differences in risk among countries.

Second Cancers Following Radiotherapy for Cervical Cancer[1]

Ruth A. Kleinerman,[2,3] **Rochelle E. Curtis,**[4] **John D. Boice, Jr.,**[2] **John T. Flannery,**[5]
and **Joseph F. Fraumeni, Jr.**[2]

ABSTRACT—Incidence of second primary cancers was evaluated in 7,127 women with invasive cancer of the cervix uteri, diagnosed between 1935 and 1978, and followed up to 38 years (average, 8.9 yr) in Connecticut. Among 5,997 women treated with radiation, 449 developed second primary cancers compared with 313 expected (relative risk=1.4) on the basis of rates from the Connecticut Tumor Registry. Excess incidence was noticeable 15 years or more after radiotherapy and attributed mostly to cancers of sites in or near the radiation field, especially the bladder, kidneys, rectum, corpus uteri, and ovaries. No excess was found for these sites among the 1,130 nonirradiated women. The ratio of observed to expected cancers for these sites did not vary appreciably by age at irradiation. The data suggested that high-dose pelvic irradiation was associated with increase in cancers of the bladder, kidneys, rectum, ovaries, corpus uteri, and non-Hodgkin's lymphoma but, apparently, not leukemia, Hodgkin's disease, breast cancer, or colon cancer.—JNCI 1982; 69:1027–1033.

Conflicting data on risk of second primary cancers following radiotherapy for cervical cancer have been reported. Increased rate has been suggested for urinary bladder cancer (*1–5*), uterine cancer (*1, 2*), uterine sarcoma (*6*), rectal cancer (*2, 7*), lung cancer (*1–3, 8*), and osteosarcoma (*9*). However, no excess of leukemia has been reported in several studies (*1, 2, 6, 10–13*). To further investigate risk of second cancers, we evaluated data reported since 1935 to the Connecticut Tumor Registry. Previously, these data were analyzed through 1951 (*4*) and 1964 (*14*). The present evaluation is through 1978, increasing the number of cervical cancer patients and years of observation.

SUBJECTS AND METHODS

Of 8,247 women with primary diagnosis of invasive cancer of the cervix uteri, 7,127 women were eligible for study. Patients were excluded for any of the following reasons: unknown treatment (442), identification by death certificate or autopsy only (349), survival less than 3 months (236), occurrence of a second primary cancer within 3 months of cervical cancer diagnosis (48), or incomplete follow-up (45). Women were classified as radiotherapy patients if treatment occurred within 4 months of cervical cancer diagnosis.

Histologic confirmation was available for 96% of cervical cancers and 85% of all second primary cancers. Confirmation varied only slightly by calendar year. Cancer diagnoses were coded according to the eighth revision of the International Classification of Diseases (ICD) (*15*). Digestive cancers (ICD8 150–158) were not confirmed as often as other second primary cancers (75 vs. 89%). All second primary cancers were determined by a pathologist at the hospital where the cancer was diagnosed.

We calculated WY 3 months from date of cervical cancer diagnosis to date of diagnosis of second primary cancer; death; date lost to follow-up; or December 31, 1978, whichever occurred first. At the closing date of the study, 65% of the cervical cancer patients had died, and 13% had been reported lost to follow-up.

We derived expected numbers of cancers by multiplying age-, sex-, and calendar time-specific incidence rates by appropriate WY (*16*). RR was measured as ratio of observed to expected incident cancers. Absolute risk was computed as the difference between observed and expected events divided by the WY. Exact and approximate confidence limits were calculated with the use of the Poisson model for the observed number of cancers (*17*).

We decided not to compare incident cancers in the 2 treatment groups but to compare each group with the general population for two reasons. First, number of second primary cancers in the nonirradiated group was too small to provide stable rates, especially for evaluation of latency and effect of age at exposure to radiotherapy. Second, except for breast cancer and other genital cancer, the rate of second cancers in the nonirradiated group did not differ significantly from the rate in the general population. We stress that this analysis cannot be used to evaluate the therapeutic efficacy of different treatment regimens for cervical cancer.

Although individual dose data were not available from the registry, risk of cancer could be crudely evaluated for organs proximal, intermediate, and remote to the pelvis. Bladder, colon, rectum, uterine corpus, ovaries, bone and connective tissue, bone marrow, and lymphatics were considered proximal sites and thus heavily irradiated. Stomach, pancreas, kidneys, and liver were designated intermediate sites. Buccal cavity, lungs, breasts, brain, and thyroid gland were classified remote sites. Nonmelanoma skin cancers were excluded from all analyses.

RESULTS

Comparability of treatment groups.—Among the 7,127 women eligible for study with invasive cancer of the cervix uteri, 5,997 (84%) were treated with radiation and 1,130 (16%)

ABBREVIATIONS USED: CI=confidence interval; RR=relative risk; WY=woman-years at risk.

TABLE 1.—*Number of women by age at diagnosis of cervical cancer and type of treatment*

Age at diagnosis, yr	Radiotherapy	No radiotherapy	Total
<40	961	426	1,387
40–49	1,550	343	1,893
50–59	1,667	209	1,876
≥60	1,819	152	1,971
Total	5,997	1,130	7,127

were not. Irradiated women received either radiation only (86%); radiation and surgery (6%); radiation, surgery, and either hormones or chemotherapy (6%); or radiation and either chemotherapy or hormones (2%). Radiation treatment was external beam (22%), radium implant (20%), or a combination of both (58%). Women in the nonirradiated group received surgery alone (52%), surgery and either chemotherapy or hormones (46%), or either chemotherapy or hormones or both (2%).

Tables 1 and 2 compare age distributions and WY for the 2 treatment groups. Mean ages at diagnosis of cervical cancer for the irradiated and nonirradiated groups were 53 and 45 years, respectively. Maximum follow-up was 38 years for both. Mean follow-up was 7.8 years (45,392 WY) for irradiated women and 9.9 years (11,041 WY) for nonirradiated women.

All sites.—An excess of cancer occurred in both treatment groups (table 3). The observed-to-expected ratio for the irradiated group was 1.44, a statistically significant 44% excess over expectation. The ratio for the nonirradiated group was 1.30, a significant 30% excess. With the exception of breast cancer and other genital cancer, second cancer incidence in the nonirradiated group was not substantially different from that expected in the general population.

Lymphatic and hematopoietic system.—Nine leukemias were

[a] *Numbers in parentheses* are numbers of women at start of intervals.
[b] *P*<0.05, one-sided test.

TEXT-FIGURE 1.—Ratio of observed (obs) and expected (exp) incident cancers and absolute risk [(obs−exp)/WY] of proximal and intermediate sites by years since first radiation treatment.

diagnosed compared with 7.4 expected (RR=1.2, 95% CI=0.6–2.3) in the radiotherapy group. Incidence of reticulum cell sarcoma and lymphosarcoma in that group was also greater than expected (12 observed vs. 4.7 expected). Multiple myeloma, however, was not in excess (4 observed vs. 3.4 expected) nor was Hodgkin's disease (1 observed vs. 2.2 expected). No excess of lymphatic or hematopoietic cancers was found in the women treated without radiation.

Proximal sites.—With the exception of the colon, excess cancers occurred for all heavily irradiated proximal organs. The greatest excess was for cancer of the bladder: 26 observed compared with 7.7 expected (RR=3.4, 95% CI=2.2–5.0). Risks were elevated for cancers of the uterine corpus (RR=1.4, 95% CI=1.0–2.0), rectum (RR=1.6, 95% CI=1.1–2.3), and ovaries (RR=1.6, 95% CI=1.0–2.3). Two bone cancers of the pelvis were diagnosed, and less than 1 cancer was expected. A significant excess of cancer of the connective tissues occurred (RR=3.3, 95% CI=1.1–7.8). Of the 5 connective tissue cancers, 2 were in the trunk and 1 was in the hip; the site was not specified for the other 2 cancers.

Intermediate sites.—Among irradiated women, a definite excess of kidney cancer and a slight excess of stomach cancer were found. Fourteen kidney cancers were diagnosed versus 4.9 expected (RR=2.8, 95% CI=1.6–4.8). For all proximal and intermediate sites combined, there was a significant excess of cancer among radiotherapy patients (215 vs. 151), but this excess did not occur among the nonirradiated women (20 vs. 26.9).

Remote sites.—There were 64 cancers of the lungs, whereas 12.6 were expected (RR=5.1, 95% CI=4.0–6.5). No excess of pancreas cancer was seen (10 observed vs. 9.4 expected). A deficit of breast cancer occurred in the irradiated group (RR=0.7, 95% CI=0.5–0.9), compared with an excess of breast cancer in the nonirradiated group (RR=1.4, 95% CI=1.0–2.1). Thyroid cancer was not observed in either treatment group.

Time since radiotherapy.—For several organs, a substantial

TABLE 5.—*Observed and expected cancers of proximal and intermediate sites[a] by age at radiotherapy among 10-year survivors*

Category	No. of cancers at age at exposure, yr				
	<40	40–49	50–59	≥60	Total
No. of women	369	567	469	331	1,736

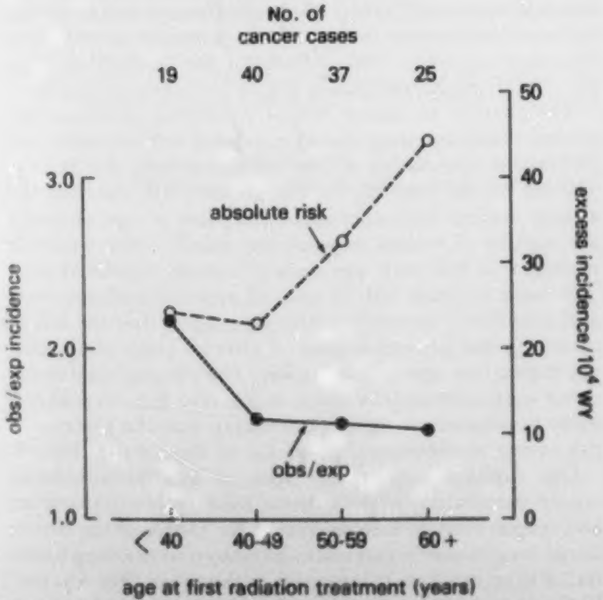
[c] $[(\text{Observed}-\text{expected})/\text{WY}]\times 10^4$.

excess of cancer occurred 15 years or more after radiotherapy (table 4). These included bladder (9 vs. 2.8), kidneys (9 vs. 1.7), ovaries (10 vs. 4.1), and corpus uteri (15 vs. 7.4). For women receiving radiotherapy, both the ratio of observed to expected cancers and the absolute risk of cancers of proximal and intermediate sites increased substantially after 10 years since exposure (text-fig. 1). The small risk observed in the early years might be related to close medical surveillance or metastases. Lung cancer rates were elevated during the first 19 years following radiotherapy (RR=6.1, 95% CI=4.7–7.8), but they decreased to normal levels thereafter. Breast cancer rates were lower than expected during each interval after radiotherapy.

Age at radiotherapy.—RR of cancer of irradiated proximal and intermediate sites did not vary appreciably by age at initial exposure (table 5, text-fig. 2), although those under 40 years of age had a slightly higher RR than did older women. Since the incidence of cancer generally increases with age, the constant RR implied a substantial increase in the number of cancers attributable to radiation exposure (text-fig. 2). Breast cancer rates were lower than expected for all ages, including women irradiated after 60.



TEXT-FIGURE 2.—Ratio of observed (obs) and expected (exp) incident cancers and absolute risk [(obs−exp)/WY] of proximal and intermediate sites 10 yr or more after first treatment by age at first radiation treatment.

DISCUSSION

This study of cervical cancer patients revealed an increased incidence of second primary cancers arising in several irradiated proximal organs. However, we found surprising that no excess of leukemia occurred in the radiation group because the dose to the bone marrow was large and leukemia is frequently seen as an irradiation effect.

Published risk estimates for leukemia, on the basis of studies of atomic bomb survivors and patients irradiated for ankylosing spondylitis, are about 2 leukemia cases per million persons/year/rad (*18*). Assuming an average dose of 750 rad to the total body bone marrow, we expected an excess of 68 cases in addition to the 7–8 cases anticipated from nonirradiation causes; a total of only 9 leukemias occurred. These results, however, are consistent with other large studies of cervical cancer patients (*10, 11*).

The radiation doses used to treat cervical cancer patients have been suggested as being too large to be leukemogenic. High doses to small volumes of bone marrow may sterilize cells rather than transform them, thereby reducing the number of cells available for cancer induction (*19*). In experimental studies, large doses of radiation can kill or inactivate cells in culture, and the incidence of myeloid leukemia in mice decreases at high doses (*20*). The bone marrow outside the pelvic region received an intermediate dose of radiation; why this dose did not increase the incidence of leukemia is yet to be explained. If the smaller dose received by the bone marrow outside the pelvis is the primary determinant for leukemogenesis, then the number of women exposed to radiation in our study may not be large enough for detection of the possible low risk involved.

Radiation dose to the lymphatic system was large, and an excess of reticulum cell sarcoma and lymphosarcoma but not Hodgkin's disease was observed. This finding is consistent with previous reports (*18*).

Because cervical cancer patients are more likely to smoke cigarettes compared with other women (*21*), the smoking-related sites have to be evaluated carefully. Cancers of the bladder, lungs, buccal cavity, and the esophagus but not the pancreas were increased. Bladder cancer was increased in the first 5 years after diagnosis of cervical cancer and again at 15 years or more after treatment. Early bladder cancer risk may be related to smoking habits or metastases misclassified as primary tumors. The nine bladder cancers diagnosed 15 years after treatment are consistent with the expected latent period for irradiation-related neoplasms. Interestingly, the temporal pattern of risk for bladder cancer differs from the risk for lung cancer. Risk for bladder cancer increased over time, whereas risk for lung cancer decreased. No increase in cancer of these smoking-related sites, except for the buccal cavities, was observed in the nonirradiated group.

Lung cancer excess occurred within the first 19 years after diagnosis of cervical cancer. This pattern might be explained by cigarette smoking habits, in view of the low radiation dose to the lungs and of cervical cancer patients possibly smoking more than other women. Misclassification is also possible, because the lungs are a common site of extrapelvic spread in cervical cancer patients (*22*). Why no excess of lung cancer was observed among the nonirradiated women is difficult to explain. However, social class differences (*23*), which may be related to smoking habits, are probably associated with the stage of disease and in turn to the use of radiotherapy.

Kidney cancer has been weakly associated with smoking, mainly in men (*24*). An excess of this cancer occurred in the irradiated group only, especially 15 years after radiation exposure. Kidney cancer has not been prominently linked to irradiation, and only a slight excess in mortality was seen in one follow-up study of patients irradiated for ankylosing spondylitis (8 observed vs. 4.1 expected) (*18, 25*). In the spondylitis study, the kidneys were thought to be lightly irradiated and not directly in the radiation field. In our series, the kidneys were designated an intermediate site, but during external beam therapy the kidneys may have occasionally received substantial doses of radiation.

A deficit of breast cancer was found among irradiated women (58 vs. 86), whereas a slight excess appeared among nonirradiated patients (27 vs. 19). Ablation of the ovaries by radiotherapy may have lowered the risk of breast cancer in prememopausal women (*26, 27*), but how this disruption of ovarian function in older women would also be equally protective is not clear. A protective effect, independent of age at irradiation, however, was suggested also by Smith and Doll (*28*) in their study of 2,000 women whose ovaries were irradiated for treatment of benign gynecologic disease. Cervical cancer patients who had received radiotherapy may be at low risk of breast cancer due to greater parity and lower socioeconomic status than women in the general population. If so, the expected number of breast cancer cases from the general population would lead to overestimation of the true expected number. Unfortunately, we had no information on menopause status that could have affected breast cancer risk. Thus irradiation-induced menopause, reproductive history, and socioeconomic factors may all contribute to the observed deficit of breast cancer. Slightly elevated breast cancer risk in the nonexposed group of cervical cancer patients is difficult to be explained, although the numbers are comparatively small. Breast cancer risk was increased only within the first 5 years after exposure, and the early detection due to medical surveillance may have contributed to this excess.

Radiation doses to all pelvic organs were large. Risk of rectal cancer was increased 15 years or more after treatment, but no increase was seen for colon cancer. Socioeconomic status has been correlated positively with colon cancer (*29*) and inversely with cervical cancer, so that use of general population rates for colon cancer may have somewhat underestimated the risks of radiogenic colon cancer in this population. However, no convincing evidence was seen that the colon is particularly radiosensitive on the basis of data from the A-bomb survivors (*18*).

Excess of cancers of the corpus uteri and ovaries occurring 15 years post treatment is consistent with a radiation etiology, but one finds difficult to exclude the possibility of metastatic lesions. At least 12% of the irradiated women also had surgical treatment, and they may not have been at risk of developing these 2 cancers. Therefore, the expected number may have been too large, which would result in an underestimate of risk. Other genital cancers also occurred in excess in both treatment groups, but again the possibility of mestastases cannot be discounted. Unfortunately, information on hysterectomy and oophorectomy status was unavailable.

Ionizing radiation is the only environmental agent known to cause bone cancer, and both osteosarcomas in our series occurred in the radiation field. Cumulative incidence of bone cancer was 0.04% and is consistent with other data (*30*). Of the 5 connective tissue cancers, 3 arose in heavily irradiated proximal areas as well. Although very little quantitative data are available on the association between soft tissue sarcoma and radiation exposure, evidence of irradiation effect appears only after very high-dose therapeutic exposures (*6, 31*).

Pattern of cancer risk over time for irradiated proximal and intermediate organs (text-fig. 1) is consistent with studies of atomic bomb survivors (*32*) and ankylosing spondylitis patients (*25*). Among cervical patients, cancer risk for other sites was increased 10 years after radiotherapy and remained elevated. Metastases may account partially for the early increased incidence, but metastases are unlikely to have greatly influenced the cancer risk in long-term survivors.

The pattern of cancer risk of irradiated proximal and intermediate organs by age at exposure, excluding the first 10 years of observation, is also consistent with the findings of other studies (text-fig. 2). The greatest RR was observed among women irradiated under 40 years of age, although the number of women exposed was small. There was little variation in RR with age among women irradiated after they were 40 years old. Studies of atomic bomb survivors and ankylosing spondylitis patients suggest that the RR of cancer among persons irradiated after 20 years of age does not depend on age at irradiation. The cervical cancer patients were substantially older as a group than the other 2 study populations, and it is interesting that the patterns of risk by age at exposure were similar in these 3 populations.

Our findings suggest an excess of irradiation-induced cancer, particularly of the kidneys, bladder, rectum, ovaries, and corpus uteri in women treated for cancer of the cervix. Large lung cancer excess could be related to smoking habits rather than irradiation inasmuch as the organ dose was low. Risk of breast cancer may have been diminished by ovarian ablation or by reproductive and socioeconomic characteristics that may be protective. No increased risk was found for leukemia, Hodgkin's disease, or colon cancer. Most, but not all, inferences were based on comparisons with the general population, and they should be viewed cautiously. Additional studies of cervical cancer patients should determine to what extent the risk of second cancers may be influenced by differences in radiation dose, smoking, endocrine status, and other host and environmental factors.

Association of Breast Cancer Risk With Age at First and Subsequent Births: A Study in the Population of the Estonian Republic[1,2]

Brian MacMahon,[3] Maret Purde,[4] Daniel Cramer,[3] *and* Evi Hint[4]

ABSTRACT—Information on reproductive history was obtained from 362 urban breast cancer patients attending the oncological dispensaries at Tallinn and Tartu, Estonian Republic, and from 694 urban women participating in gynecologic screening programs offered by the same centers. The 2 groups were compared by means of Mantel-Haenszel and logistic regression procedures to estimate age-adjusted odds ratios. Women whose first birth occurred before 20 years of age had a breast cancer risk less than one-third the risk of nulliparous women. Risk increased with increase in age at first birth (AFB) but remained below 1.0 (relative to nulliparae), even in the highest AFB categories. The fertility rate in Estonia during the period of this study was relatively low, which facilitated an evaluation of the effect of births subsequent to the first. After adjustment for AFB, it appeared that in this population subsequent births had a protective effect additional to that conferred by the first birth. Moreover, for women who had only 2 children, the age at the time of birth of the second child was a determinant of that effect. Compared to nulliparous women, the breast cancer odds ratio for uniparous women who had their child before age 25 was 0.62, and the ratio for duoparous women who had both their children under that age was 0.18. Neither lactation nor menarche was a risk factor for breast cancer in this population.—JNCI 1982; 69:1035-1038.

Cooperation between the United States and the Soviet Union in the fields of medicine and public health was pledged by both governments in 1960 and reaffirmed in 1972. The development of this cooperation in the area of cancer research has been documented by Saunders (*1*).

A U.S.-U.S.S.R. working group on the epidemiology of cancer was established in 1974. One of the first cancer sites to be selected for cooperative activity was cancer of the breast—a dominant cancer in the United States as well as in certain parts of the Soviet Union. The Epidemiology Group of the Institute of Experimental and Clinical Medicine of Estonia had been designated by the Cancer Epidemiology Council of the U.S.S.R. Academy of Medical Sciences as the All-Union Center for the Epidemiologic Study of Breast Cancer. This group had undertaken case-control studies in several parts of the Soviet Union, but it had just completed a particularly large study in Estonia. Analyses of these data have appeared in the Soviet literature (*2*). It was agreed that the data from this study would be made available to U.S. epidemiologists for comparison with similar data that had been collected in other areas of the world.

Some results of this analysis are presented in this paper.

MATERIALS AND METHODS

Cases were breast cancer patients diagnosed between 1968 and 1973 and referred to the oncological dispensaries at Tallinn and Tartu. These are the only two oncological dispensaries in Estonia. While most breast cancer patients residing in Estonia would be seen at one of these dispensaries, only about one-third are included in the study. The reasons for including some patients and not others were logistical (especially, shortage of staff); there is no reason to suspect bias in the selection of cases for inclusion. Controls were systematically selected from women participating in the gynecologic cancer screening programs offered by the same centers. These programs were targeted on particular subpopulations of women (such as employees) and attendance rates among those asked to attend were very high—generally over 90%. Control subjects who were found to have benign breast disease at the time of their screening were excluded. Since 27% of the cases but only 8% of the controls were from rural areas, this analysis is restricted to urban subjects.

All subjects were interviewed at the dispensary, and questions were asked on a variety of factors including parity, AFB, breast-feeding experience (only for the first 2 children), menstrual history, current weight and height, and medical history.

Table 1 shows the distribution of subjects by age. Only 1 cancer patient under 30 years of age was interviewed, and she has been excluded along with controls below the same age. Even after these exclusions, the cases and controls show different age distributions, the cancer cases being older than the controls. For this reason, all comparisons stratify on age. Associations were evaluated by means of the crude and adjusted OR, the adjusted ratios being adjusted for age in decades, and other variables as specified in context by the method of MH (*3*) and its extension for trend in polychotomous exposure variables (*4*). Computations utilized the programs developed by Rothman and Boice (*5*) as well as standard computer programs for logistic regression. The CL of OR are 95% limits based on logarithmically transformed values.

RESULTS

Reproductive History

The proportion of nulliparous women among the cases (25.1%) was significantly higher than among the controls

(16.9%). The crude OR associated with being nulliparous was 1.7, and the MH estimate was 1.6 with CL of 1.2–2.0. Table 2 gives data on risk associated with AFB. The similarity of the crude and age-adjusted OR suggests that age at interview is not an important confounding variable in this relationship. Breast cancer risk was lowest for women whose first birth occurred at ages below 20. Such women had less than one-third the risk of nulliparous women. The OR for the three categories of AFB over 25 were similar, i.e., there was no further increase in risk with increasing AFB over that age. Furthermore, OR for the highest AFB categories remained well below 1.0. These data show no excess of risk, relative to that of nulliparae, for women whose first birth is delayed until over 30 years of age.

The fertility rate in Estonia during the period of this study was relatively low. Fifty percent of the parous cases and 42 percent of the parous controls in this study had only 1 child; only 17% of the parous women in both groups had more than 2 children. This low fertility provides a favorable opportunity to examine the effect on breast cancer risk of births subsequent to the first. These data indicate that there is a substantial reduction in risk associated with having children subsequent to the first, even when one takes into account the fact that women who have their first child early are more likely to have subsequent children. A multiple logistic regression analysis comparing women of parity 1 with women of parity 2+, with adjustment for AFB in individual years and age at interview in decades, gives a point estimate of the breast cancer OR for women of parity 2+ of 0.78 with CL of 0.58–1.07. This is of the same order of magnitude as the OR for primiparous women compared to the OR for nulliparous—0.71 with CL of 0.51–1.01.

Table 1.—*Distribution of cases and controls by age*

Age, yr	No. of women		Percent	
	Cases	Controls	Cases	Controls
30–39	50	146	13.8	21.0
40–49	111	239	30.7	34.4

[c] 95% CL.

Table 3.—*OR for women of parity 2, relative to those of parity 1, by AFB and age at second birth*[a]

AFB, yr	Age at second birth, yr			Total
	<25	25–29	≥30	
<25	0.29 (0.09–0.92)	0.98 (0.51–1.90)	1.04 (0.47–2.32)	0.68 (0.40–1.14)
25–29	—	0.49 (0.20–1.24)	0.70 (0.40–1.23)	0.64 (0.38–1.08)
≥30	—	—	0.91 (0.43–1.92)	0.91 (0.43–1.92)

[a] Within each category of AFB, data are stratified by single years of AFB, except that categories ≥35 yr are combined. OR are expressed relative to the risk for uniparous women whose first birth occurred in the same AFB category. *Numbers in parentheses* are 95% CL.

Table 4.—*Number of cases and controls and estimates of OR by total parity*

Total parity	No. of women		Crude OR	Adjusted OR[a]
	Cases	Controls		
0	91	117	1.00	1.00
1	136	245	0.71	0.71
2	90	236	0.49	0.50
3	28	69	0.52	0.41
4+	17	27	0.81	0.95
Total	362	694	—	—

[a] OR for parities 2, 3, and 4+ are adjusted for age at first birth in single years of age to the distribution of the first births.

We can further inquire whether the age at which births occur after the first one is a relevant factor. Since, in addition to AFB, data are available only for age at the last birth, we confine ourselves to women of parity 2, the age at last birth being then the age of the mother when the second child was born. An analysis of this group is shown in table 3. The pattern is somewhat similar to that shown for AFB in table 2. That is, the OR associated with second births over the age of 25 is somewhat, though not significantly, below 1, indicating some relatively small additional protection associated with a second birth over that age. However, a second birth below the age of 25 is associated with a substantial and statistically significant reduction in risk—to one-third of the risk for a uniparous woman who does not have a second child before that age. Note that the referent risk in table 3 is not that of nulliparous women but that of uniparous women whose childbirth occurred in the same age range. Compared to the breast cancer OR for *nulliparous* women, the breast cancer OR for women who have 2 children before they are 25 is 0.18 with CL of 0.07–0.49.

Table 4 gives the distributions of cases and controls and estimates of OR by total parity. There is no evidence of any additional protective effect for births after the second.

Lactation

Data were collected on breast feeding only for the first two live births. our analysis was restricted to women who had only one or two live births so that their total lactation experience is represented. The distributions of cases and controls are compared in table 5. For no category of duration of lactation does the OR differ significantly from that for those who did not lactate. Although the OR for all women

TABLE 5.—*Distribution of cases and controls by duration of lactation and estimates of OR and CL*[a]

Duration of lactation, mo	No. of women		Crude OR	MH estimates[b]	
	Cases	Controls		OR	CL_{95}[c]
0	24	37	1.00	1.00	—
1–6	71	185	0.59	0.60	0.32–1.11
7–12	54	138	0.60	0.64	0.35–1.17
13–24	60	107	0.86	0.80	0.43–1.49
≥25	17	15	1.75	1.35	0.56–3.25
Total	226	482	—	—	—

[a] Restricted to women with one or two live births.

[b] MH estimates are stratified over age at interview in decades and are expressed relative to a risk of 1.0 for women who did not lactate.

[c] 95% CL.

TABLE 6.—*Number of cases and controls and estimates of OR and CL by reported age at menarche*

Age at menarche	No. of women		Crude OR	MH estimates[a]	
	Cases	Controls		OR	CL_{95}[b]
≤12	47	92	1.00	1.00	—
13	74	193	0.75	0.71	0.45–1.12
14	107	177	1.18	1.27	0.81–1.98
15	53	79	1.31	1.25	0.75–2.10
16	39	89	0.86	0.74	0.43–1.26
≥17	42	64	1.28	1.07	0.62–1.84
Total	362	694	—	—	—

[a] Estimates stratified over age in decades, with the odds for women reporting age at menarche ≤12 yr as the referent.

[b] 95% CL.

who lactated relative to those who did not—0.69—is below 1.0, it is not significantly so (CL, 0.40–1.21). Further, the lower OR are seen in the shorter categories of duration of lactation, a direction of relationship that seems inconsistent with their being a true reduction in breast cancer risk associated with lactation. The data in table 3 include women of both parity 1 and parity 2 which may introduce some confounding by parity. The analysis was therefore repeated, with the data being confined to women of parity 1. The patterns were essentially identical.

Age at Menarche

Despite a wide range in the ages at menarche reported by cases and controls (table 6), there is no evidence of association of breast cancer risk with variation in age at menarche. The mean age at menarche was 14.24 years for cases and 14.12 years for controls. The difference (0.12 ± 0.12) is not statistically significant. An analysis limited to women in the two youngest decades (30–49 yr) did not alter this conclusion.

DISCUSSION

The striking reduction of breast cancer risk associated with having a full-term pregnancy early in reproductive life was first observed in data from a case-control study of some 4,000 breast cancer cases and 12,000 controls from seven areas of the world (*6*). In these data almost the entire association between breast cancer risk and parity was explained in terms of the association with early first birth, and births subsequent to the first appeared to have little or no additional protective effect when consideration was given to the fact that women whose first birth occurs at an early age tend to become of higher total parity than those whose first birth is delayed.

The inverse association of risk with early first birth has been widely confirmed. However, in studies from Burma (*7*), Iceland (*8*), Sweden (*9*), and Buffalo, New York (*10*), women of high parity appeared to have additional protection independent of AFB. Looked at retrospectively in the light of these later studies, the data from the international study suggested to one observer that there was an additional protective effect of parity in two of the seven centers (*11*).

The only previous attempt to examine the effect of age at births other than the first was in the seven-center study (*6*). The risk for women having 2 births or more under the age of 25 years, after adjustment for AFB, was estimated to be 13% lower than that for women who only had one birth under that age. In contrast, the reduction in risk for a woman having a first birth at age 22, which was the mean age at which the second births under 25 occurred, was 40%. Also, in the smaller group of women having a first birth under age 20, no additional protective effect of having a second birth under that age could be detected.

Contrarily, in the data for Estonia presented here, the protective effect of a second birth, after adjustment for AFB, was almost as great as that of the first birth. Moreover, if the second birth occurred under the age of 25, the risk of breast cancer was only one-third that of uniparous women whose only birth occurred under that age. Compared to nulliparous women, the breast cancer OR for uniparous women who had their child before age 25 was 0.62, and that for duoparous women who had both their children under that age (with adjustment for age at first birth) was 0.18. We conclude that, in this population, not only are births after the first associated with additional protection but also, as with the first birth, the extent of protection depends on the subject's age at the time of the birth.

This conclusion is, as noted, contrary to that suggested by the data in at least most of the centers in the seven-center study. The number of cases and controls was substantial in all but one of these centers, and we believe the analysis was sufficiently detailed to detect an association with births after the first, had one been present. It seems to us that these differences are not due to the common vagaries of observational data, but they reflect real differences between populations in the effect of births after the first. Conceivably, birth spacing is a factor that in some as yet unidentified way changes the influence of the second pregnancy. However, populations with a wide divergence of total female parity, in Burma and Estonia, are both among those populations that show an effect of births after the first. We believe it more likely that nutritional or other environmental circumstances produce real biological differences in susceptibility to the effect of pregnancy. The effect of early first birth, in relative terms, appears to be as great in populations that show an additional effect of births subsequent to the first as in those that do not. It seems, therefore, that the difference is not a matter of the first pregnancy not exerting its full effect in certain populations, and thus leaving more of the protective mechanism of pregnancy to be stimulated by subsequent pregnancies, but is rather a matter of a difference between populations in the overall level of protection that can be achieved by the pregancy mechanism.

There also appears to be a difference between the Estonian data and most previous observations with respect to the effect of having a first birth in the second half of reproductive life. In the seven-center study (*6*), women whose first birth occurred at 30–34 years of age had approximately the same risk as nulliparae (OR, 0.9), and those whose first birth occurred at age 35 or later actually had higher risks than nulliparae (OR, 1.2). In Estonia, both these groups had OR lower than 1.0 (0.6 and 0.8, respectively). However, neither OR is significantly below 1.0, and in both instances the confidence interval of the estimate includes the point estimate from the seven-center study. Although it is possible that differences also exist among populations with respect to this characteristic, these differences cannot be said to have been established on the basis of the present data.

We have no explanation for the absence of an association with age at menarche in these data. Most, though not all, previous studies have shown an inverse association between age at menarche and breast cancer risk (*11*).

In Vitro Growth Stimulation of Human Ovarian Cancer Cells by Xenogeneic Peritoneal Macrophages[1,2,3,4]

Charles E. Welander, *M.D.*,[5,6] **Ronald B. Natale,** *M.D.*,[5,7] *and* **John L. Lewis, Jr.,** *M.D.*[5]

ABSTRACT—For improvement of the in vitro growth rate of human ovarian tumors, an irradiated xenogeneic feeder layer of adherent peritoneal cells was added to such cultures. This adherent peritoneal cell population was obtained from oil-primed adult (C57BL/6J × DBA/2J)F_1 mice and contained predominantly macrophages. After irradiation of the feeder layer with 3,000 rad ^{137}Cs, cell suspensions prepared from fresh, solid human ovarian cancers were cocultivated with the feeder cells. Two end points were used to evaluate the growth enhancement added by such a feeder layer: 1) Primary monolayer cultures of ovarian tumors were successfully grown in continuous culture through five or more serial subcultures in 25 of 64 different patient specimens studied. Control cultures without the feeder layers did not continue growing through serial subcultures. 2) With the use of the soft agar clonogenic assay, addition of the feeder layer to the petri dishes increased the number of tumor cell colonies in each of six separate experiments, compared to the number seen in control plates without the feeder layer.—JNCI 1982; 69:1039–1047.

One of the difficult problems in tissue culture has been to grow human tumors in vitro and to subsequently establish these tumors in long-term culture. It is not known how often attempts have been made to grow human cancers in vitro; published results of successful attempts are only anecdotal (*1*). We have been concerned in particular with the difficulties encountered when attempting to culture human ovarian cancers. A review of the literature of the past 10 years reveals descriptions of only 15 long-term established ovarian cancer cell lines (*1–7*). At the Memorial Sloan-Kettering Cancer Center, efforts to establish ovarian cancers in tissue culture between the years 1973 and 1978 resulted in only one established cell line out of 72 attempts (Resnick LA, Kim WS: Unpublished data).

To improve the past experience with tissue culture of ovarian cancers, we have investigated the effects of incorporating a feeder layer into cultures of ovarian tumors. The feeder layer consists of adherent murine peritoneal cells—predominantly macrophages. In this report we describe two specific methods to determine the role of such a feeder layer in the alteration of tumor cell growth. The first method has been to incorporate an irradiated feeder layer into primary monolayer cultures prepared from solid tumor specimens of ovarian cancers. The second method is the short-term agar clonogenic assay technique that uses primary solid tumor specimens of ovarian cancers. We present data describing increased tumor cell growth through five or more serial subcultures in the monolayer cultures as well as enhanced tumor cell colony growth in the agar cultures.

MATERIALS AND METHODS

Tumor procurement.—The monolayer culture experiments were done between March 1978 and December 1979, with the use of specimens of human ovarian epithelial tumors obtained from 64 patients undergoing treatment at Memorial Sloan-Kettering Cancer Center. Of the specimens, 51 were solid tumors and 13 were malignant effusions. All of the specimens were adenocarcinomas, with only 4 reported as poorly differentiated. Subsequent to these monolayer culture experiments, selected solid ovarian tumor specimens, obtained between April and December 1980, were used for growth in soft agar. These 6 ovarian adenocarcinomas were chosen for use in the agar clonogenic assay because of their high viability.

Specimens were transferred from the operating room to the laboratory in a sterile container without any culture medium or saline solution. The time from surgical removal until processing in the laboratory was less than 1 hour.

Monolayer culture preparation.—Solid tumor specimens were washed in HBSS containing antibiotics and then minced with scalpels into small fragments. The single cells and cell clusters released by this mechanical means were stained with trypan blue for viability determination (trypan blue exclusion test), and all the viable nucleated cells were counted. Cell aggregates were counted as one cell. Viability ranged from 30 to 90% after mechanical disaggregation; the majority of specimens had more than 70% viable cells. After disaggregation, the tumor cells were resuspended in EMEM enriched with 2 m*M* glutamine, 1% nonessential amino acids, 100 IU penicillin/ml, 100 μg streptomycin/ml (all obtained from Grand Island Biological Co., Grand Island, N.Y.), 10% fetal calf serum, 10% human cord serum, and 0.1 U insulin/ml (Eli Lilly & Co., Indianapolis, Ind.). The cells were then ready for plating.

Malignant effusions are peritoneal or pleural fluids that contain tumor cells. These cells were concentrated by centrifugation (1,000 rpm for 10 min). When erythrocytes were present in the cell pellet, we used sterile distilled water to lyse the red blood cells. Viability staining was done and the

cells were resuspended in EMEM and were ready for plating.

The above methods of cell preparation are adequate for monolayer cultures, but soft agar cultures require a single cell suspension. To prepare a single cell suspension, we incubated the mechanically dissociated tumor fragments for 2 hours at 37°C in a stirring flask that contained 0.5% collagenase Type II (Worthington Biochemical Corp., Freehold, N.J.) in HBSS. The suspension was then passed sequentially through 45- and 27-µm Swinnex filters (Millipore Corp., Bedford, Mass.) to remove cell clumps. After viability staining with trypan blue, viable nucleated cells were again counted before plating.

Macrophage feeder layer preparation.—The feeder layer consisted of xenogeneic macrophages obtained from peritoneal washings of oil-primed mice. Adult (C57BL/6J × DBA/2J)F_1 mice (The Jackson Laboratory, Bar Harbor, Maine) were used. Each mouse received an ip injection of 0.5 ml Pristine (2,6,10,14-tetramethylpentadecane; Aldrich Chemical Co., Milwaukee, Wis.) at least 2 weeks before treatment. Peritoneal cells were harvested by irrigation of the peritoneal cavity with HBSS containing 5 U heparin/ml. After the cells were washed two times in HBSS, they were plated at a density of $5–8\times10^6$ cells per 25-cm^2 flask for monolayer cultures or 1×10^5 cells per 35-mm petri dish for the agar cultures. Standard EMEM was added with the same additives as used for monolayer cultures. After 2 hours of incubation at 37°C to allow macrophage attachment to the flask or petri dish, the cultures were washed two times with HBSS to remove nonadherent cells. The feeder layer was then irradiated with 3,000-rad cesium-137 teletherapy given in one fraction to prevent replication of any of the adherent peritoneal cells. The morphology of the adherent cells and the relative plating density are illustrated in figure 1. This feeder layer does not form a confluent monolayer, as is commonly seen with fibroblast feeder layers.

Plating and maintenance of cultures.—Monolayer cultures: The cell suspension obtained from the solid tumor specimens was plated over a newly prepared feeder layer as well as in control flasks without the xenogeneic feeder cells and was fed our enriched EMEM. Plating density of tumor cells was 1×10^6 cells and/or cell clusters per 25-cm^2 flask. The flasks were incubated at 37°C with 5% CO_2. Cultures prepared from malignant effusions were plated in the same fashion, but without a xenogeneic feeder layer.

When the tumor cell growth reached confluence, we subcultured the monolayer cultures with the use of 0.1% trypsin in Puck's saline A. We prepared duplicate sets of flasks with each subculture to receive the cells—one set of flasks with a fresh irradiated feeder layer and one set without feeder layer.

Soft agar cultures: After the macrophage feeder layer was attached to the bottom of the 35-mm petri dish, an agar underlayer of 0.5% molten Bacto-agar (Difco Laboratories, Detroit, Mich.) was poured over the feeder layer cells, effectively separating them from the tumor cell plating layer, which was poured over the top. Tumor cell plating density was 5×10^5 cells per petri dish, suspended in 0.3% molten Bacto-agar. The culture medium added to the agar underlayer and to the tumor cell plating layer was similar to that described by Hamburger and Salmon (*8*), except for our deletion of conditioned medium and 2-mercaptoethanol. We incubated these plates in a humidified incubator at 37°C with 7.5% CO_2.

After 7–14 days, colonies were visible and were defined as aggregates of greater than 50 cells. Colony numbers in control plates without feeder layer were compared to numbers of colonies growing in the cultures with a feeder layer.

Nude mouse heterotransplantation.—Six-week-old female nude mice of Swiss/*nu/nu* (ICR/*nu/nu*) background were obtained from the Animal Facility of the Sloan-Kettering Institute. These animals have been bred in a pathogen-free environment but were transferred to limited-access conventional animal facilities for tumor transplantation and subsequent maintenance. Each mouse received approximately 3×10^6 tissue-cultured tumor cells by sc injection and was subsequently observed twice weekly for tumor growth. We considered an enlarging palpable nodule that reached greater than 5×5 mm in size as a successful heterograft.

RESULTS

Monolayer Cultures

Each of the 51 separate specimens of solid ovarian tumors received in the laboratory was grown over a feeder layer of irradiated peritoneal macrophages as well as in control flasks without the feeder layer. During each subculture of the confluent monolayers, duplicate flasks were made to receive the cells, one with a feeder layer and one without. When the cells showed equal growth with or without a feeder layer, the feeder layer was discontinued. None of the cell lines required continuation of the feeder layer beyond passage 5, by which time each line had successfully adapted to growth in vitro without the requirements for continued macrophage presence.

From this group of 51 solid adenocarcinoma specimens, 21 tumors (41%) could be grown past passage 5. Only 1 of these 21 tumors was poorly differentiated histologically. Comparing cultures grown in the presence or absence of the feeder layer (figs. 2A, 2B), we noted two differences: 1) In flasks with the feeder layer there was an increase in the initial attachment of epithelial cells during the first 24 hours after plating primary cultures and 2) in flasks with the feeder layer there was persistence of "epithelial-looking" cells in the first few passages. None of the cell lines growing past passage 5 were successfully grown without feeder layers. Each required feeder cells during the first few culture passages. Our experience has been that 6 of the 23 primary solid ovarian tumors have grown past passage 5 in culture, whereas 15 of 28 metastatic nodules grew successfully past passage 5.

We studied 13 specimens of malignant effusions as well. Ascitic and pleural fluids were grown without feeder layers, on the basis of the observation that abundant autologous macrophages are contained in the effusion. We presumed that these autologous adherent cells (presumably the macrophages) would provide a feeder layer effect in these cultures. From these 13 specimens, 4 resulted in tumor cell growth past passage 5 (table 1).

Of the 25 tumor specimens that grew past passage 5, 7 grew successfully past passage 20. Of this group, 3 originated from primary ovarian adenocarcinomas, 3 from ovarian tumors metastatic to other sites, and 1 from ascitic fluid. Each of them was a papillary adenocarcinoma.

Soft Agar Cultures

Two groups of primary tumor cell suspensions were plated in soft agar for comparative purposes. One group of plates was prepared without a feeder layer and the other group with it. The end point measured was the difference in tumor cell colony formation between the 2 groups. The results of the colony counts are shown in table 2, reported as an average of triplicate plates in each group. The *P*-value was calculated by Fisher's exact probability test. Although the end point of tumor cell colony formation was not an all or nothing result, colony growth seemed to be enhanced by the macrophage feeder layer. Figures 3A and 3B illustrate ovarian carcinoma colony formation in soft agar.

Nude Mouse Heterotransplantation

Demonstration of the continued malignant nature of the cultured cells requires criteria other than cell morphology and growth through serial subcultures. Two criteria of the transformed phenotype are the ability of cells to grow in soft agar (*9*) and the ability of cells to grow as a heterograft in nude mice (*10*). From this group of 25 monolayer cultures grown past passage 5, 22 were injected into nude mice. Of these 22 attempts, 10 (45%) resulted in successful progressive growth as a heterograft in the mice.

DISCUSSION

Cell-to-cell interactions between both benign and malignant cells can stimulate substances produced by one cell population that affect the growth of other cells, not only in vitro but also in vivo (*11, 12*). Although tumor cell populations escape from normal homeostatic growth control mechanisms, the rate of tumor cell division can often be affected by growth factors (*13, 14*). Recently, evidence has been published suggesting that a soluble substance is produced by adherent phagocytic cells from effusions (presumably macrophages) that can enhance the growth of human tumor cells in vitro (*15*). One experiment that supports this conclusion involved the addition of conditioned medium obtained from the supernatant of adherent spleen cell cultures (a majority of which are macrophages) to cultures of human tumor cells, which resulted in a notable augmentation of tumor cell growth (*8*). Another experimental method has been to deplete malignant effusions of autologous macrophages with a resulting decrease in tumor cell growth, which can be restored by replacement of the macrophages (*16*). The demonstration in this report that macrophages produce some soluble substance which enhances in vitro tumor cell growth is in keeping with these other published observations.

We have raised the question of macrophage proliferation in culture flasks with the feeder layer. We believe that the xenogeneic macrophages do not proliferate when cocultivated with human cells. However, the adherent mouse peritoneal cell population does include morphologically apparent mesothelial cells which do proliferate in the cultures and can contaminate the human cell lines. Therefore, to avoid such contamination problems, we elected to administer 3,000 rad of cesium teletherapy in one fraction to the macrophage feeder layer after the adherent peritoneal cells had attached to the flask. This dose effectively rendered any mouse mesothelial cell incapable of division but did not destroy the short-term metabolic and secretory functions of the feeder layer cells.

With regard to the preparation of the peritoneal exudate cells, we initially used peritoneal washings from normal, non-oil-primed mice. Although such cells did provide a degree of stimulation of human tumor cell growth, up to a tenfold increase in the number of peritoneal exudate cells could be recovered after oil priming of the mice.

Criteria of malignancy must be applied to tumor cell growth in agar. Growth in an unanchored state is one of the manifestations of the transformed phenotype. To form tumor colonies that arise from a single cell suspension in agar, viable clonogenic cells must be present. Stromal fibroblasts, a constant contamination in monolayer cultures, will not grow in soft agar.

Growth of tissue-cultured cell lines in nude mice as a demonstration of malignant phenotype has been a goal, but there are reasons reported in the literature by others why nude mouse heterotransplantation is not always successful. Such reasons include subthreshold cell inoculum size, inadequate length of observation, and varying levels of immunodeficiency in nude mice (*17*). Because of lack of time we have not done multiple repeated attempts at heterotransplantation of tissue-cultured cells and have achieved successful growth in nude mice in only 10 of these 22 attempts.

The observations reported here are only preliminary and empiric. They must be followed by attempts to identify and characterize the substance produced by the adherent peritoneal cell population that enhances ovarian tumor cell growth in vitro.

Effect of Natural Protease Inhibitors and a Chemoattractant on Tumor Cell Invasion In Vitro[1]

U. P. Thorgeirsson,[2,3] **L. A. Liotta,**[4] **T. Kalebic,**[4] **I. M. Margulies,**[4] **K. Thomas,**[5] **M. Rios-Candelore,**[5] *and* **R. G. Russo**[4, 6]

ABSTRACT—The effects of natural protease inhibitors and a chemoattractant on tumor cell invasion were studied with the use of a new in vitro quantitative assay of tumor cell penetration of native connective tissue. Human amnion membrane denuded of its epithelium is composed of a continuous basement membrane (BM) attached to a dense avascular collagenous stroma. M5076 reticulum sarcoma cells, known to be highly invasive in vivo, were placed on the BM side of the amnion connective tissue. Tumor cells penetrating the full thickness of the connective tissue barrier were collected on the stromal side with a Millipore filter. *N*-Formylmethionyl-leucyl-phenylalanine (FMLP) at an optimal concentration of 10^{-7} M stimulated the penetration of up to 600% more tumor cells into the connective tissue after 20 hours in comparison to the number of tumor cells spontaneously penetrating in serum-free media. Natural protease inhibitors blocked both FMLP-stimulated and spontaneous invasion. A bovine cartilage extract containing inhibitors of both serine proteinases and metalloproteinases caused a 500% decrease in invasion. Furthermore, a 500% inhibition of invasion was produced by a purified collagenase (metalloproteinase) inhibitor. In contrast, soybean trypsin inhibitor and bovine serum albumin did not significantly alter the invasion rate. The protease inhibitors were nontoxic and did not reduce tumor cell proliferation, attachment to the amnion, and the rate of tumor cell migration through Nuclepore filters. These data support the hypothesis that collagenolytic metalloproteinases play a necessary role in tumor cell invasion of native connective tissue.—JNCI 1982; 69:1049–1054.

Many investigators have suggested that proteases may play a role in tumor cell invasion of connective tissue (*1–8*). This supposition is based largely on the finding that tumor cells elaborate a variety of proteases (*1, 3, 7, 9*). Connective tissue barriers such as BM and interstitial collagenous stroma do not normally contain passageways for cell movement. Therefore, it is logical that localized disruption of connective tissue by proteases may play a role in tumor invasion. However, it is still possible that tumor cells penetrate connective tissue barriers by a mechanical means not requiring any proteases. Therefore, the objective of the present study was to test whether proteases actually played a necessary role during tumor cell penetration of native connective tissue barriers.

We utilized our recently described (*10–12*) amnion invasion system for counting the number of tumor cells penetrating human BM and collagenous stroma in vitro. A variety of neoplastic and normal cells have been previously tested in this system (*10, 12*). Epithelial cells, fibroblasts, and endothelial cells fail to invade the amnion. Polymorphonuclear leukocytes, macrophages, and different types of malignant cells, however, do invade the amnion (*11, 12*). In the present study we focused on the mechanism of invasion by a specific well-characterized tumor cell line (M5076) known to be highly invasive in vivo (*13, 14*). This reticulum cell sarcoma elaborates collagenolytic proteases capable of degrading all the genetically distinct types of collagens (*8*). We tested the capacity of this tumor cell to invade connective tissue with and without the addition of a synthetic peptide chemoattractant and protease inhibitors in an attempt to assess which classes of proteases were most important. The first inhibitor was a CE that contains inhibitors of both serine proteinases (such as trypsin and plasmin) and metalloproteinases (such as collagenase). CE have previously been shown to inhibit tumor cell collagenase (*15, 16*), to block neovascularization (*17*), and to prevent tumor cell invasion of extracted cartilage as determined by histologic tests (*18*). The second natural inhibitor tested for its effects on invasion was TIMP. TIMP (*19, 20*) specifically inhibits all types of metalloproteinases. The third inhibitor used was SBTI that blocks serine proteinases. These inhibitors differed markedly in their effects on tumor cell invasion in the present system.

MATERIALS AND METHODS

Cell cultures and media.—The M5076 reticulum sarcoma cells (*13, 14*) were supplied by Dr. Ian R. Hart, NCI-Frederick Cancer Research Facility, Frederick, Md. M5076 cells were grown in RPMI-1640 medium supplemented with 2 mM L-glutamine, 1 mM sodium pyruvate, 50 U penicillin/ml, 50 µg streptomycin/ml, and 10% equine serum (all purchased from Flow Laboratories, Inc., McLean, Va.). The cells were subcultured at a ratio of 1:2 twice weekly and grown at 37°C in humidified air containing 5% CO_2. Viability was determined by trypan blue exclusion.

Protease inhibitors.—We prepared the CE from bovine nasal

[6] We are grateful for the editorial assistance of Ms. Pattie Moyer and for the placentas for the amnion invasion assays supplied by the nursing staff at the Bethesda Naval Hospital.

septum cartilage that was obtained from Pel-Freez Biologicals, Inc., Rogers, Ark. The noncartilage tissue was removed, and pieces of cleared cartilage (400 g) were cut into 1-mm-thick slices and stirred in 1 liter of 20 m*M* 2-(*N*-morpholino)ethane sulfonic acid (pH 6.0) containing 1 *M* guanidine chloride at room temperature for 20 hours. The extract was spun at 12,000×*g* for 20 minutes and the supernatant passed through a coarse-porosity paper filter. The filtered supernatant was dialyzed in 3,500 molecular ratio exclusion membranes against three changes of 15 liters of distilled water at 4°C over a 3-day period. The final lyophilized extract was 1% by weight of the original tissue.

We used a purified TIMP that was supplied by Dr. J. Reynolds (Strangeways Research Laboratory, Cambridge, England). The method of purification has been previously described (*19, 20*). TIMP has an MW of 28,000 (*20*). We verified that this inhibitor markedly reduces the degradation of type I collagen, type IV collagen, and type V collagen by tumor cell-derived metalloproteinases. TIMP failed to reduce the activities of the serine proteinase human urokinase or human plasmin.

SBTI, pancreatic trypsin inhibitor, and BSA were all purchased from Sigma Chemical Co., St. Louis, Mo. The serine proteinase inhibitors abolished the activity of human plasmin (*9*) but had no effect on the tumor cell metalloproteinases (*21*).

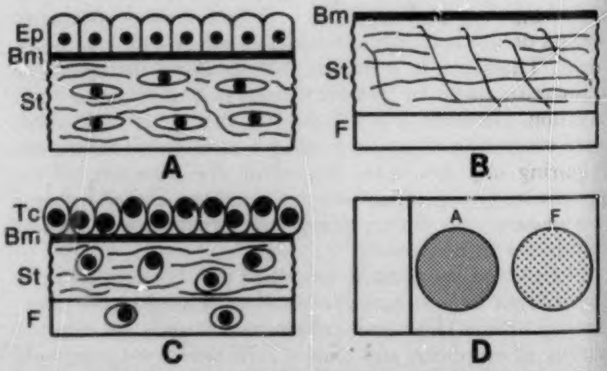
FMLP was purchased from Peninsula Laboratories, San Carlos, Calif. This chemotactic peptide (MW=437.6) was solubilized in dimethyl sulfoxide (Sigma Chemical Co.) at a stock concentration of 2 m*M* and then made up to the desired concentration (10^{-4}–10^{-8} *M*) in RPMI-1640 medium.

Amnion invasion system.—Fresh human amnion was obtained from placentas of normal term deliveries as described previously (*10–12*). The amnion membrane is highly uniform in composition and contains a single layer of epithelium attached to a continuous BM overlying a dense nonvascular collagenous stroma (*10*). The epithelium was rendered nonviable and was removed after a 30-minute treatment with 0.1 *M* ammonium hydroxide (*9, 11*). Colloidal carbon (size, 0.5–5 μm), applied to the continuous BM surface or to the stromal surface, failed to diffuse into the stroma even when it was applied after a 20-day incubation of the amnion. The amnion was also impermeable to labeled high-MW glycoproteins (*10, 22*). The nonviable amnion connective tissue was clamped in a chemotaxis chamber in a serum-free tissue culture medium as described previously (*11*). The connective tissue separated two chambers without hydrostatic pressure difference (*11, 12*). Tumor cells were applied to the upper side of the chamber facing the BM, and an 8-μm pore size Millipore filter (Millipore Corp., Bedford, Mass.) was placed in contact with the opposite stromal surface (*11, 12*) (text-fig. 1). The chemoattractant FMLP was routinely placed in the lower chamber facing the filter. In some experiments FMLP was placed only in the top chamber or in both top and bottom chambers. Tumor cells penetrating the full thickness of the BM and collagenous stroma were collected on the filter. At the end of a 20-hour incubation at 37°C, amnion and filter were fixed in 70% ethanol overnight, stained with H & E, dehydrated in ethanol, and cleared in xylene. Lastly, the filter was peeled away from the stroma and both the amnion and filter were mounted on the same microscopic slide (text-fig. 1). For each assay the total number of tumor cells attached to the BM surface (0.76 cm^2) and the total number of tumor cells in the Millipore filter were counted at 400× magnification. The reproducibility and variability of this assay have been documented previously (*11, 12*). Histologic studies of the M5076 cells penetrating the amnion connective tissue have also been presented previously (*12*).

Protease inhibitor assays.—In the second group of tests, the following agents were dissolved in culture medium and incubated with the M5076 cells at 37°C for 30 minutes before introduction into the assay: 10 μg or 100 μg bovine CE/ml, 10 μg purified metalloproteinase inhibitors/ml, 100 μg SBTI/ml, and 100 μg BSA/ml. Individual assays were performed in triplicates. Tumor cells were incubated on the amnion for 20 hours.

To assess the migratory capacity of the tumor cells separately, an 8-μm pore size Nuclepore filter (Nuclepore Corp., Pleasanton, Calif.) was used in place of the amnion. The migration assay was therefore a modification of that used by Varani et al. (*23*). Tumor cells were placed on the surface of the Nuclepore filter in the presence of 10^{-7} *M* FMLP in the lower compartment of the amnion chamber. Cells that migrated through the Nuclepore filter were collected on the lower Millipore filter. The filters were fixed and stained, and 10 fields were counted at 250× magnification on each of the triplicate Millipore filters. The data were expressed as average number of cells per field.

The inhibitory effect of the protease inhibitors was tested on the collagenolytic enzymes secreted into the culture supernatant by M5076 cells. The assay method for determining proteolysis of ^{14}C-labeled type IV collagen, type V collagen, and type I collagen was used as described previously (*8*). The CE inhibitors or TIMP was preincubated with the enzyme for 30 minutes prior to addition of the substrate.



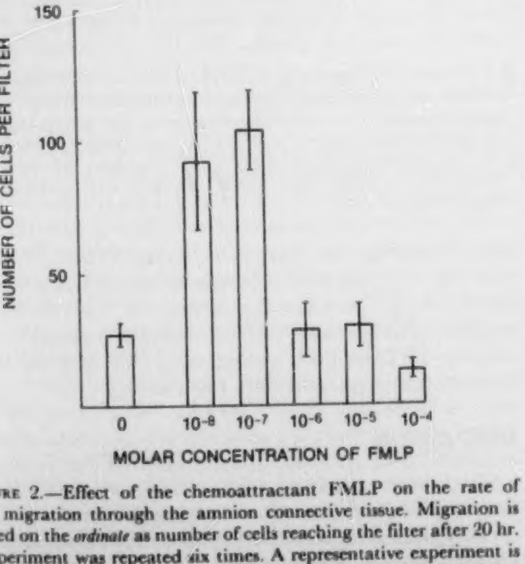
TEXT-FIGURE 1.—Diagrammatic illustration of the amnion invasion assay. A) Normal human amnion has a single layer of epithelium (Ep), a continuous BM (Bm), and a nonvascular collagenous stroma (St). B) The amnion is divested of its epithelium and a Millipore filter (F) is placed against the stromal surface. C) The amnion and filter are held in a chemotaxis chamber. Tumor cells (Tc) attach to the BM surface and a small proportion of cells penetrates the BM and stroma and is collected on the filter. D) The H & E-stained amnion (A) and filter (F) are mounted on a microscopic slide.

RESULTS

Stimulation of M5076 Tumor Cell Invasion of Amnion Connective Tissue in Vitro by FMLP

A small fraction (<1%) of the tumor cells attached to the BM surface of the amnion migrated through the entire thickness of amnion within 20 hours and entered the Millipore filter. Many more tumor cells were identified within the amnion stroma by light microscopy focusing at various levels. These cells were in various stages of migration through the stroma and could not be easily quantified.

The chemoattractant FMLP was added to the lower compartment of the amnion invasion chamber. A series of FMLP concentrations were chosen to cover the range used previously (*11*) for FMLP chemoattraction of inflammatory cells and tumor cells through porous filters (*24*). Previous experiments with labeled FMLP diffusion across the amnion system had shown that an equilibrium of the FMLP gradient across the amnion was reached in 17 hours at 37°C (*11*). Time course invasion assays demonstrated that 78% of the tumor cells had migrated through the amnion at 17 hours compared with the 20-hour incubation time used in subsequent experiments. After a 20-hour incubation there was a 400–600% increase in tumor cell migration in response to the optimal concentration of 10^{-7} *M* FMLP (text-fig. 2). At high concentrations of FMLP (10^{-4} *M*), the cell migration was actually slightly decreased. When FMLP (10^{-7} *M*) was placed in the upper chamber alone or in both the upper and lower chambers, there was no stimulation of tumor cell migration compared to that seen in controls with no FMLP. As shown in tables 1 and 2, 10^{-7} *M* FMLP had no effect on cell proliferation, either in tissue culture wells or on the amnion BM, and did not significantly increase the amount of collagenase produced. It can be concluded that the major effect of FMLP in this system was to stimulate directed locomotion of M5076 tumor cells. It is also evident from table 1 that the M5076 cells do not replicate in serum-free medium during the 20-hour incubation time.



TEXT-FIGURE 2.—Effect of the chemoattractant FMLP on the rate of M5076 migration through the amnion connective tissue. Migration is expressed on the *ordinate* as number of cells reaching the filter after 20 hr. The experiment was repeated six times. A representative experiment is shown. On the *abscissa*, spontaneous cell migration is labeled as 0 (no FMLP). FMLP in concentrations ranging from 10^{-4} to 10^{-8} *M* was placed in the lower chamber. *Bars* represent standard error of the mean. The value for 10^{-7} *M* (No.=9) FMLP was significantly different from that for spontaneous migration (No.=12) ($P<0.005$); 10^{-4} *M* FMLP was different from spontaneous migration ($P<0.1$).

TABLE 1.—*Effect of FMLP on the survival and type IV collagenase secretion of M5076 tumor cells*[a]

Expt No.	Mean No., $\times 10^6$, of viable M5076 tumor cells/well after 20 hr	Presence or absence of FMLP	Type IV collagenolytic activity, mean %[b]
1	2.0	–	49.3
	2.0	+	37.0
2	2.5	–	51.0
	2.9	+	50.3

[a] Tumor cells were suspended in serum-free RPMI-1640 medium with penicillin, streptomycin, and sodium pyruvate. Duplicate samples of 2.0×10^6 viable cells in 20-ml volume were seeded in T75 tissue culture flasks and incubated at 37°C for 20 hr in the presence (+) or absence (–) of 10^{-7} *M* FMLP. At the end of the incubation, the total number of viable cells were counted and the type IV collagenolytic activity of the conditioned medium was assayed in duplicate (*4*). The cells failed to proliferate or grew slowly in serum-free medium, and FMLP did not alter their collagenase activity.

[b] Linear range of assay is between 0 and 60% of maximum substrate degraded by bacterial collagenase (*4*).

TABLE 2.—*Effect of FMLP and CE on growth of M5076 cells on the amnion BM surface*[a]

Treatment	Attached M5076 cells/amnion surface, mean No., $\times 10^5$, ± SEM
M5076 untreated	1.86±0.4
M5076 + FMLP	1.71±0.24
M5076 + CE	1.97±0.16
M5076 + FMLP + CE	1.67±0.11

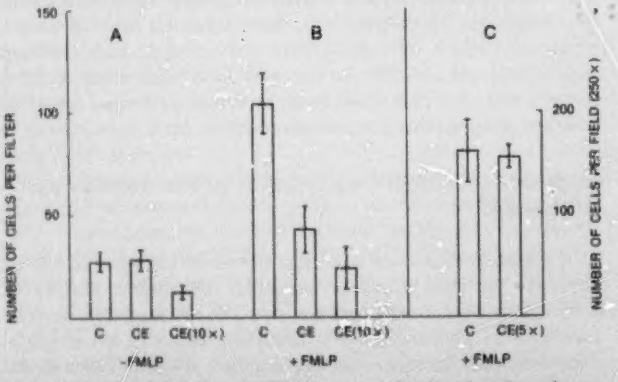
[a] The tumor cells were suspended in serum-free medium as in table 1 and 5×10^5 cells inoculated in triplicate samples onto the amnion BM surface (0.76 cm^2), in the presence or absence of 10^{-7} *M* FMLP or 100 µg CE/ml. After incubation for 20 hr at 37°C, the surface was washed and the total number of attached cells was counted in 10 fields of each sample.

Inhibition of Tumor Cell Invasion of the Amnion by Bovine CE

Resistance of normal cartilage to tumor invasion has been observed in vivo. Hyaline cartilage contains a variety of different protease inhibitors as well as an antiangiogenesis factor (*17*). Therefore, we studied the effect of a CE on in vitro invasion measured in the amnion system. The extract was determined to have a metalloproteinase inhibitor (table 3) and inhibitors for chymotrypsin, trypsin, and plasmin. The trypsin inhibitors are of two sizes, one at an MW of about 13,000 by gel filtration and a second at an MW of 60,000. The bovine CE in two concentrations was tested for inhibitory effect on M5076 invasion of the amnion. The entire series of experiments with CE were repeated three times. The data were combined and are shown in text-figure 3. The lower concentration (10 μg/ml) without FMLP had no effect, and the higher concentration (100 μg/ml) caused 250% inhibition (text-fig. 3A). In the presence of FMLP a 250% inhibition was observed with the lower concentration, and a 450% inhibition with the higher concentration (text-fig. 3B). In some individual assays the CE completely abolished invasion of M5076 cells through the amnion connective tissue. The number of cells on the amnion at the end of the 20-hour incubation was not affected by the CE at concentrations that markedly inhibited in vitro invasion (table 2). Furthermore, CE had no effect on number of viable cells after a 20-hour incubation in serum-free medium in T75 flasks (data not shown). The extract was a potent inhibitor of tumor cell-derived proteases (table 3). Since the extract may have directly interfered with the FMLP chemotactic process or may have reduced tumor cell locomotion, we studied the effect of the extract on tumor cell migration through 8-μm Nuclepore filters used in place of the amnion. As shown in text-figure 3C, the CE failed to significantly inhibit locomotion of the tumor cells through Nuclepore filters in the presence of 10^{-7} FMLP. These data indicate that inhibition of tumor cell invasion by the CE in this system was not due to a direct effect on tumor cell viability, attachment, or locomotion.

Effects of Purified Protease Inhibitors

To assess separately the importance of metalloproteinases and serine proteinases in the amnion invasion system, we used two types of purified inhibitors. A purified metalloproteinase inhibitor was compared with a serine proteinase inhibitor, SBTI. BSA was used as a negative control. The TIMP had an MW of approximately 28,000, measured by molecular sieve chromatography, and is conceivably similar to the TIMP of similar MW found in the bovine CE. The data are shown in text-figure 4. The TIMP reduced invasion of the M5076 tumor cells 450% in the presence of 10^{-7} *M* FMLP (text-fig. 4B). In contrast to the TIMP, SBTI or BSA (text-fig. 4A) had no significant effect on invasive capacity either in the presence or absence of FMLP. Pancreatic trypsin inhibitor also did not inhibit invasion (data not shown). SBTI or BSA was not cytotoxic and did not affect attachment or growth (data not shown).



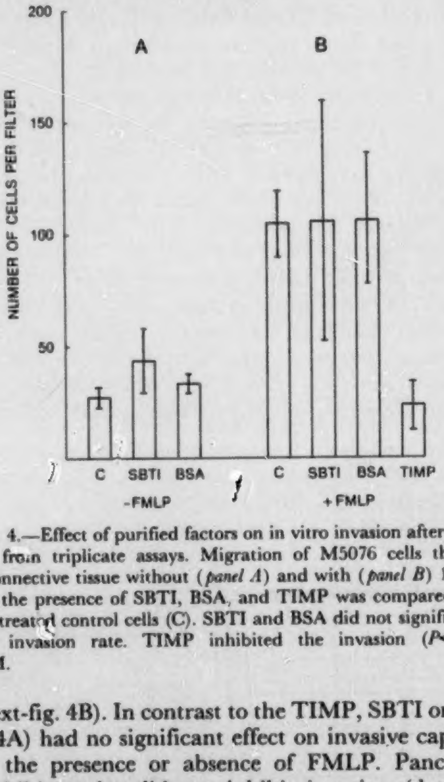
TEXT-FIGURE 3.—Inhibition of M5076 tumor cell migration through amnion by bovine CE. Each assay was performed in triplicate, and the mean value determined. Data are combined from three separate experiments (No.=9). Compared to untreated M5076 cells (C), the CE, 10 μg/ml (CE) and 100 μg/ml [CE(10×)] without (*panel A*) and with (*panel B*) 10^{-7} *M* FMLP, inhibits cell migration. CE(10×) was significantly different from control ($P<0.05$). *Panel C* shows the effect of CE on the migration of M5076 cells through Nuclepore filters in the presence of 10^{-7} *M* FMLP. *Bars*=SEM.

TABLE 3.—*Effect of 10 μg CE/ml and 1 μg TIMP/ml on type I, type IV, and type V collagenolytic activities of tumor cells*[a]

Treatment	Collagen-type substrate	Collagenolytic activity, cpm[b]
Metalloproteinase alone	I	3,050
+ CE	I	540
+ TIMP	I	—
Metalloproteinase alone	IV	2,800
+ CE	IV	410
+ TIMP	IV	620
Metalloproteinase alone	V	1,250
+ CE	V	230
+ TIMP	V	375

[a] The enzymes were extracted and assayed as described previously (*8*). Means of duplicate assays.

[b] Substrate degraded at 35.5°C during 6 hr.



TEXT-FIGURE 4.—Effect of purified factors on in vitro invasion after 20 hr. Data are from triplicate assays. Migration of M5076 cells through amnion connective tissue without (*panel A*) and with (*panel B*) 10^{-7} *M* FMLP in the presence of SBTI, BSA, and TIMP was compared with that of untreated control cells (C). SBTI and BSA did not significantly alter the invasion rate. TIMP inhibited the invasion ($P<0.05$). *Bars*=SEM.

DISCUSSION

The present report on the in vitro invasion of a tumor cell line, M5076, indicates that metalloproteinases and chemotactic agents play an important role in the invasive process. Human amnion, which is used as a connective tissue barrier in our in vitro invasion system, contains a continuous BM, comparable in structure and composition to BM elsewhere in the body. It is a uniform, transparent membrane devoid of vessels, nerves, and host immune cells. The amnion invasion system provides a means for quantitative measurement of the rate of tumor cell migration in contrast to previous in vitro assays that consisted of histologic evaluation of either tumor cell invasion of cultured organ fragments (*25–29*) or penetration of radiolabeled tumor cells through thick complex structures such as a chorioallantoic membrane or a canine large vessel (*30, 31*). We have found that only a few (<1%) of the attached M5076 cells went through the amnion. This phenomenon is possibly analogous to the low proportion of iv injected tumor cells that initiate metastatic foci (*32*).

A variety of substances induce chemokinesis and chemotaxis of inflammatory cells (*33, 34*). Such substances are thought to direct polymorphonuclear leukocytes or macrophages out of the circulation, across the vessel wall, and into the site of an inflammation. Since the extravasation of inflammatory cells is analogous in some respects to the hematogenous metastatic process, investigators such as Ward and Varani (*23, 24, 35, 36*) have searched for chemotactic agents that attract tumor cells. FMLP is a synthetic tripeptide that is one of the most potent chemoattractants for phagocytic cells (*31, 32*). Wass et al. (*24*) reported that FMLP is also a chemoattractant for Walker tumor cells. Since FMLP is of low enough MW to diffuse through native connective tissue (*11*), we studied whether it could attract the M5076 tumor cells through the amnion in serum-free conditions. All previous in vitro studies of tumor cell chemotaxis were performed in the Boyden chamber with the use of a porous artificial filter (Millipore or Nuclepore) as a barrier. No previous chemotaxis assay was performed with native connective tissue as the migration barrier. As shown in text-figure 2, FMLP significantly stimulated the migration of M5076 tumor cells through the amnion connective tissue at an optimal concentration of 10^{-7} *M*. This concentration is similar to that found optimal for stimulating migration of phagocytes and tumor cells across artificial porous filters (*11, 24, 34*). FMLP did not elicit its effect through a change in cell number in serum-free medium (table 1). At the concentration of FMLP that was optimal for stimulation of cell migration, there was no increase in collagenolytic activity produced per tumor cell. Since the major effect of FMLP was not an increased secretion of collagenolytic enzymes, it might therefore stimulate directed invasion through an enhancement of cell locomotion. However, a tumor cell, enhanced in its tendency to migrate, may still require a proteolytic mechanism to penetrate connective tissue barriers. Therefore, we tested the effect of natural protease inhibitors on tumor cell invasion in this system with and without FMLP.

A CE containing inhibitors for both metalloproteinases and serine proteinases blocked both spontaneous and FMLP-stimulated M5076 cell invasion through the amnion (text-fig. 3). The CE inhibition was dose-dependent and was not due to an effect on cell proliferation or cytotoxicity. The CE was not a purified substance. Therefore, it was impossible to distinguish which of the factors were responsible for the observed blocking effect. To further distinguish the classes of proteases relevant in this system, purified TIMP and a serine proteinase inhibitor were also tested. The metalloproteinase inhibitor reduced migration through the amnion 450% (text-fig. 4B). In contrast, SBTI and BSA had no significant effect on invasion (text-fig. 4). The M5076 tumor cells and many other types of tumor cells have been found to elaborate metalloproteinases that degrade collagen (*8*). A subset of the family of metalloproteinases is classic mammalian collagenase, which makes a single cleavage of stromal collagens I, II, and III (*5*). Separate types of metalloproteinases produced by tumor cells (and nonneoplastic cells) can degrade collagen type IV found exclusively in the BM and collagen type V associated with stromal–BM interface (*8, 37*). Except for type II collagen, which is predominant in cartilage, all the above types of collagens have been localized in the amnion by extraction and by immunohistologic tests (*3, 8, 21, 37, 38*). The ability of the M5076 cell to elaborate metalloproteinases may play a major role in its ability to move through the amnion connective tissue. Whether this requirement is true for other types of tumor cells remains to be determined.

Tumor cells can also elaborate serine proteinases such as plasminogen activator and chymotrypsin-like enzymes (*39*). These enzymes may be associated with the cell surface and have been implicated in tumor invasion (*39*). At least one form of plasminogen activator, urokinase, does not significantly degrade any type of collagen (*9*). Plasminogen activator can generate plasmin from plasminogen (*9, 39*). Plasmin can go on to degrade glycoprotein components of connective tissue (*9*). In the present in vitro system, tumor cells invaded the amnion connective tissue in the absence of exogenous plasminogen. SBTI, a potent inhibitor of plasmin, failed to reduce invasion. This effect is not unexpected, since plasminogen was not present to generate plasmin. However, it can be concluded that in this system enzymes susceptible to inhibition by SBTI do not play a major role in invasion. SBTI is not an optimal inhibitor for plasminogen activator, and therefore the importance of this enzyme is unknown in the present invasion system.

The process of tumor invasion is complex with multiple sequential steps and a variety of possible interactions between the tumor cells and the host cellular and extracellular components. Any type of in vitro assay is obviously not equivalent to the metastatic process in vivo. Furthermore, in vitro invasion mechanisms used by one specific type of tumor cell may not necessarily relate to a general mechanism used by all types of tumors in vivo. Nevertheless, one approach to the study of tumor invasion is to break it down into defined steps upon which to focus experimental studies. The present in vitro system is designed to study one defined step of tumor invasion, i.e., the penetration of tumor cells through whole native BM and collagenous stroma. These data indicate that collagenolytic metalloproteinases play an important, and possibly even a necessary, role in tumor invasion.

Androgen Conjugates in Human Breast Cyst Fluids[1,2]

W. R. Miller,[3] M. M. Roberts,[3] R. J. Creel,[3] P. L. Yap,[4] R. W. Kelly,[5] *and* A. P. M. Forrest[3]

ABSTRACT—Dehydroepiandrosterone sulfate (DHAS) has been measured by radioimmunoassay in 100 breast cyst fluids obtained from 82 women. Values ranged from 1.5 to 1,155 μM with a median of 140 μM. These concentrations are in excess of those for plasma but are comparable or less than values for breast secretions obtained by nipple aspiration. Levels of DHAS in cyst fluid were not significantly affected by age, menopausal status, or parity of the subject or by the volume of cyst fluid obtained. In patients with multiple cysts, DHAS values from cysts aspirated from the same breast on the same date were relatively comparable, but wide variations were frequently observed between cysts aspirated on different occasions from the same breast and between cysts from different breasts of the same patient, whether sampled simultaneously or sequentially. Such variability must complicate comparative studies among women.—JNCI 1982, 69:1055–1058.

Evidence that the hormonal milieu of a woman may influence her risk of breast cancer has been reviewed by Vorheer and Messer (*1*). Most investigations on endocrine profiles have centered on levels of circulating or excreted hormone; the immediate hormonal environment of the breast has been relatively ignored. Recently, we reported that breast secretions collected by nipple aspiration from nonlactating women may contain remarkably high levels of DHAS, which are much in excess of those in the circulation (*2*).

We now report on measurements of DHAS in breast cyst fluids and factors that might influence its concentration.

MATERIALS AND METHODS

Collection of breast fluids and plasma.—A total of 100 cyst fluids were obtained by needle aspiration from 82 women who presented with tension cysts of the breast. Multiple cysts were aspirated in 10 women, and 5 patients had cysts aspirated on more than one occasion. Menopausal status was documented for 77 of the women, and volume of aspirated fluid was measured in the last consecutive 32 women studied. In 4 women, secretions were also collected by application of negative pressure to the nipple (*3*) of a breast containing a cyst, which was also immediately aspirated.

Peripheral blood was taken by venipuncture immediately before aspiration of breast fluids and collected in heparinized tubes. Plasma was separated within 30 minutes by centrifugation. All samples were stored at −20°C until assayed.

Radioimmunoassay of DHAS.—Radioimmunoassay was performed directly on diluted cyst fluids, secretions, and plasmas with the use of the method of Buster and Abrahams (*4*). The antibody was supplied by Mr. B. A. Morris, Department of Biochemistry, University of Surrey, England. The specificity of this antibody has been described previously (*2*).

GLC-MS analysis of cyst fluids.—Aliquots of six cyst fluids were diluted to 10 ml with distilled water. $[7\text{-}\alpha\text{-}^{3}\text{H}]$DHAS (25,000 cpm, ≈5 pmol) was added, and the diluted cyst fluid was extracted with an equal volume of diethyl ether for removal of unconjugated steroids. The aqueous fraction was then solvolyzed as described previously (*2*). An aliquot was removed for estimation of radioactivity for measurement of procedural losses. The remainder was derivatized as tertiary butyl dimethyl silyl ethers as described previously (*2*) with the use of deuterated epiandrosterone as internal standard. Steroids and internal standards were measured in a Dupont 490B mass spectrometer coupled through a glass jet separator to a Varian 1400 gas chromatograph. A 10-m SE 30 support-coated open tubular column maintained at 200°C was used. Transfer lines were maintained at 250°C, and the source temperature was 240°C. Steroids were quantitated by measurement of peak heights of the M-57 peaks (m/z 345 for DHA, m/z 347 for androsterone and epiandrosterone, and m/z 349 for the tetradeutero-epiandrosterone internal standard). Standard mixtures derivatized with samples were used for construction of a ratio-mass plot from which the mass of the various steroids was read.

RESULTS

Radioimmunoassay of DHAS—All 100 cyst fluids contained material that cross-reacted with the antibody to DHA and its sulfate. Concentrations ranged from 1.5 to 1,155 μM with a median value of 140 μM (text fig. 1).

GLC-MS.—Six cyst fluids were analyzed by MS, and the values are shown in table 1. Levels of DHA conjugate were detected in all, but in only two was there a good correlation with results from radioimmunoassay; in the remainder values obtained by GLC-MS were lower, although the dimensions were similar. Significant amounts of androsterone and epiandrosterone were also detected by GLC-MS in solvolyzed extracts of cyst fluids. Extracts that contained the highest proportion of epiandrosterone were derived from cyst fluids showing the greatest disparity between GLC-MS and radioimmunoassay (table 1). It is thus pertinent that

ABBREVIATIONS USED: DHA=dehydroepiandrosterone; DHAS=dehydroepiandrosterone sulfate; GLC=gas-liquid chromatography; MS=mass spectrometry; m/z=mass divided by elementary charge.

TEXT-FIGURE 1.—DHAS levels as estimated by radioimmunoassay in human breast cyst fluids. *Horizontal line* represents median value.

the antibody used in the radioimmunoassay also cross-reacted significantly with epiandrosterone sulfate (*2*). Values from radioimmunoassay probably reflect levels of both DHAS and closely related 17-oxosteroid conjugates, although for simplicity, in the text, we shall refer to them as concentrations of DHAS.

Effects of age, menopausal status, and parity.—The median age of the 82 women studied was 45 years (range 31–55). There was no significant correlation between DHAS levels in cyst fluid (as measured by radioimmunoassay) and the age of the patient from whom it was derived.

Menopausal status was known in 77 women; 64 of those were experiencing regular periods, and the remainder were perimenopausal. The median value for DHAS was lower in cysts from perimenopausal patients, but the difference between the 2 groups failed to reach statistical significance by the Wilcoxon rank sum test (text-fig. 2).

Parity was documented in 67 women; 28 were nulliparous, the remainder parous. There was no significant difference between DHAS levels in cyst fluids from nulliparous and parous women (text-fig. 3) and, within the parous group, between DHAS levels and the number of full-term pregnancies.

Effects of volume of cyst fluid.—Volume of aspirated fluid was measured in 32 cysts and varied from 1.5 to 25 ml. There was, however, no significant correlation between levels of DHAS and volume of fluid aspirated from the cysts (text-fig. 4).

Multiple cysts.—Among the patients, 10 had multiple cysts aspirated on the same visit to the clinic. In 6 women fluid was obtained from different cysts in the same breast and, in 5, cysts were obtained from both breasts (table 2). Generally, levels of DHAS were similar in cysts from the same breast, but the variation between cysts became more marked when they were derived from different breasts in the same women. (In 1 woman DHAS concentrations were completely different in cysts from the left and right breasts.)

Five women had cysts aspirated on more than one occasion at intervals that varied between 3 and 76 weeks. Large

[a] — = not measured.

Comparative levels in cyst fluids, breast secretions, and plasma.—Blood was taken from 4 women at the same time as their cysts were aspirated. In each case levels of DHAS in the cyst fluid were much in excess of those in the plasma (table 3). In 4 women nipple secretions were obtained from breasts containing cysts immediately before cyst aspiration. In 1 woman, the concentrations of DHAS in the cyst fluid and breast secretion were remarkably similar, but in the remaining 3 patients DHAS values in breast secretions were much higher than in the corresponding cyst fluids.

DISCUSSION

In a recent study, Bradlow et al. (*5*) have shown that human breast cyst fluids may contain high levels of DHA and androsterone sulfates much in excess of those in plasma and that the amount of these steroids in cyst fluid is not correlated with the volume of the cyst. The results of the present study would confirm these findings. Most cyst fluids contained large quantities of DHAS, but there was an extensive range of concentrations present in different cysts. In addition, GLC–MS confirmed the presence of large amounts of androsterone conjugate. Epiandrosterone conjugates were also present, and their high concentration probably accounts for the inconsistencies sometimes observed between the methods of radioimmunoassay and GLC–MS in the estimation of DHAS in cyst fluids. The antibody used in the radioimmunoassay cross-reacts significantly with epiandrosterone sulfate (*2*). It thus seems likely that in some cyst fluids, results from radioimmunoassay represent not only DHAS but also a contribution from other closely related steroid conjugates.

Because of the broad range of DHAS found in cyst fluids, it was of interest to examine factors that might influence these levels. Although most cyst fluids were obtained from premenopausal patients, no account was taken of the stage of the menstrual cycle in which they were collected. No cyclic pattern has been observed for DHAS levels in either plasma (*6*) or breast secretions (*7*). We could detect no significant correlation between cyst fluid concentration of DHAS and age, menopausal status, or parity of the patients. A similar lack of correlation has been reported by Bradlow et al. (*5*).

In a small number of cases we were able to analyze several cysts from the same women. There was a good correlation between DHAS levels in cysts aspirated from the same breast at the time, but larger variations were apparent between cysts from different breasts of the same women even when these were sampled at the same time. Cysts aspirated from the same women on sequential visits showed broad differences in DHAS concentrations, even though they may have been derived from the same breast. Similar observations have been made by others (*7*). The widely different values that may be observed in cysts aspirated from the same breast on separate occasions and, indeed, from both breasts of the same women when studied at the same time, makes comparative studies between different groups of women very difficult. It will be necessary to discover why such variations exist and the mechanism by which steroid conjugates accumulate in breast cysts. They may be derived from the breast secretory units or represent a transudate from the circulation. It is thus significant that breast secretions obtained by nipple aspiration also contain high levels of DHAS. Our limited comparison of breast secretions and cyst fluids obtained from the same women suggests that breast secretions invariably contain the higher concentration. It therefore seems likely that certain cyst fluids represent accumulation and dilution of breast secretions by blockage of the ducts in which they reside. Our observation (*8*) that cyst fluids with high DHAS concentrations contain only low levels of albumin, whereas those with low DHAS have high concentrations of albumin would support this contention and suggest that the diluent is plasma derived. It may be necessary to subdivide cyst fluids according to whether the derivation of their major constituents is breast or plasma before meaningful studies on their composition can be performed.

Parity and Colorectal Cancer Risk in Women[1,2]

Tim Byers, *M.D., M.P.H.*,[3,4] **Saxon Graham**, *Ph.D.*,[3,4] *and* **Mya Swanson**, *B.A.*[3]

ABSTRACT—A case-control study is reported of reproductive history and colorectal cancer risk based on information obtained from interviews with white women 40–79 years old who were admitted to Roswell Park Memorial Institute between the years 1957 and 1965. Women with the primary diagnosis of carcinoma of the colon (*n*=284) and carcinoma of the rectum (*n*=270) did not differ significantly in their prior reproductive histories as compared to those of a control group of women (*n*=1,763) with nonneoplastic diseases not affecting the breast or reproductive sites. The pertinent literature suggesting a parity-colorectal cancer association in women is reviewed. The conclusion reached is that the evidence for a parity-colorectal cancer association is equivocal; but that if such an association exists, it is probably weaker than that seen for cancers of the breast, ovary, and uterine corpus.—JNCI 1982; 69:1059–1062.

Several investigators have noted similarities in the epidemiologic features of breast, ovarian, endometrial, and colorectal cancers in women. Colon and breast cancers are positively correlated in international mortality statistics (*1*). Cancers of the colon have appeared more frequently than expected as second primary neoplasms in women with previous cancers of the breast or genital organs, and second primary neoplasms of the breast and genital organs have appeared more frequently than expected in women with previous cancers of the colon (*2, 3*). Nuns, who have experienced higher than expected mortality rates for cancers of the breast, ovary, and uterine corpus, have also been reported to have higher than expected rates of colon cancer (*4*). In the Third National Cancer Survey, single women experienced a higher incidence rate of colon cancer than did married women, a phenomenon also seen in women with cancers of various other sites including breast, ovary, and uterine corpus (*5*). All of these studies considered together suggest that cancer of the colon may share common etiologic factors with cancers of the breast and reproductive organs in women (*6*).

If there are specific common etiologic factors, however, they are yet to be clearly identified. Parity, being inversely associated with risk of cancers of the breast, ovary, and uterine corpus, has been a prime suspect for a common etiologic factor. McMichael and Potter (*7*), noting the evidence presented above and observing that birth cohort decreases in fertility have been followed later by subsequent cohort increases in colon cancer incidence in women, have suggested that hormonal factors related to pregnancy may be causally related to colon cancer in women. Three case-control studies have directly examined reproductive history as a risk factor for colorectal cancer in women. Bjelke (*8*), studying women with colorectal cancer in Norway and Minnesota, found that women with three or more live births had a reduced risk of colon cancer, but an increased risk of rectal cancer, compared to women with zero to two live births. Dales et al. (*9*), studying colorectal cancer in 52 black women in the San Francisco area, found that nulliparous women showed an apparent doubling of risk as compared to the risk for parous women. Weiss et al. (*10*), studying 148 women with colorectal cancer in the Seattle area showed an approximate doubling of risk for nulliparous women as compared to the risk for women with three or more children, but this finding was limited to the 94 women with colon cancer and was not seen in the 49 women who had rectal cancer.

The purpose of this paper is to present findings from our study of the pregnancy history of a much larger series of women with cancers of the colon and rectum, studied separately, and to review the evidence of a parity risk factor for female colorectal cancer as presented in the literature to date.

METHODS

This is a case-control study. Cases were all white women 40–79 years of age who were admitted to RPMI (Buffalo, N.Y.) between the years 1957 and 1965 with the primary diagnosis of cancer of the colon (*n*=284) or rectum (*n*=270). Although RPMI is a referral center for cancer treatment, most of these patients were admitted before definitive diagnosis or soon after their diagnosis was made. Ninety-two percent of the rectal cancer cases and 88% of the colon cancer cases were admitted within 2 years of the date of their initial diagnosis. Controls were 1,763 white women 40–79 years of age who were admitted to RPMI for nonneoplastic disease during the same years. Women with diseases of the breast or reproductive systems were excluded because of the well-established associations between diseases of these sites and prior pregnancy history. Table 1 lists the diagnoses of the women comprising the control group. Information on cancer risk factors as well as other health information, including pregnancy history, was routinely ascertained from all patients admitted to RPMI by mailed questionnaire prior to admission. This information was then verified with the patient by personal interview at the time of admission. Statistical analysis of these data was conducted controlling for age by the method described by Mantel and Haenszel (*11*) with the use of 5-year age groups. Analyses are presented separately for colon and rectal cancer cases.

[c] Includes never-married women.

RESULTS

Tables 2 and 3 present the essential findings of the study. They show no significant differences between either the colon or rectal cancer cases and the controls with regard to marital status or the number of live births. Although the ages are pooled in the data as presented, detailed analysis revealed no pattern of association between either colon cancer or rectal cancer and marital status or parity across the various levels of age. Other reproduction variables were also examined. When patients with both colon and rectal cancers were compared to controls, no association was seen between disease status and the total number of pregnancies, the total number of miscarriages and stillbirths, or the age at first marriage. Age at first pregnancy was not examined since this information is yet to be coded from the questionnaire.

DISCUSSION

Hospital-based case-control studies may be affected by subtle biases either in the selection of cases or in the selection of controls or in both. Although a previous study has demonstrated that cases referred to RPMI during the 1957–65 era closely resemble those seen in the surrounding community with regard to such factors as socioeconomic status, marital status, religion, and tobacco use, there is the possibility that other unidentified case selection factors may in some way result in a relative underrepresentation of nulliparous cases in this series.

However, because RPMI is primarily a cancer treatment center, of more concern would be possible selection factors relative to the control group that might tend to make it not representative of the general reference population from which the cases are drawn. To test the representativeness of the control group relative to pregnancy history, we examined data from the 1960 U.S. census (collected within the study period) (*12*). Eighty-seven percent of the control series resided in the eight western-most counties of New York State and 62% resided in the two-county Buffalo, N.Y., SMSA. There were no significant differences in numbers of live births reported for those women who resided within as compared to those who resided outside the Buffalo SMSA. Parity of the 1960 census population of white women in the Buffalo SMSA is compared in an age-adjusted analysis in table 4 with that of the RPMI control group used in this study. This comparison demonstrates that, although the controls are a hospital-based series, the parity of the controls used in this study nonetheless closely resembles that of the general reference population, thus strengthening our confidence that there were not significant selection biases in the control group associated with our major independent study variable. An additional way to assess the representativeness of the control group is to compare the group to patients with other diagnoses known to be related to parity. Cancers of the breast, uterine corpus, and ovary have well-established associations with pregnancy history (*13–15*). All white women admitted to RPMI during this same 1957–65 study period with diagnoses of cancer of the breast, uterine corpus, or ovary are compared in table 5 to the same control group used in the current study. The expected finding of statistically significant associations between the reported number of live births and cancers of these three sites further strengthens our confidence in the validity of the negative findings of the colorectal cancer study presented here.

That colon cancer and cancers of the reproductive organs are by some means associated in women seems likely, though the precise determinants of this association are unclear. The

same type of correlation noted between female colon and breast cancer rates in international mortality statistics can also be seen between female breast cancer and male colon cancer rates (*1*). This correlation argues for a common etiologic factor for colon and breast cancers that is unrelated to pregnancy. The studies demonstrating an association between colon, breast, ovarian, and uterine corpus cancers in women with second primary cancers (*2, 3*), though also suggesting common etiologic factors (assuming the excess second primary neoplasms are not iatrogenic), do not, by design, specify those factors. It would be of interest to examine the pregnancy histories of women with these associated multiple primary cancers to determine the extent to which the observed association might be attributed to parity. The increase in risk of colon cancer among never-married women as compared to married women in the Third National Cancer Survey (a finding not seen in our data) suggests a marital status-associated risk factor, but the observation of a similar association in men in the same survey (*5*) would argue against prior pregnancy history as the specific etiologic component of the marital status risk. The reported excess of mortality rates from cancers of the colon and breast in nuns (*4*) could, of course, in addition to differences in pregnancy history, be a result of various other potential etiologic factors associated with this particular life role. It is important to note also that the excess in "intestinal" cancer in nuns was observed only in those women over 70 years of age (23 expected and 39 observed), whereas at younger ages, there was actually a lower than expected mortality rate for gastrointestinal cancers (site not specified).

The case-control study by Bjelke (*8*) demonstrated a decreased risk of colon cancer for multiparous women, but this finding was limited only to women with blood type O, and an actual increase in risk of rectal cancer for multiparous women was noted. Case-control studies by Dales et al. (*9*) and by Weiss et al. (*10*), though studies of defined populations, were both limited by small numbers of study subjects and low response rates (40% for Dales et al. and 61% for Weiss et al.). Thus case selection biases might have significantly affected the estimates of relative risk, inasmuch as these studies were of small numbers of cases and controls (resulting in relatively small contingency table cell sizes). The failure of our study to replicate the same parity-colorectal cancer association shown in these previous case-control studies might be due as well to various other factors, including a birth cohort effect. Our study (1957-65) was based on data collected on the average of 14 years previous to the more recent studies (1973-77). During these years, there were changes in the reproductive experiences of women that might account for the discordant findings. The more prevalent usage of oral contraceptives, for instance, in more recent cohorts of women could be such a change. Though not statistically significant, possibly because of small numbers of cases, Weiss' data do suggest an oral contraceptive risk factor acting in rectal cancer. Whether oral contraceptive usage is in fact related to rectal cancer risk has not been determined, however.

In summary, we have presented a case-control study that demonstrates no apparent association between prior pregnancy history and colon or rectal cancer risk in women who were diagnosed in the 1957-65 era. We conclude that the evidence for such an association is equivocal. If there is such an association, it appears to be weaker than that seen in cancers of the breast, ovary, and uterine corpus. Other possible etiologic factors that might be common to colon, breast, ovarian, and uterine corpus cancers in women should be further considered, such as diet, prior use of medications, the activity of gut flora (*16*), and, more likely, as yet unidentified common etiologic factors. In the future, the more prevalent clinical use of hormone receptor assays of colorectal neoplasms (*17*) and a more detailed study of the determinants of cancer risk for subsites of the colon (e.g., proximal vs. distal) might allow us to better define specific subsets of women with colorectal cancers of hormone-related etiologies.

Correlation Between Cancers of the Uterine Cervix and Penis in China[1]

Jun-Yao Li,[2,3] Frederick P. Li,[4] William J. Blot,[2,5] Robert W. Miller,[4] *and* Joseph F. Fraumeni, Jr.[2]

ABSTRACT—A national survey of cancer mortality in the People's Republic of China during 1973–75 revealed concurrent geographic variation for cancers of the uterine cervix and penis, including clustering of both tumors in central parts of the country. The findings are consistent with recent reports from other countries that the cancers tend to aggregate in spouses and with the hypothesis of an etiologic factor in common.—JNCI 1982; 69:1063–1065.

In the People's Republic of China, cancer of the uterine cervix is one of the most common cancers among Chinese women, and several older reports have noted exceptionally high frequencies of penis cancer in autopsy and biopsy series of men (*1–6*). Using data collected in a nationwide survey of mortality from cancer during 1973–75 (*7–10*), we examined the geographic patterns of the two cancers within China. Particular attention was paid to the correlation between the cervical and penis cancer rates, in view of recent literature suggesting that the two diseases may be etiologically related (*11–16*).

METHODS

The National Cancer Control office of the Ministry of Health, Beijing, organized a survey to gather data on mortality from cancer and other causes among a population of over 800,000,000 Chinese over the 3-year period 1973–75. Details of the survey have been described elsewhere (*7–10*). Nearly 1 million workers (barefoot doctors, physicians, and community representatives) were mobilized to identify systematically all deaths attributed to cancer and to determine age-specific population estimates. The diagnosis of cancer was made at a commune hospital or higher level for 93% of all deaths. The determination was based on pathologic or cytologic examination for 17%; radiology, endoscopy, or other laboratory tests for 54%; clinical examination alone for 23%; and history of symptoms given by relatives after death for 6%. From the collected information, age-specific and age-adjusted [world standard (*17*)] rates of mortality for 15 cancers were calculated for 29 provinces, 396 prefectures and independent cities, and 2,136 counties of China during 1973–75. For 24 of the provinces in China and their 324 prefectures and independent cities, mortality rates for cancer of the penis, a rare tumor in the general population, were listed separately from rates for other genital cancers. Using the 324 areas as sampling units, we calculated the correlation between the age-adjusted rates for cancers of the cervix and penis and prepared maps of the relative distributions of the two cancers.

RESULTS

National Rates

There were approximately 53,000 deaths per year from cancer of the cervix and 4,000 deaths per year from cancer of the penis in China during 1973–75. The average annual age-adjusted national rates per 100,000 population were 14.6 and 0.64, respectively. Cervical cancer ranked third behind cancers of the stomach (15.9/100,000) and esophagus (15.9/100,000) as the leading causes of cancer death among females, whereas penis cancer was the eleventh most common cause of fatal cancer among males. Cervical cancer accounted for 18.1% of all cancer deaths among women, and penis cancer accounted for 0.5% of all cancer deaths among men. The age-specific rates of mortality for cervical cancer increased steadily with age before they began to plateau after age 50, whereas penis cancer rates increased monotonically with advancing age.

Geographic Variation Within China

Age-adjusted rates of mortality from cervical cancer ranged from a low of 4.1 per 100,000 for Xizang province to a high of 29.4 in Shanxi province, a sevenfold difference. Rates in several prefectures exceeded 40. The penis cancer rates ranged from a low of 0.11 in Xizang to a high of 0.93 in Hunan, an eightfold gradient among the 24 provinces. Prefectural rates in certain provinces often exceeded 1.0. In contrast, differences in the total cancer mortality rates between these high- and low-risk areas were small. Text-figure 1 identifies prefectures with rates for either cancer that were in the highest 10% of all prefectures and significantly ($P<0.05$) higher than the national rate. High rates for both cancers tended to cluster in central China, notably in the provinces of Jiangxi, Nei Mongol, Shanxi, and Hunan.

Table 1 shows that the average penis cancer rate was about 50% higher in prefectures with high (top quartile) compared to low (bottom quartile) cervical cancer rates. A regression analysis, with the use of the rates for the 324 prefectures, showed a highly significant ($P<.0001$) linear gradient between the cervical and penis cancer rates. The correlation coefficient was $r=0.25$. Text-figure 2 illustrates the scatter relationship between the more stable rates for the 24 provinces, where the correlation was $r=0.41$.

Penis cancer rates tended to be higher in rural than in urban prefectures. When the 324 areas were divided into

those encompassing independent cities and those not, the average annual penis cancer rate was 0.45 per 100,000 population in the cities, significantly ($P<0.01$ based on a *t*-test comparison of means) lower than the corresponding rate of 0.60 in the rural prefectures. No clear-cut urban–rural differences were observed for cervical cancer. On the average, death rates were somewhat higher in the urban than in the rural prefectures (16.5 vs. 14.9), but they were lowest in the major urban provinces of Beijing (10.9), Tianjin (13.1), and Shanghai (7.9).

DISCUSSION

The 1973–75 survey provided the first comprehensive and standardized determination of cancer mortality rates in China. The survey revealed the national rate of cervical cancer to be one of the highest in the world (*18*). The risk of death from cervical cancer exceeded the similarly adjusted U.S. rate for 1973–77 (*19*) by more than fourfold, as did the death rate for cancer of the penis. Penis cancer mortality figures are not reported in many countries, but incidence data have been reported for certain cancer registries around the world (*17*). Although we have only mortality information, it appears that the penis cancer rates in certain central Chinese prefectures may approach those reported in high-incidence areas of Latin America, Africa, and India.

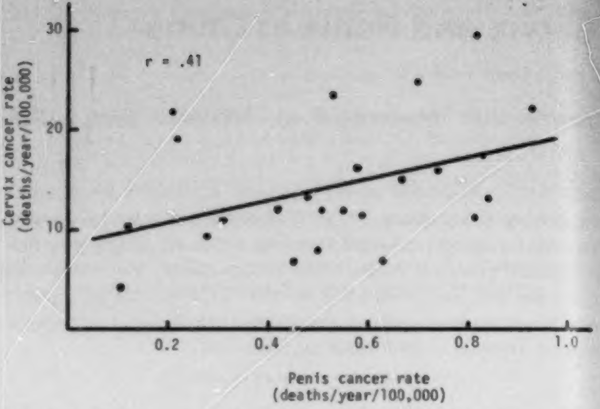
Quartile rank[a] of cervical cancer rate	Penis cancer rate[b]
1—low	0.43±0.04
2	0.51±0.04
3	0.52±0.05
4—high	0.68±0.06

[a] The 4 groups consisted of prefectures with average annual age-adjusted cervical cancer mortality rates per 100,000 population of 1) <10.8, 2) 10.8–14.4, 3) 14.5–18.8, and 4) >18.8.

[b] Values are means ± SE.



TEXT-FIGURE 2.—Average annual age-adjusted (world standard) mortality rates for cancers of the uterine cervix and penis among 24 Chinese provinces, 1973–75.

National data are not available to examine trends in mortality over time in China, but evidence from specific locales within the country suggests that rates for both cancers are declining. Hospital surveys in the 1950's and earlier listed cancer of the uterus (mostly cervical cancer) as the most common cause of cancer death among women (*1–3*), and the Shanghai cancer registry has recorded death rates for uterine cancer in 1976–77 to be only one-half those in 1963–65 (*20*). In the 1930's to 1950's, penis cancer was reported to account for 9–22% of all male cancers identified at selected hospitals in some cities (*2–6*), including Beijing where the tumor now represents only 0.2% of all cancers.

In addition to the high rates by world standards and the apparent decline in mortality, cervical and penis cancers show other similarities in China. Most striking is the geographic correlation in mortality from both tumors throughout the country, highlighted by the concurrence of elevated rates in central China. Since the findings are based on considerably larger numbers of deaths than reported elsewhere, they provide the strongest descriptive evidence to date that the diseases vary concomitantly. Some clustering has been reported within Japan (*21*) and Puerto Rico (*22*), and international correlation of the incidence rates between the two cancers has been reported, particularly in nonwhite populations (*23*). The data from China are also consistent with recent epidemiologic studies in other countries indicating an excess risk of cervical cancer among the wives of men with penis cancer (*11–16*).

Reasons for the association between cervical and penis cancers are not clear. Although penis cancer has not been extensively studied, personal hygiene, early circumcision, and the early management of phimosis appear to be protective factors (*24*). Both penis and cervical cancers occur excessively in persons with poor hygiene, a history of venereal disease, and low socioeconomic status (*24, 25*). In the United States both cancers are more common in blacks and Hispanics than in whites, with intermediate rates among

Chinese Americans (*19*). Since venereal transmission of herpes simplex virus type 2, or a human papilloma virus, is suspected in the etiology of cervical cancer (*25,27*), it is possible that the same agents may be responsible for penis cancer. To further elucidate the origins of cervical and penis cancers, investigations are planned in areas of China where rates for both cancers are high. If concurrence of the two cancers in spouses was found in China, early detection might be achieved by examination of partners of patients with cervical or penis cancer.

Use of Circulating Pregnancy-Specific β_1 Glycoprotein as a Marker in Carcinoma of the Breast in Women[1,2]

Saul W. Rosen, *Ph.D., M.D.*,[3,4] **Mitchell H. Gail**, *M.D., Ph.D.*,[5] *and* **Douglass C. Tormey**, *M.D., Ph.D.*[6,7]

ABSTRACT—Pregnancy-specific β_1 glycoprotein (SP_1) was determined by radioimmunoassay in sera from 27 normal women, 33 women with benign breast disease, and 191 women with carcinoma of the breast, staged for extent of the disease. All diagnostic groups exhibited substantial overlap in SP_1 values. Those with benign breast diseases tended to have values at least as high as those with cancer. Normal patients tended to have slightly lower values, but this difference may well have been due to the younger ages of the normal patients in our sample, because SP_1 values tended to increase with age. Immunochemical dilutions of SP_1 in the serum with the highest value (10.2 ng/ml) did not differ significantly from standard placental SP_1.—JNCI 1982; 69:1067–1071.

The use of placental and fetal proteins as cancer markers has been well established since the pioneer studies of Li et al. (*1*) with chorionic gonadotropin in trophoblastic neoplasia, Abelev (*2*) and Tatarinov (*3*) with α-fetoprotein in hepatoma, and Gold and Freedman (*4*) with carcinoembryonic antigen in adenocarcinoma of the colon.

During the past decade, 2 groups (*5–7*) isolated and purified a new placental glycoprotein, originally detected in pregnancy plasma by Tatarinov and Masyukçvich (*8*). Following Bohn's suggestion (*5*), we refer to this material as SP_1, although it has been given a variety of names in the literature (*9*). SP_1 appears to be produced by the syncytiotrophoblast in pregnancy (*10*). Its concentration in plasma, like that of placental lactogen,[8] increases as gestation proceeds and at term reaches levels as high as 100,000–400,000 ng/ml (*11*). This increase is due, in part, to the relatively long half-time of disappearance of SP_1 from the circulation ($\approx$34 hr) (*12*). Measurements of SP_1 in the sera of nonpregnant women, or of men, reveal very low concentrations—a few nanograms per milliliter at most (*13–18*). Placental lactogen (*19*) and chorionic gonadotropin (*20*), two other placental proteins, also circulate at low or undetectable concentrations in nonpregnant individuals. Like the concentrations of both placental lactogen and chorionic gonadotropin, the concentration of SP_1 is increased in the sera of most women with gestational choriocarcinoma (*14, 21, 22*) and in many men with nonseminomatous germ cell cancers of the testis (*14, 23, 24*).

Several workers have explored the possibility that SP_1 might be useful as a marker in carcinoma of the breast. Results have been conflicting. Some workers propose that SP_1 may be a useful marker in breast cancer (*14, 17, 25*), whereas others have suggested that SP_1 measurements, at least in the circulation, have little or no value in the diagnosis of this disease (*26, 27*). We have looked at this question with a sensitive and specific radioimmunoassay for SP_1 (*16*) applied to sera from a large group of women with breast cancer at various stages and to sera from normal women and women with benign diseases of the breast.

MATERIALS AND METHODS

Patients and sera.—Blood was drawn from 251 women, all of whom lived within a few hundred mile radius of Madison, Wis. Twenty-seven normal women were blood bank volunteers. Thirty-three women had benign diseases of the breast, and histologic diagnoses were obtained in 30; these included 18 with fibrocystic disease, 7 with epithelial dysplasia, 4 with adenoma, fibroadenoma, or papilloma, and 1 with lipoma. Of the 191 women with breast cancer, blood samples were taken from 12 women 1–3 weeks before operation. None of these 12 had evidence of metastatic disease, but 7 were later found to have ipsilateral axillary nodes. Blood samples were taken from the remaining 179 cancer patients 3 weeks to 6 months after completion of local therapy (radical or modified radical mastectomy, followed in a few cases by radiotherapy); the cancers were staged according to standard criteria (*28*), and patients with T_1, T_2, and T_3A lesions were represented. Of these 179 women, 84 had no evidence of distant metastases. Sixty-nine of these 84 women had positive axillary nodes, and 15 had negative nodes; blood samples were taken from all these women before any systemic therapy. The remaining 95 women had stage IV (*28*) metastatic disease; blood samples were taken from 68 women before chemotherapy and from 27 women who had failed (*29*) at least one chemotherapeutic regimen, one hormonal regimen, or both. The previously published therapeutic regimens for metastatic disease and the sampling

TEXT-FIGURE 1.—Distribution of serum concentrations of SP_1 in normal women, women with benign disorders of the breast, and women with breast cancer at various stages.

schedule in relation to drug dose (*30*) were followed with minor modification.

Blood samples were drawn at the Wisconsin Clinical Cancer Center; the serum was separated promptly and stored at −70°C. Coded samples were sent in Dry Ice to the National Institute of Arthritis, Diabetes, and Digestive and Kidney Diseases for radioimmunoassay.

Radioimmunoassay of SP_1.—Serum concentrations of SP_1 were determined in duplicate in a double antibody radioimmunoassay as previously reported (*16*). To eliminate interassay variation, we examined all serum samples in the same assay. Each serum sample containing more than 2.9 ng of SP_1/ml was incubated with labeled SP_1 and excess anti-SP_1, in a separate experiment, to exclude nonspecific damage to the radioligand as the cause of the high value; in every instance, more than 93% of tracer was bound.

Statistical methods.—Simple descriptive statistics, including sample percentiles, were computed by standard methods (*31*). For adjustment for differences in age distribution, analysis of covariance (*31*) was performed with the SPSS regression procedure (*32*). The model used had expectation (α) (age)$+\beta_j$, where the β_j's were disease category param-

TABLE 1.—*SP_1 distribution and mean age for various disease categories*

Diagnostic category	No. of subjects	SP_1 distribution, ng/ml					Mean age, yr
		Mean	Sample standard deviation	Percentiles		Maximum	
				50th	95th		
Normal	27	1.61	0.27	1.6	2.0	2.0	32.4
Benign breast disease	33	1.87	0.37	1.8	2.6	2.7	43.7
Preoperatively in patients with negative nodes	5	1.74	0.61	1.5	2.8	2.8	50.0
Preoperatively in patients with positive nodes	7	1.70	0.38	1.9	2.1	2.1	55.4
Postoperatively in patients with completely resected disease and negative nodes	15	1.85	0.61	1.8	3.7	3.7	43.1
Postoperatively in patients with completely resected disease and positive nodes	69	1.75	0.43	1.7	2.4	3.2	50.2
Prior to treatment in patients with metastatic disease	68	1.87	0.48	1.8	2.8	3.3	57.3
Following treatment failure in patients with metastatic disease	27	2.21	1.69	1.9	3.6	10.2	54.2

eters. Only 3 of the 251 SP_1 measurements fell below the sensitivity threshold of the assay (1.0 ng/ml), and these measurements were assigned the value 1.0 ng/ml; the percentiles used were unaffected by this convention.

RESULTS

The distribution of SP_1 measurements is indicated in text figure 1 and table 1 for each of the patient categories shown. The categories, which define when the sample was taken in relation to breast cancer status, are preoperatively in patients with negative nodes, preoperatively in patients with positive nodes, postoperatively in patients with completely resected disease and negative nodes, postoperatively in patients with completely resected disease and positive nodes, prior to treatment in patients with metastatic disease, and following treatment failure in patients with metastatic disease. Normal women and women with benign breast diseases are included for comparison.

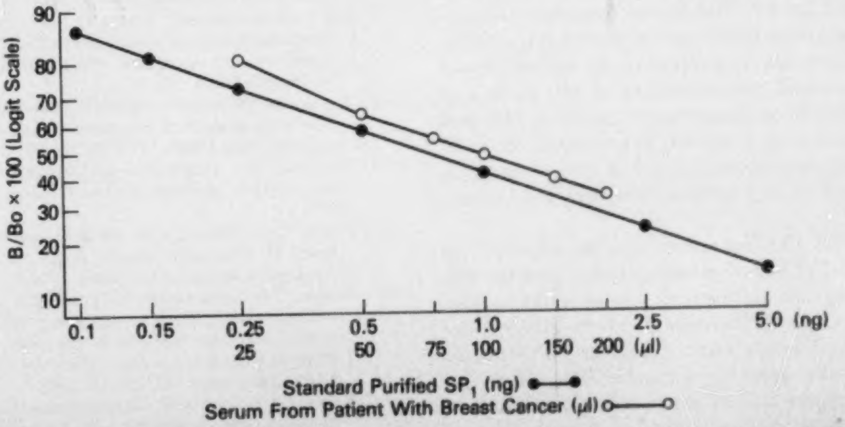
The distributions were reasonably symmetrical and exhibited substantial overlap among the disease categories. Women with benign breast disease had a mean value of 1.87 ng/ml, which was as large as mean values found in all the cancer groups except those who failed treatment and had metastatic disease (mean, 2.21 ng/ml). If the patient with value 10.2 ng/ml was excluded from the group with treatment failure and metastatic disease, the group mean fell to 1.91.

TABLE 2.—*Unadjusted and age-adjusted differences in mean SP_1 values*

Diagnostic category	Unadjusted, ng/ml, disease group−normal group	Age adjusted, ng/ml, disease group−normal group
Benign breast disease	0.26	0.14
Preoperatively in patients with negative nodes	0.13	0.14
Preoperatively in patients with positive nodes	0.09	0.08
Postoperatively in patients with completely resected disease and negative nodes	0.24	0.18
Postoperatively in patients with completely resected disease and positive nodes	0.14	0.04
Prior to treatment in patients with metastatic disease	0.26	0.09
Following treatment failure in patients with metastatic disease	0.60	−0.04

Normal women had slightly lower mean serum SP_1 concentrations than the diseased groups. The 95th percentile of the normal group was 2.0 ng/ml, which was exceeded by 9 of 33 patients with benign disease, 1 of 5 in the preoperative-negative node group, 1 of 7 in the preoperative-positive node group, 3 of 15 in the postoperative-negative node group, 17 of 69 in the postoperative-positive node group, 22 of 68 in the pretreatment-metastatic disease group, and 12 of 27 in the treatment failure-metastatic disease group. However, as we discuss below, much of the difference between normal women and women with disease was accounted for by the younger age distribution in normal patients. Moreover, values above 2.0 ng/ml were found about as often among women with benign breast disease as among those with cancer.

The patients from whom blood samples were taken tended to be younger in the normal, benign disease, and postoperative-negative node groups and older in the 2 metastatic disease groups and the preoperative-positive node group (*see* table 1). Regression analysis indicated that SP_1 values tended to increase by roughly 0.007 ng/ml per year for each diagnostic group except the 2 preoperative cancer groups, which had very few cases and were subject to large sampling variation. Because normal women were about 20.5 years younger than cancer patients on the average, an adjusted mean SP_1 value for the normal group would have been roughly $1.61+(20.5\times 0.007)=1.75$ ng/ml; this value is in line with values for other diagnostic groups. Table 2 contains both unadjusted and adjusted differences in mean SP_1



TEXT-FIGURE 2.—Immunochemical behavior of placental SP_1 and serum SP_1 from patient #1 with metastatic breast cancer. Serial dilutions of serum were compared to highly purified placental SP_1 (supplied by Dr. Hans Bohn, preparation #13) in their ability to displace ^{125}I-labeled SP_1 (Bohn preparation #17, 75 μCi/μg, 20 pg) from rabbit anti-SP_1 (#184; bleeding of Aug. 12, 1977; final dilution, 1:950,000). Relative percentage of radioligand bound ($B/B_0\times 100$) has been corrected for nonspecific binding (4.7%).

values between each disease group and the normal group. A separate analysis of covariance was performed on each disease group and the normal group for estimation of the adjusted group difference for each row in table 2. The unadjusted differences were obtained by simple subtraction of means in table 1. For example, 1.74−1.61=0.13 is the difference between the mean of the preoperative–negative node group and the mean of the normal women in table 1. In most cases, age adjustment reduced the apparent difference in mean SP_1 values between the disease groups and the normal group. This was especially true in the comparison of patients with metastatic disease, who tended to be older, with normal women, who tended to be younger.

We looked more closely at sera from patient #1, a 68-year-old woman who had undergone left radical mastectomy 7 years before she presented with metastases in the liver and lungs. She failed to respond to combination chemotherapy with cyclophosphamide, doxorubicin, 5-fluorouracil, fluoxymesterone, and prednisone. The serum concentration of SP_1 before this course of chemotherapy was 10.2 ng/ml, the highest value we have encountered among all the patients reported here. Serial dilutions of serum from patient #1, over an eightfold range, were not recognized by our anti-SP_1 serum as significantly different from standard SP_1 purified from placenta (text-fig. 2). We obtained a second serum sample 3 weeks after she had completed her first therapy course, and the SP_1 level had fallen to 5.9 ng/ml. The patient received a second course of therapy and, 3 weeks after its completion, another serum sample was obtained. This time, the SP_1 had risen to 8.4 ng/ml; she died 3 weeks later.

DISCUSSION

In a retrospective examination of tissues by an immunoperoxidase method, Horne et al. (*25*) detected SP_1 in 38 of 50 sections from patients with breast cancer but in none of 12 sections from patients with benign breast diseases. Moreover, women whose breast cancers were negative for SP_1 had significantly longer survival times than women whose cancers showed positive staining for SP_1. Searle et al. (*14*) used a radioimmunoassay for SP_1 and found increased concentrations in 6 of 21 sera from breast cancer patients, including two sera with concentrations exceeding 20 ng/ml. Wurz (*17*) also found increased concentrations of SP_1 in 18% of the 82 sera she studied from breast cancer patients; 11% had SP_1 levels between 10 and 50 ng/ml. Wurz noted, in addition, that the SP_1 concentration rose in 7 of 10 patients with recurrent disease and fell in 5 patients who received chemotherapy.

In contrast, Engvall and Yonemoto (*26*) detected SP_1 in the serum of only 1 of 22 breast cancer patients, and the SP_1 concentration in this case (1.0 ng/ml) was near the extinction of their assay. Indeed, Bremner et al. in Horne's department also assayed breast cancer sera for SP_1 and, in contradistinction to the conclusions reached from their immunocytochemical study (*25*) of tissue (mentioned above), found "little relation to disease spread in the majority of cases" (*27*).

Our data, likewise, do not support the usefulness of circulating SP_1 as a marker in carcinoma of the female breast. Although the mean serum SP_1 in a group of normal women was slightly lower than that in women with breast cancer, we found values above 2.0 ng/ml (95th percentile for the normal women) with equal prevalence in women with benign disease of the breast as in women with breast cancer. Moreover, there was no clear-cut tendency toward higher levels of SP_1 as the body burden of tumor increased.

Serum SP_1 from a breast cancer patient with the highest value in this series was immunochemically similar to standard SP_1 of normal placenta. Although we have yet to find a single instance of eutopic or ectopic SP_1 that differed from standard (Rosen SW, Calvert I: Unpublished data), one such case has been noted briefly (*14*).

Data for circulating SP_1 in the normal women reported herein agree well with those we reported earlier (*16*) in a different population of mixed normal men and women 18–70 years of age. Our finding that SP_1 values tended to increase with age was unexpected but was also noted in a group of normal men (data not shown). We are unaware of similar analyses of the effect of age on serum concentrations of other placental proteins. SP_1 has been detected in cultured human fibroblasts (*33–35*), but its physiologic role in the normal person—much less the gravid woman—remains unknown.

Carcinoembryonic Antigen in Nonhuman Primates [1,2,3]

Darrow E. Haagensen, Jr., [4,5,6] **Richard S. Metzgar,** [7,8] **Brent Swenson,** [8] **William G. Dilley,** [9] **Charles E. Cox,** [9] **Sarah Davis,** [4] **Janet Murdoch,** [9] **Norman Zamcheck,** [4,10] *and* **Samuel A. Wells, Jr.** [9]

ABSTRACT—Blood levels of carcinoembryonic antigen (CEA) have been measured in several nonhuman primate species. Only gorillas and chimpanzees were found to have significant elevations of CEA-like activity in their blood compared to the normal values of less than 2.5 ng/ml in humans. The average CEA level in 134 chimpanzees was 25.2 ng/ml (range, 4.2–95 ng/ml) and in 13 gorillas it was 32 ng/ml (range, 12.4–61.9 ng/ml). These levels were not related to sex. Blood levels repeatedly taken over a 1½-year period remained relatively stable in both species. Analysis of parallelism of immunologic reactivity showed chimpanzee CEA to be similar to but not identical with human CEA. The molecular size of chimpanzee CEA was also similar to that of human CEA.—JNCI 1982; 69:1073–1076.

CEA was identified by Gold and Freedman (*1*) to be a glycoprotein expressed on colon carcinoma cells and by the fetal colon. Subsequent investigations have indicated that CEA is associated with carcinomas derived from both ectodermal and endodermal origins and is present as a luminal secretion from normal colon mucosa cells (*2, 3*). Circulating plasma levels of CEA are less than 2.5 ng/ml in normal individuals (*2*). Elevated plasma levels of CEA are useful in detecting and monitoring disease status of metastases for colon carcinoma and possibly for other major forms of carcinoma [breast, pancreas, lung, stomach, ovary, and cervix (*4*)].

The presence of CEA in species other than humans has not been studied extensively. Engvall et al. (*5*) have examined *Macaca* monkey lung and spleen tissues and have isolated a molecule that is immunochemically cross-reactive with CEA; however, the molecule most closely resembles human normal cross-reactive antigen. We report here our finding of a substance immunologically similar to CEA present in the circulation of certain nonhuman primates.

MATERIALS AND METHODS

Primate blood samples.—Chimpanzee (*Pan*) blood was obtained for CEA analysis from Yerkes Primate Center, Lemsip Primate Center (Tuxedo, N.Y.), and ICES (Holloman Air Force Base, N. Mex.). Blood samples from gorillas (*Gorilla*), black apes (*Cynopithecus*), and orangutans (*Pongo*) were obtained from Yerkes Primate Center. Baboon (*Papio*) and macaque (*Macaca*) blood samples were from Yerkes and Duke University Primate Centers. Blood samples were predominantly collected as serum for analysis; however, K_3 EDTA plasma samples were also collected from some chimpanzees, orangutans, and old-world monkeys. No differences in mean level of CEA were noted between plasma and serum samples of each of the species when both were tested.

CEA assay.—CEA levels were determined by a modification of the Hansen assay procedure (*6*). Aliquots of 0.5 ml of serum or plasma were PCA extracted, and the PCA was separated from the CEA by a buffer exchange column (*7*) to give a final assay sample volume of 6.5 ml. The CEA RIA utilized Roche CEA-kit reagents (Hoffmann-La Roche, Inc.) in an isotope dilution assay in which ^{125}I-labeled CEA and goat anti-CEA were added simultaneously to the assay tubes. The assay tubes were incubated overnight at room temperature and then the assay was terminated by the addition of 1 ml of a 2% suspension of donkey anti-goat antibody attached to a vinylidene fluoride bead (from Dr. Hans Hansen, Hoffmann-La Roche, Inc.). Assay tubes were centrifuged, the supernatant was decanted, and the pellets were counted. The binding of radioactive CEA by antibody in the absence of added cold antigen (Bo) was set at approximately 50% of added counts. A 6-point inhibition curve was generated with 0, 1.25, 3.125, 6.25, 9.375, and 12.5 ng of unlabeled CEA. The binding at 12.5 ng of added cold CEA was approximately 20% of added counts.

When CEA values were above 25 ng/ml, we determined the CEA level by assaying a 1.5-ml aliquot from the initial 6.5-ml PCA extract sample volume. The aliquot volume was brought up to 6.5 ml for analysis by addition of 5 ml of standard curve buffer (⅒ dilution of Roche EDTA stock buffer).

Comparison of chimpanzee CEA activity with human CEA activity in RIA was performed with a pool of 20 different PCA-extracted chimpanzee blood samples, which were concentrated by ultrafiltration on a PM 10 membrane (Amicon Corp., Lexington, Mass.) to approximately 50 ng/ml of CEA activity. This concentrate was tested in RIA

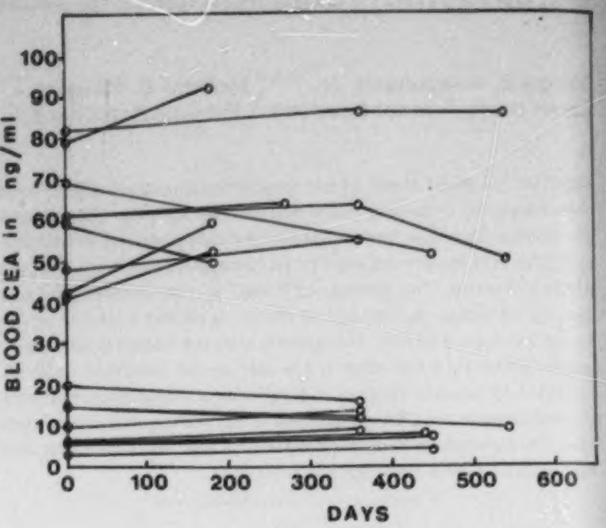
versus a human CEA preparation also at 50 ng/ml for parallelism of inhibition at 25, 50, 75, 100, 150, and 200 µl of sample added to 6.4 ml of ⅒ EDTA buffer. Roche goat and baboon anti-CEA antibodies were used in separate assays to identify the CEA activity in the human versus the chimpanzee CEA antigen preparations. The baboon anti-CEA antibody inhibition assay was performed in a manner identical to that of the assay with goat anti-CEA antibody, except that the baboon anti-CEA antibody inhibition assay was terminated by addition of 1 ml of Roche Z-gel as described previously (*6*).

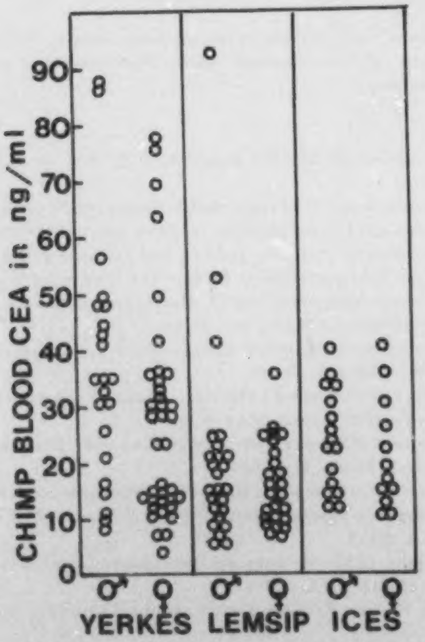
Chromatography.—Column chromatography was performed with Sephadex G-200 (Pharmacia Fine Chemicals, Piscataway, N.J.) in a 2.5×90-cm column. The column was equilibrated in 0.01 *M* ammonium acetate buffer (pH 7.0) containing 0.001 *M* Na azide. The pooled PCA-extracted chimpanzee blood sample concentrate used above for RIA assay was also used for column chromatography. The concentrate was adjusted to be approximately 250 ng/ml by Amicon ultrafiltration, and then to 1 ml of the concentrate was added 20 mg of crystalline bovine albumin (Miles Laboratories Inc., Kankakee, Ill.) for internal standardization before application to the column. Column fractions of 5.5 ml were collected for analysis.

RESULTS

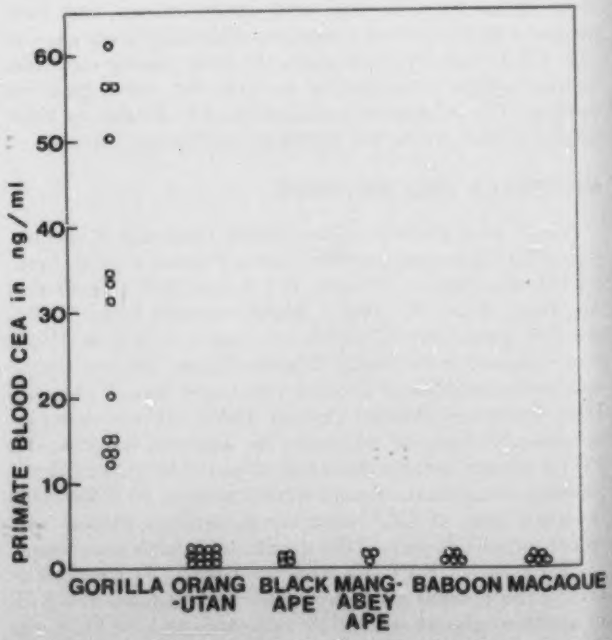
A total of 134 chimpanzee blood samples were analyzed for CEA content. These samples had been obtained from three separate primate centers that maintained colonies of chimpanzees (text-fig. 1). All chimpanzee blood samples had detectable CEA levels (range, 4.2–95 ng/ml; average, 25.2 ng/ml). The average CEA level in 63 male chimpanzees was 27 versus 23.5 ng/ml in 71 females. Twenty of the blood samples from the ICES colony were obtained from chimpanzees less than 1 year of age. The CEA levels in this group ranged from 12.1 to 35.1 ng/ml, with an average value of 23.4 ng/ml. Two young female chimpanzees from the nursery at the Yerkes primate colony were analyzed for blood CEA level at 4½ months of age. One of the 2 chimpanzees had been taken from the mother on the day of birth (CEA level, 28.1 ng/ml). The other chimpanzee had been kept



TEXT-FIGURE 2.—Repeated analysis of blood CEA levels for 17 chimpanzees.



TEXT-FIGURE 1.—Blood CEA levels for 134 chimpanzees maintained at three primate colonies.



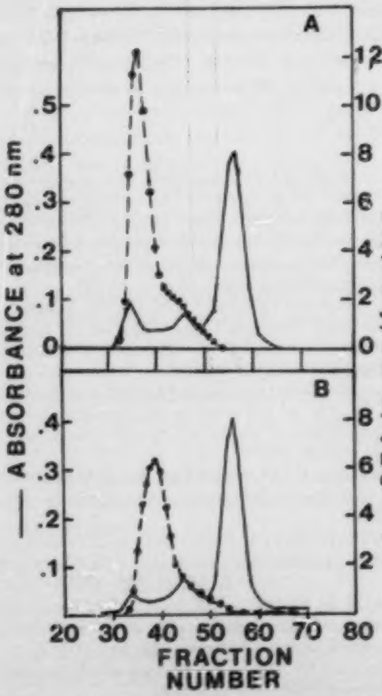
TEXT-FIGURE 3.—Blood CEA levels for several species of primates. Only gorillas had CEA levels above the normal range found in humans.

with the mother for 10 days before being separated (CEA level, 23.4 ng/ml).

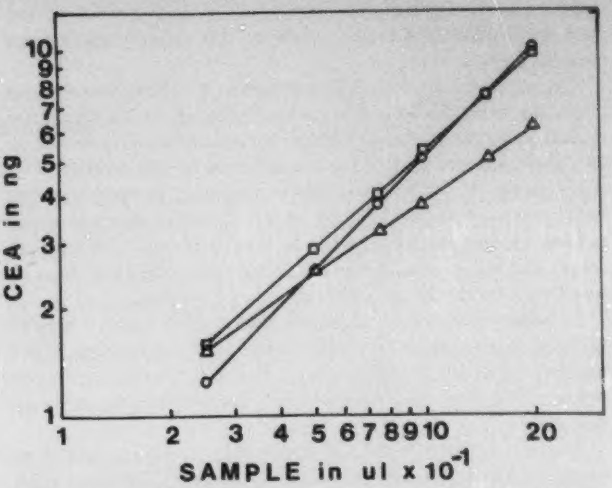
Measurement of CEA levels was repeated on 17 of the Yerkes primate colony chimpanzees at approximately 6 months to 1½ years (text-fig. 2). Eight of these chimpanzees had CEA levels below 20 ng/ml, whereas 9 chimpanzees had levels above 40 ng/ml. In both groups some fluctuation of CEA level occurred. However, on repeated analysis, no change in the CEA level greater than ±50% of the initial value was observed, and only 2 of the 17 chimpanzees had CEA level changes greater than ±30% of the initial value.

Six other nonhuman primate species were tested for CEA level and only the gorilla had CEA levels above 2.5 ng/ml (text-fig. 3). The range of CEA levels in the 13 gorillas studied was 12.4–61.9 ng/ml, with an average value of 32 ng/ml. Three of these animals had repeated CEA determinations, which showed less than a ±15% variation in CEA level over a 1-year time span.

For a further definition of the CEA activity in the chimpanzee blood, PCA extracts from 20 blood samples were pooled, concentrated, and then column chromatographed on Sephadex G-200. Depicted in text-figure 4 (A and B) is the molecular size elution pattern of chimpanzee CEA versus human CEA. The chimpanzee CEA eluted from Sephadex G-200 as a single peak of an approximately 200,000-dalton molecular size, which was similar to the CEA peak found in a human plasma sample.



TEXT-FIGURE 4.—Sephadex G-200 elution profile of CEA activity in the PCA extract of serum. A) Twenty 0.5-ml samples of chimpanzee serum were PCA extracted, buffer exchanged, pooled, and concentrated to an activity of ≈250 ng/ml. To 1 ml of this concentrate was added 20 mg of bovine albumin. This sample was applied to the Sephadex G-200 column, and 5.5-ml fractions were collected for analysis. B) Plasma (6 ml) from a patient with 40 ng/ml of CEA activity was processed in a fashion identical to that used for the chimpanzee serum.



TEXT-FIGURE 5.—Depicted on a log–log scale is a 6-point inhibition assay for 20 PCA-extracted chimpanzee sera that were buffer exchanged, pooled, and concentrated to a CEA activity of ≈50 ng/ml. This concentrate was assayed at 6-sample volumes (25, 50, 75, 100, 150, and 200 µl) for CEA activity in comparison with a human CEA standard at 50 ng/ml activity (○). Chimpanzee CEA activity was detected by Roche goat anti-CEA antibody (□) and by baboon anti-CEA antibody (△). Human CEA activity showed a steeper inhibition line than chimpanzee CEA activity detected by either antiserum.

We compared the immunologic similarity between the chimpanzee CEA and the human CEA by determining the parallelism of antigenic activity in RIA for a 6-point inhibition curve of human CEA versus the pooled chimpanzee blood samples that had been PCA extracted (*see* "Materials and Methods"). Both goat and baboon anti-CEA antibodies were used to detect the CEA activity. The chimpanzee CEA activity more closely paralleled the human CEA activity with goat anti-CEA antibody than with baboon anti-CEA antibody (text-fig. 5). However, human CEA showed a steeper inhibition slope than chimpanzee CEA with both types of anti-CEA antibody.

DISCUSSION

In humans the luminal CEA produced by normal mucosal cells does not appear to cause elevations of CEA (>2.5 ng/ml) in the circulation. It is only in disease states where tight junctions and basement membranes are disrupted that CEA enters the circulatory system in detectable quantities. Various pathologic types of carcinoma of both endodermal and ectodermal origins can produce CEA, and with metastatic disease very high plasma levels of CEA can occur (up to 100,000 ng/ml). Inflammatory disease (ulcerative colitis, pancreatitis, emphysema, and benign liver disease) can also cause modest elevations in blood levels of CEA up to approximately 20 ng/ml.

Two of the great apes (chimpanzees and gorillas) had normal CEA plasma levels, which in humans would be considered significantly abnormal. The mean value in 134 chimpanzees was 25 ng/ml, and in 13 gorillas the mean value was 32 ng/ml. All chimpanzees and gorillas tested had detectable CEA levels; however, the values ranged from 4 to 95 ng/ml.

On repeated analysis, CEA levels in 17 chimpanzees and 3 gorillas were fairly stable over a 6-month to 1½-year time frame. Also the elevated CEA level occurred early in life in the chimpanzees and did not appear to be sex related. The wide range of CEA blood levels observed in chimpanzees and gorillas (4–95 ng/ml), however, indicates that variation occurs between animals in the factors regulating CEA blood level. We were unable to attribute this variation to any health problems in the chimpanzees or gorillas.

In addition to the chimpanzee and gorilla, 5 other species of nonhuman primates were tested for circulating CEA activity (text-fig. 3). All 5 species had CEA levels that were below 2.5 ng/ml and that were at the lower limit of assay detectability.

The chimpanzee CEA on molecular sizing appeared to be quite similar to human CEA (≈200,000 daltons). RIA inhibition analysis for serial dilutions of chimpanzee CEA showed a close similarity to human CEA when assayed against Roche goat anti-CEA antibody. However, less identity of human and chimpanzee CEA activities was shown when baboon anti-CEA antibody was used for CEA identification (text-fig. 5). The differences in chimpanzee CEA activity versus human CEA activity recognized by goat and baboon anti-CEA antibodies indicates that some antigenic determinants on the chimpanzee CEA are quite similar to those on the human CEA, whereas others have undergone some antigenic variation. Baboon anti-CEA antibody has previously been shown to have a narrower range of CEA determinant recognition than does goat anti-CEA antibody (*6*). The baboon anti-CEA antibody does not recognize the "common-site" determinant(s) on CEA, which is one of the two predominant determinants recognized by goat anti-CEA antibody (*6*).

The finding that human CEA and chimpanzee CEA are not absolutely immunologically identical means that measurements of the chimpanzee CEA level with the use of a human CEA standard result in some degree of underestimation of the level of chimpanzee CEA activity in blood samples. This situation is most evident when the baboon anti-CEA antibody is used for detection of chimpanzee CEA activity (text-fig. 5).

The molecular sizing and parallelism of inhibition studies indicate that chimpanzee CEA is similar but not identical to human CEA. This is not an unexpected finding because chimpanzees and humans appear to have evolutionally separated approximately 6 million years ago (*8*).

For the primate species less closely related to humans than the chimpanzee or gorilla, similar CEA-like substances may still exist in the blood. However, due to evolutionary structural diversity these substances may no longer be capable of being recognized antigenically as CEA by either goat or baboon anti-CEA antisera. Also, evolutionary divergence may have occurred in the site and/or amount of CEA production and in the metabolism of CEA.

Elucidation of why elevated blood levels of CEA immunologic activity occur in the chimpanzee and gorilla will require determination of organ and tissue location(s) of the CEA as well as metabolic half-life studies. A predominant route of clearance of human CEA in experimental systems appears to be the liver (*9*). If the clearance mechanism for chimpanzee CEA and gorilla CEA is different from that for human CEA (we have no evidence that it is), this could explain in part the observed elevated CEA levels in these 2 species. However, in the Yerkes chimpanzees and gorillas in which CEA levels were elevated, compared to levels in humans, serial measurements of liver function by enzyme levels and serum chemistry values were normal. Also, the health status of the chimpanzees with CEA levels above 40 ng/ml was in general good and did not differ from that of the chimpanzees with lower CEA levels.

Also important is the potential for immunologic recognition of CEA by various primate species. Ruoslahti et al. (*10*) have immunized the *Macaca iris* monkey with human CEA and observed a predominantly specific site response. The common baboon (*Papio*) anti-human CEA antibody that we have produced is also a high-titer specific site antibody to CEA (*6*). Since the normal chimpanzee has a circulating molecule immunologically similar to human CEA, one might expect the chimpanzee to be immunologically tolerant to CEA. However, we have been able to generate in the chimpanzee an antibody response to human CEA. This antibody is very ineffective in recognizing the chimpanzee's own CEA activity but recognizes human CEA equivalent to baboon or goat anti-CEA antibody. This is further evidence of some genetic diversity between human CEA and chimpanzee CEA and will be the subject of a separate report (Haagensen DE, et al: Manuscript in preparation).

Spontaneous Leukemia Viruses: Lymphomagenic Ecotropic Viruses of AKR Mice[1,2,3]

Esther F. Hays,[4,5] Nadine Margaretten,[4] *and* Stephen K. Swanson[4,6]

ABSTRACT—The spontaneous leukemia (SL) viruses are ecotropic lymphomagenic viruses isolated from AKR spontaneous lymphomas. These viruses are produced stably by continuous cell lines from spontaneous lymphomas and by a cell line derived from the bone marrow stroma of an AKR mouse neonatally inoculated with an SL virus. All cell lines cloned from the parent lymphoma cell lines consistently produce SL viruses. These viruses can be passaged in vivo and maintain their leukemogenic properties. Cloned isolates of SL viruses accelerate lymphoma in AKR mice and induce thymic lymphoma in mice of other strains. Thus their lymphomagenic properties are conclusively shown. In a study with the use of a sensitive host range assay, xenotropic and/or dual-host range viruses are consistently found in spontaneous lymphomas and cell lines derived from them. However, viruses able to replicate in mink lung cells are not expressed in SL virus-induced lymphomas or their derived cell lines.—JNCI 1982; 69:1077-1082.

Previous experiments have determined that viruses found in young AKR mice were not lymphomagenic, whereas viruses found in the spleen and thymus of older animals as well as in spontaneous lymphomas had lymphomagenic properties (*1, 2*). Lymphomagenesis was measured by the acceleration of onset of thymic lymphoma after neonatal inoculation of test virus in newborn AKR mice. In addition, cell lines from spontaneous thymomas of AKR mice were established, and the properties of viruses found in the supernatants of these cell cultures were studied (*3*). Most cell lines produced ecotropic viruses. Six of eight lines produced viruses that accelerated AKR lymphoma. One line produced xenotropic viruses, and one line produced viruses with dual-host range. All viruses produced by these lines were negative with the XC plaque assay, formed foci with the S^+L^- assay, and had the property of "converting" to XC positivity when grown on mouse embryo cells (*4*). We consider these ecotropic viruses to represent a late-appearing class of lymphomagenic viruses of AKR mice. The following report describes further studies with these viruses and documents that they are stable in culture and in cloned lymphoma cell lines, that they can be cloned, and that they are lymphomagenic in other mouse strains.

MATERIALS AND METHODS

Mice.—Mice were of the inbred AKR and SJL strains maintained in this laboratory. The inbred C3H/HeJ mice were obtained from The Jackson Laboratory, Bar Harbor, Maine.

Viruses.—The ecotropic-oncogenic viruses obtained from lymphoma cell lines are referred to as SL viruses and designated by the cell line from which they were derived; e.g., AKR SL3 cell line produced AKR SL3 viruses. Viruses were harvested 24 hours after the cultures were split. Medium and cells were removed and frozen at −70°C and then thawed and filtered prior to use. MCF-247, AKv-1, and AKR xenotropic virus were obtained from Dr. Janet W. Hartley, National Institute of Allergy and Infectious Diseases, Bethesda, Md. Cloned G-MuLV was obtained from Dr. D. Buchhagen, Downstate Medical Center, Brooklyn, N.Y.

Cell lines.—The cell lines described below produce ecotropic viruses that accelerate lymphoma when they are inoculated into newborn AKR mice.

Lymphoma cells: The lymphoma cell lines AKR SL1, AKR SL2, AKR SL3, AKR SL4, AKR SL7, AKR SL10, and AKR SL11 were established in continuous culture as described previously (*3*). They are maintained in RPMI-1640 medium with 10% NCS and split at 3-day intervals. They are comprised of Thy 1.1-positive lymphoblasts that, when inoculated ip, iv, and sc into young AKR mice, produce progressively growing lymphomas. Lines AKR SL3-A and AKR SL3-B were established from the thymuses of 2 AKR mice with thymic lymphomas accelerated by AKR SL3 virus. Line AKR A2 was derived from the thymus of a G-MuLV-accelerated lymphoma.

MAC 12: This line was derived from the adherent stromal layer of a long-term bone marrow culture from a healthy AKR mouse inoculated when newborn with the leukemia-accelerating virus AKR SL3 (*5*). These adherent cells were transferred by trypsin EDTA treatment at weekly intervals. They reached confluence 7 days after inoculation of 10^6 cells in 25-cm^2 flasks. Although these cells have the morphologic appearance of macrophages, they were not phagocytic, did not have Fc receptors, and did not stain for nonspecific esterase. They are considered to be transformed bone mar-

row stromal elements. When inoculated into syngeneic mice, they produced osteosarcomas, chondrosarcomas, and fibrosarcomas.

Cloned cell lines from AKR SL4: We made cell clones by diluting and aliquoting the cells into Falcon microtiter cell culture plates. Wells containing progeny of a single cell were observed daily and transferred to successively larger plates. After a healthy cell population derived from a single cell had been transferred a number of times in 25-cm^2 tissue culture flasks, viruses produced by the cells were studied.

Preparation of cell-free filtrates.—The cell-free filtrates were made by removal of the thymus, spleen, and lymph nodes from mice with lymphoma and preparation of a 20% (wt/vol) homogenate of the tissue in phosphate-buffered saline. The homogenate was centrifuged for 3,000×*g* for 10 minutes, and the supernatant was centrifuged at 7,000×*g* for 15 minutes. The final supernatant was passed through a 0.45-μm filter and stored frozen until animals were available for inoculation. The above procedure was done at 4°C.

Virus cloning.—Cloned viruses were derived from NIH ME cells infected with viruses derived from AKR SL3 cell culture supernatants. The viruses were selected by end-point titration. One milliliter of DMEM containing 10% NCS, 10 μg Polybrene/ml, and 2×10^4 NIH ME cells was added to each of 24 wells in Falcon microtiter cell culture plates. After cell attachment, the medium was aspirated and 0.1 ml of filtered culture fluid from AKR SL3/NIH cultures was added to each well in tenfold serial dilutions ranging from 10^{-2} to 10^{-6}. Six replicate wells were inoculated with each dilution. After 3–4 weeks with cell passage at 3- to 4-day intervals, the wells were analyzed for viral RT activity. Positive supernatants appearing in the highest dilution wells were selected as clones. The isolates derived in this manner were end point titrated two more times. The cloned viruses were designated AKR SL3- SX4, AKR SL3-SX5, and AKR SL3-H55. Cloned viruses AKR SL3-1, AKR SL3-2, and AKR SL3-3 were obtained from Haseltine (*6*).

Virus assays.—RT: The RT assay utilized the method of Roy-Burman et al. (*7*).

S^+L^- assay: This assay was performed with the use of S^+L^- cells obtained from Dr. R. H. Bassin, Laboratory of Tumor Virus Genetics, Division of Cancer Cause and Prevention, National Cancer Institute, Bethesda, Md., by means of the following method: S^+L^- cells were plated at 5×10^4 cells/35-mm tissue culture dishes in 10 μg Polybrene/ml in DMEM, 10% NCS, and 1% PS. Serial dilutions were made 24 hours later for each virus from a 1× concentration to a 1:10^4 dilution. Plates were infected with 0.2 ml of each virus dilution in duplicate. Positive and negative controls were utilized. The plates were incubated for 1 hour, during which time they were shaken several times lightly back and forth to evenly distribute the virus. At the end of 1 hour, the plates were overlaid in 2.0 ml of the above medium containing 0.5% methylcellulose. Three days later, 1 ml of medium was added per plate. When the S^+L^- cells reached confluence, the medium was aspirated, and the cells were fixed with 2.0 ml in 0.25% methylene blue–3.7% Formalin in saline. The plates were rinsed 4 hours later. Plaques were counted with the aid of a dissecting microscope.

XC assay: This assay was performed with a modification of the method described by Rowe et al. (*8*). NIH ME cells were plated at 5×10^4 cells/35-mm tissue culture dishes as above. Plates were infected 24 hours later with virus as above. The plates were overlaid with DMEM, 10% NCS, and 1% PS. When the cells reached confluence (3–4 days later), the plates were irradiated with UV light for 20 seconds at 70 erg/mm^2/second, from 28 cm above the monolayer. XC cells were overlaid with 6×10^5 cells/plate. Two days later, the medium was changed. One-half to 1 day later, the medium was aspirated and the plates were stained as described above. Syncytia formed by fusion of XC cells were counted on the stained plates by means of a dissecting microscope.

Assay for lymphomagenesis: Mice were inoculated ip within 4 days of birth with 0.1 ml of test material. AKR mice were observed for 150 days. Spontaneous thymic lymphoma did not develop in these animals before 180 days of age. SJL mice were observed for 250 days. Spontaneous thymic lymphoma is rarely seen in this strain. Between 240 and 365 days of age, 2–37% of SJL mice in our breeding colony developed the disease. After 365 days, the animals developed a characteristic reticulum cell sarcoma. In several of the SJL tests, uninoculated littermate controls were used to further control for specific oncogenicity of the inoculated materials. C3H/HeJ mice were observed for 1 year. Spontaneous lymphoma did not occur in this strain prior to 1 year and rarely occurred in older mice.

Cocultivation infection for host range determination: Indicator cells, NIH ME, SC-1, or MLC, were plated in multiwells in medium containing 10 μg Polybrene/ml. When the cells reached 25% confluence, the cells to be tested were added at a ratio of 1:1–5:1 over the indicator cells. The indicator cells were then cultured as usual (i.e., passaged twice weekly). We removed the lymphoma cells by washing the adherent fibroblasts with trypsin before subculturing the first two times. No lymphoma cells were evident after two passages. After 3 weeks, the culture medium was tested for the presence of RT.

Assay for phenotypically mixed virus: Virus-infected NIH ME cells or MLC were cocultivated with MLC or SC-1 cells, respectively, for at least four passages. Twenty-four-hour medium from each culture was then filtered (0.45 μm Millex) and added to uninfected MLC and SC-1 cells. These cultures were assayed at two passage levels (starting at passage 3) for the presence of extracellular particles containing RNA-dependent DNA polymerase. In cases in which phenotypically mixed viruses (i.e., xenotropic or dual-host range genomes with ecotropic coats) were detected, the unmasked viruses growing in MLC were assayed for host range with direct infection of MLC, NIH ME, and SC-1 cells.

RESULTS

Stability of Oncogenic Properties of SL Viruses

Continuous cultures of AKR SL3 and MAC 12 cells were monitored at 6-month intervals for 2 years for virus production and oncogenicity. The cells continuously produced viruses that had an ecotropic host range and accelerated lymphoma in AKR mice. The results of two time periods, 1 year apart, are presented in table 1.

To test the stability with in vivo passage, we inoculated filtered AKR SL3 supernatants into newborn AKR mice. A cell-free filtrate was prepared from a mouse that developed lymphoma 70 days after inoculation. This filtrate accelerated lymphoma in all inoculated animals and has done so through eight consecutive animal passages. All of the inoculated animals died of typical thymic lymphoma within 70–85 days after inoculation of the test filtrate.

Lymphoma cell lines were established from the thymomas of 2 mice with lymphoma accelerated by neonatal AKR SL3 virus inoculation. These lines were designated "AKR SL3-A and AKR SL3-B." Filtrates from the AKR SL3-A line had a titer of 4.7×10^2 PFU/ml with the S^+L^- assay and were XC-positive (2.7×10^2 PFU/ml). They produced accelerated lymphoma in 9 of 9 mice within 77–95 days after inoculation. The AKR SL3-B line filtrate had a virus titer of 3.3×10^2 PFU/ml with the S^+L^- assay. It was XC-positive (titer, 20 PFU/ml). This supernatant produced lymphomas in 6 of 6 neonatally inoculated AKR mice at 86–99 days.

Studies With Cloned Cells From the AKR SL4 Line

Four clones were established from single cells from the AKR SL4 lymphoma cell line. These lines produce XC-negative, ecotropic lymphoma-accelerating virus. The results are presented in table 2 and clearly show that production of XC-negative viruses with lymphoma-accelerating properties was a characteristic of individual cells and their progeny when cloned from the parent cell line.

Tests of AKR SL4 Viruses for Leukemia-Inducing Properties in SJL Mice

When the AKR-derived G-MuLV is inoculated into newborn SJL mice, thymic lymphomas develop within 2–4 months (Hays EF: Unpublished observation). We wished to determine if the SL viruses that we had shown to be lymphoma accelerating in AKR mice would, like G-MuLV, be lymphoma inducing (i.e., induce thymic lymphoma), or if they had lymphoma-accelerating properties (i.e., accelerate the onset of the naturally occurring reticulum cell sarcoma in the SJL mice.

TABLE 1.—*Virus studies of cell supernatants from two cell lines*[a]

Cell line	Date	Titer on S^+L^-, PFU/ml	Lymphoma acceleration[b]
AKR SL3	11/79	1.4×10^3	4/4 (93–112)
	11/80	2.2×10^4	7/7 (87–90)
MAC 12	11/79	4.8×10^4	12/13 (71–120)
	11/80	2.2×10^6	7/7 (86–98)

[a] RT of these culture supernatants was strongly positive. Supernatants and cells were removed from the cell lines in growth phase. They were frozen and thawed, then centrifuged at 3,000×*g* for 10 min. The supernatant was then passed through a 0.45-µm filter and stored in aliquots at −70°C prior to inoculation into mice and prior to test in the S^+L^- assay.

[b] Number of thymic lymphomas at <150 days/number of mice inoculated as newborn (AKR). *Numbers in parentheses* are days after inoculation.

3	3.8	3.5×10^2	6/8 (77–91)
4	6.7	1.6×10^3	14/14 (67–88)

[a] The AKR SL4 line is a continuously replicating lymphoma cell line derived from an AKR spontaneous lymphoma. It produces XC^- ecotropic lymphoma-accelerating virus. Clones 1-4 were established from single cells and grown as the parent line with RPMI-1640 medium and 10% NCS. All assays were done on filtered (0.45 µm) supernatants from the cell lines. All cell clones produced XC^- viruses.

[b] Number of thymic lymphomas at 150 days/number of mice inoculated as newborn (ARK). *Numbers in parentheses* are days after inoculation.

A filtered (0.45 µm) supernatant from AKR SL4 cells was studied on two occasions in both neonatal AKR and SJL mice. The results of each study were identical. AKR SL4 cells produced a low-titer virus, which always accelerated thymic lymphoma in AKR mice and induced a morphologically identical disease in SJL mice (table 3). Cell-free filtrates prepared from the SJL-induced thymic lymphomas had lymphomagenic properties for SJL and AKR mice. In a second experiment, the use of littermate controls unambiguously demonstrated the lymphoma-inducing properties of the test filtrates in SJL mice (table 3).

Studies With Cloned Viruses From AKR SL3 Cell Line

Three virus clones were isolated by end-point dilution from NIH mouse embryo cells infected with virus from filtered supernatants of AKR SL3 cells. These viruses were studied for host range on NIH ME cells and MLC, for plaque formation with S^+L^- cells, and for syncytia formation with XC cells, as well as for leukemia acceleration in AKR mice and leukemia induction of SJL mice.

The data are presented in tables 4 and 5. They show that ecotropic viruses that are negative or positive with the XC

TABLE 3.—*Induction of thymic lymphoma in SJL/J mice by filtrates from AKR SL4 cells*[a]

[a] Supernatants prepared from AKR SL4 cells were filtered (0.45 µm) and stored in aliquots at −7°C until used. Experiments 1 and 2 were done 2 yr apart showing the stability of the lymphomagenic properties of the viruses produced by this in vitro cell line.

[b] Lymphoma acceleration–induction is expressed as number of thymic lymphomas at <150 days/number of mice inoculated as newborn. *Numbers in parentheses* are days after inoculation.

TABLE 4.—*Properties of cloned viruses from AKR SL3 cells*[a]

Clone	S^+L^- titer, PFU/ml	XC titer, PFU/ml	AKR lymphoma acceleration[b]	SJL lymphoma induction[b]	
				Injected	Littermate control
AKR SL3-3	5.2×10^4	5.5×10^4	11/11 (69–95)	11/13 (76–97)	0/5
AKR SL3-2	1.75×10^2	0	10/10 (77–145)	7/12 (210–297)	0/7
AKR SL3-1	1×10^2	5×10^2	5/10 (125–135)	3/7 (108, 119, 295)	0/9

[a] All cloned viruses were ecotropic. They were obtained from supernatants of NIH ME cells infected with the cloned isolates. Supernatants were prepared by trypsinizing the NIH ME cells, adding them to the culture fluid, freezing them, thawing them, and centrifuging them at 3,000×*g* for 10 min. The resulting supernatant was passed through a 0.45-μm filter and frozen in aliquots to use in the in vitro and in vivo assays.

[b] Number of thymic lymphomas/number of mice inoculated in the newborn period. *Numbers in parentheses* are days after inoculation.

assay and did not contain phenotypically mixed particles can be cloned from the AKR SL3 virus-infected NIH mouse embryo cells. Lymphoma-accelerating (AKR) and lymphoma-inducing (SJL) properties are found in both XC-positive and XC-negative clones. The longer latent periods and lower incidence of accelerated and induced lymphomas with AKR SL3-1 and SKR SL3-2 probably reflect the low titer of viruses used in these studies. The AKR SL3-3 clone also induced lymphoma in C3H/HeJ mice. Of 9 mice inoculated as newborns, 7 developed thymic lymphoma at 105–176 days.

Three additional virus clones (AKR SL3-SX4, AKR SL3-SX5, and AKR SL3-H55) were isolated from AKR SL3 supernatants. At least two of these stocks were composed of a mixture of XC-positive ecotropic and phenotypically mixed viruses (table 5). All three stocks were lymphoma accelerating and induced thymic lymphoma in SJL mice. Thus six successive isolates of virus from AKR SL3 lymphoma cells done on mouse embryo fibroblasts were oncogenic.

Phenotypically Mixed Viruses

Many of the cloned SL stocks were assayed for the presence of xenotropic (ecotropic)[7] or dual-host range (ecotropic) viruses. Phenotypically mixed virus particles were found in several, but not all, virus stocks. AKR SL3-2, AKR SL3-3, and G-MuLV were all exclusively ecotropic leukemia viruses (table 5). The composition of three of the other virus stocks isolated from AKR SL3 cells was a combination of phenotypically mixed and ecotropic viruses. In the one case studied so far, the unmasked virus found in the AKR SL3-SX5 stock appears to have a dual-host range. However, this virus must be cloned to verify this.

We are in the process of determining what contribution, if any, the phenotypically mixed particles make to lymphomagenesis. As shown in table 6 and discussed below, only ecotropic virus was detected in accelerated AKR lymphomas following AKR SL3-SX4, AKR SL3-SX5, and AKR SL3-H55 virus inoculation. All lymphoma cells and cell lines were assayed by cocultivation with MLC and NIH ME cells.

TABLE 5.—*Assay for phenotypically mixed particles in virus stocks*[a]

[a] Method of assay is described in "Materials and Methods."

[b] –=no virus replicates; ±=very low-titer virus (10^1 PFU/ml); +=moderate titer virus (10^2, 10^3 PFU/ml); ++=high-titer virus (10^4, 10^5 PFU/ml).

[c] As reported by Hartley and Rowe (*9*), SC-1 cells are weakly susceptible to AKR xenotropic virus infection. However, this virus can easily be distinguished from dual-host range viruses, which are able to replicate equally well on SC-1 and MLC.

Recovery of Viruses From Cell Lines and Spontaneous and Virus-Accelerated Lymphomas

We had previously reported that most cell lines established from AKR spontaneous lymphoma produced only ecotropic XC-negative viruses (*3*). In the following experiment, cell lines and lymphomas were tested by cocultivation infection with the use of untreated lymphoma cells. The results are presented in table 6. All cell lines that were derived from spontaneous lymphomas and two cell clones from line AKR SL1 produced a mixture of viruses able to replicate in MLC and mouse cells. This was also the case when cells from thymomas of 2 spontaneously occurring AKR lymphomas were tested directly.

In contrast, host range studies of viruses produced from the cell lines established from lymphoma accelerated by SL3 viruses, SL3-A, and SL3-B showed only viruses with ecotropic properties. A cell line established from a thymic lymphoma accelerated by G-MuLV that had been maintained in vitro for 3 years (AKR A2) was also found to produce only ecotropic viruses when tested as indicated above. Similar results were obtained with fresh cells prepared from 5 lymphomas accelerated by the cloned AKR SL3 isolates AKR SL3-3, AKR SL3-SX4, AKR SL3-SX5, and AKR SL3-H55, and 3 C3H lymphomas accelerated by SL3-3. In the one case studied so far, AKR SL3 xenotropic virus was not oncogenic in AKR or SJL mice. Thus the

[a] Cell lines are lymphoma cells originally derived from spontaneous or virus-accelerated lymphomas and maintained as continuous in vitro suspension cultures. Notations *in parentheses* after the accelerated lymphomas are the virus stocks used to accelerate the lymphoma. Cells from spontaneous lymphomas 1 and 2 and accelerated lymphomas A50-1, A51-2, A53-3, A53-4, A54-4, and C3H lymphomas 1, 2, and 3 were obtained from the thymic tumors of animals with generalized lymphoma and cocultivated directly with NIH ME cells or MLC.

spontaneous lymphomas or cell lines established from them produced a mixture of virus able to replicate in both mouse cells and MLC, whereas cells and cell lines from lymphomas accelerated by AKR-derived ecotropic viruses produced only ecotropic viruses.

DISCUSSION

These experiments show that AKR spontaneous lymphomas maintained as continuous lines in vitro produce ecotropic viruses that we have called SL viruses, which not only accelerate thymic lymphomas in AKR mice but also induce thymic lymphomas in SJL/J, C3H/HeJ, and CBA/H mice (Hays EF: Unpublished observation). These findings, as well as the published observations from Pedersen et al. (*6*), which show leukemia induction in C3H$_f$/Bi mice by the cloned AKR SL3 viruses, conclusively prove the oncogenicity of this virus class. The lymphomagenic SL viruses, described in this report, are produced by lymphoma cells from in vitro lines over long periods of time. They are also continuously produced by an in vivo transformed bone marrow stromal cell line from an AKR mouse neonatally inoculated with AKR SL3 virus. We point out that the lymphoma-accelerating properties of the SL viruses persist with in vivo passage and that XC-positive SL viruses are found in lymphoma cells established as in vitro lines from tumors accelerated by SL viruses. We present evidence to show that the ecotropic and lymphomagenic properties are found in cloned isolates of SL viruses. Further evidence for the lymphomagenicity of the AKR SL3 virus genome is provided by the fact that molecularly cloned SL3-3 virus DNA has been found to be leukemogenic for C3H$_f$/Bi mice (Haseltine W: Unpublished observation). We have also shown that the lymphomas accelerated by the cloned SL viruses produce only ecotropic virus, suggesting that these lymphomas produce the virus repsonsible for their development. It is also noteworthy, as we have shown in this report, that SL virus-induced thymic lymphoma of SJL mice contains virus that can again accelerate AKR lymphoma and induce disease in the SJL mice. This is also true for MCF viruses inasmuch as MCF virus was found in an AKR lymphoma accelerated by the dual-host range virus MCF-247 (*10*).

The results of the experiments presented in this report are compatible with the idea that AKR mice develop thymic lymphomas when viruses that appear during aging interact in an as yet unknown way with progenitors of thymic lymphocytes. These viruses are usually ecotropic and always induce thymic lymphomas. The G-MuLV (*11*), which was derived from an AKR spontaneous lymphoma, is ecotropic as determined by cocultivation infection (table 5). It accelerates lymphoma in AKR mice and induces lymphoma in SJL mice as well as in mouse strains with a low incidence of spontaneous lymphoma (*11*).

Viruses with dual-host range, i.e., properties of growth on both mouse cells MLC, can also be isolated from age AKR thymocytes and AKR lymphoma cells when they are cultivated initially on MLC (*12*). Cloned isolates of some of these viruses have been shown to accelerate lymphomas in AKR mice (*3, 13, 14*); they also induce a lymphoma in other strains (*15*). In our laboratory, we have tested two of these polytropic viruses, MCF-247 and MCF-13. Both of these viruses accelerate AKR lymphoma, and MCF-247 induces lymphoma in SJL mice (Hays EF: Unpublished observation).

The inability to form syncytia on XC cells is a characteristic of ecotropic SL virus, G-MuLV (derived from cell lines established from G-MuLV-accelerated lymphomas), and MCF viruses. However, some of the SL viruses "convert" to XC-positive on mouse embryo cells (*4*) and, as noted in the present study, both of the cell lines established from a lymphoma accelerated by AKR SL3 virus (SL3-A and SL3-B) produce XC-positive lymphoma-accelerating virus. The property of leukemia acceleration–induction is therefore associated with three classes of viruses: 1) SL XC$^-$ (AKR SL3, AKR SL4, AKR SL4 cell clones 1–4, G-MuLV from AKR A2 cell line, and cloned virus AKR SL3-2); 2) SL XC$^+$, (AKR SL3-A and -B and cloned viruses AKR SL3-1, AKR SL3-3, and possibly AKR SL3-SX4, AKR SL3-SX5, and AKR SL3-H55; and 3) MCF XC$^-$ (MCF-247 and MCF-13). Thus the phenotypic characteristics of host range and XC syncytia-forming ability are not necessarily related to lymphomagenic properties of these AKR-derived viruses. This fact is corroborated by the finding of SL XC⁻ and MCF XC⁻ viruses that are not associated with leukemogenesis (*3, 13, 15*). Additional recent confirmation of the uniqueness of the SL virus is provided by studies of the viral genome by oligonucleotide mapping. These studies have shown the AKR SL3 viruses (cloned and uncloned) and AKR SL4 virus to be a distinct class with variant 3′ region. Their oligonucleotide map is different from that of the MCF viruses (*16*).

Published studies show that viruses able to induce a T-cell lymphoma in mice are recombinants of two endogenous viruses carried in the germ line plus additional cellular sequences (*6, 17–20*). Although the MCF viruses are the most widely studied of these viruses, this class is clearly not the exclusive domain of lymphomagenic viruses. Undoubtedly, there are specific nucleotide sequences necessary for oncogenic properties, but these are separate from those responsible for host range and XC fusion. In fact, Pedersen et al. (*6*) have evidence that these oncogenic sequences are not present in the *env* gene but are located much closer to the 3′ end of the viral genome.

It is not clear whether phenotypically mixed viruses are merely annoying byproducts of viral interactions, which only confuse the situation, or whether their formation is an important part of lymphomagenesis. The experiments described here would suggest that the first explanation is correct. In cases in which MCF viruses are involved, however, pseudotype formation may be important because MCF viruses do not replicate well in all mouse cells.

The sensitive method of cocultivation-infection with untreated cells was able to detect xenotropic and/or dual-host range viruses in all of the spontaneous lymphoma cells and lines when supernatants from these lines were negative for virus replicating on MLC. However, even with cocultivation, xenotropic virus and/or dual-host range virus was not produced by the accelerated lymphomas. These lymphomas occur in young mice, and xenotropic virus does not appear in the AKR mouse thymus at 8–12 weeks of age (*21, 22*). From these studies, we conclude that thymic lymphomagenesis is not dependent on host xenotropic virus expression after introduction of an ecotropic SL virus.

Prostaglandin-Induced Differentiation or Dimethyl Sulfoxide-Induced Differentiation: Reduction of the Neoplastic Potential of a Rat Mammary Tumor Stem-Cell Line[1, 2]

Philip S. Rudland,[3] Anna Twiston Davies,[3] *and* Michael J. Warburton[3, 4]

ABSTRACT—Differentiation of the rat mammary stem cell line Rama 25 to alveolar-like cells was monitored both by the increased production of domes (hemispherical blisters) in the cell monolayer and by immunoreactive casein in the tissue culture medium. In addition to the synthetic inducer dimethyl sulfoxide (DMSO), prostaglandin (PG)E_1, and to a lesser extent PGE_2 and $PGF_{2\alpha}$ (concentration range, 50–500 ng/ml) in the presence of the hormones prolactin (Pr), hydrocortisone (HC), insulin (I), and 17β-estradiol (E) also accelerated this step. A combination of PGE_1, HC, and I was active in promoting doming even in serum-free medium, whereas PGE_1, all four hormones, and serum were required for maximum production of immunoreactive casein. The DNA synthetic rate was concomitantly reduced during this differentiation step. Rama 25 readily formed tumors in young, female *nu/nu* mice. When Rama 25 cells were treated with PGE_1 or DMSO and the four hormones yielding the droplet and doming cultures, subsequent injection of these cultures into *nu/nu* mice led to a reduced incidence of tumors compared with injections of untreated cultures. Variant cell lines were selected from a subclone of elongated, myoepithelial-like Rama 29 cells that had been derived from Rama 25 and directly from Rama 25 itself. The former were elongated cells and termed "Rama 521," and the latter were cuboidal epithelial cells and termed "Rama 259." Both these variants were resistant to the actions of PGE_1 or DMSO and to the mammotropic hormones in accelerating the rate of formation of domes, producing immunoreactive casein, in substantially reducing the DNA synthetic rate, and in reducing the incidence of tumors when injected into *nu/nu* mice. We have therefore shown that conversion of Rama 25 stem cells to alveolar-like cells in culture is specifically accompanied by a reduction in their neoplastic potential in *nu/nu* mice.—JNCI 1982; 69:1083–1093.

Three main types of epithelial cells are distinguishable in rat mammary glands: those lining the alveoli, those lining the ducts, and the myoepithelial cells (*1*). These three cell types can also be recognized in carcinogen-induced tumors (*2*). Whether these three cell types, and in particular the ductal and alveolar cells, represent discrete cell types or the same cell within different glandular compartments is uncertain [*see* (*3*)]. For clarification of this point, a clonal cuboidal epithelial stem cell line, Rama 25, has been isolated from a DMBA-induced rat mammary adenocarcinoma (*3*). This cell line can differentiate in culture into either droplet and doming (alveolar-like) or elongated (myoepithelial-like) cells (*4, 5*). One such elongated cell line is Rama 29. Differentiation to alveolar-like cells can be followed by the appearance of two markers, the ability of the monolayer cultures to form hemispherical blisters or domes (*6*), and the secretion of immunoreactive casein into the culture medium. This differentiation process is directly accelerated by a combination of DMSO, an agent that induces differentiation in Friend erythroleukemia cells(*7, 8*), together with the mammotropic hormones Pr, HC, and I. This stem cell line, Rama 25, also readily forms tumors in immunodeficient *nu/nu* mice (*3, 9*), and hence this cell line can be used to test whether alveolar-like cells formed from it have an altered tumor-forming ability when injected into *nu/nu* mice.

DMSO and other Friend cell inducers, however, are synthetic compounds that must be used at relatively high concentrations to produce their differentiation-inducing effects. Thus the physiologic relevance of these effects may be open to question. We have therefore sought to replace the artificial inducers by more naturally occurring compounds. One such group, the PG, can exert many diverse hormone-like actions in vivo, including luteinic and renal antihypertensive effects (*10, 11*). However, whether the PG act directly on the target tissue or work by stimulating the production of secondary hormone agents is open to doubt (*10, 11*). The PG also promote erythroid progenitors to differentiate and form erythroid colonies in vitro (*12*), and there is an inverse correlation between the spontaneous differentiation rates in vitro of different Friend murine erythroleukemia cell lines and their ability to form tumors in syngeneic mice (*13*). We have therefore investigated the ability of the PG to replace DMSO in inducing the differentiation of our stem cell line to alveolar-like cells in culture, and we relate this change to the concomitant change in our stem cell line's neoplastic potential when injected into *nu/nu* mice.

MATERIALS AND METHODS

Routine tissue culture.—The isolation of the rat mammary cloned cell lines Rama 25 and Rama 29 has been described previously (*3*). Rama 25 and Rama 29 were routinely grown

[4] We thank Mrs. Ruth Thompson, Mrs. Sharon Ferns, Miss Linda Lovell, Mr. Geoffrey Webby, and Miss Christine Hughes for expert technical assistance; Prof. A. J. Davies, Institute of Cancer Research, London, England, for supplying the nude mice; and Dr. J. Pike, The Upjohn Co., Kalamazoo, Mich., for gifts of PGE_1, PGE_2, and $PGF_{2\alpha}$.

in DMEM containing 10% (vol/vol) FCS, 50 ng HC/ml, and 50 ng I/ml (this formulation constituted RM) in 9-cm petri dishes (A/S Nunc, Roskilde, Denmark) at 37°C in an atmosphere of 10% (vol/vol) CO_2. The cell lines were transferred subconfluently at a dilution factor of 1:8 by detachment with trypsin-EDTA, as previously described (*3*). Experiments were done in which initial stocks of Rama 25-25 and Rama 29-31 were used with not more than two and six subsequent transfers, respectively. Rama 25-25 cells contained less than 1% contamination of elongated cells, as determined in a single cell cloning assay. CLM was prepared from 50% CM plus 40% DMEM plus 10% fresh FCS, 50 ng HC/ml, and 50 ng I/ml. CM consisted of Ham's medium F12 that contained 5% FCS and was adjusted to 3.7 mg/ml $NaHCO_3$ and which was then exposed for 1 day to 2×10^6 Rama 29 cells/10 ml medium (*3, 5*). Ham's medium F12 (catalog #176) was purchased from Gibco Europe Ltd. (Paisley, Scotland).

Living cells were photographed by a Zeiss ICM 405 automatic inverted microscope fitted with phase-contrast optics. Photography was done on Ilford Pan F film, and a green filter was used.

Production of doming cultures.—Because the higher concentrations of Ca^{2+} and Mg^{2+} in DMEM could interfere in the casein assay, DMEM was replaced by Ham's medium F12 before the experiment commenced. Thus Rama cell lines were plated at 10^6 cells/5-cm petri dish and grown to confluence in 5 ml of RM. Two protocols were subsequently used. In protocol I, the medium was changed on day 5 to 5 ml of Ham's medium F12, 10% FCS, 50 ng I/ml, 50 ng HC/ml, 500 ng Pr/ml, and an extra 2.1 mg $NaHCO_3$/ml. On day 7, the medium was removed and replaced with 5 ml of fresh Ham's medium F12 containing HC, extra $NaHCO_3$, 500 ng I/ml, 5 μg Pr/ml, 2.7 ng E/ml, and various additives. In protocol II, the medium was changed on day 4 to 5 ml of RM supplemented with 500 ng Pr/ml and 2.7 ng E/ml; then on day 7, the RM was changed to the same medium as that used on day 7 in protocol I, but no additives were used. Finally, on day 9, the medium was again changed to that of day 7, but at this time the various additives were included. For experiments in serum-free medium, the medium of protocol II was removed on day 7 and the monolayer cultures were washed twice with Ca^{2+}- and Mg^{2+}-free PBS; then, Ham's medium F12 containing 2.1 mg $NaHCO_3$/ml was added to each dish. Finally, on day 9, Ham's medium F12 with extra $NaHCO_3$ and the hormones HC, I, Pr, and E were added as before in protocol II together with various additives as indicated. The number of domes per 14-mm^2 field was measured in an Olympus CK inverted microscope (40 ×), usually after 24 or 48 hours. All results are the average of two dishes in which four fields/dish were counted.

Measurement of casein production and DNA synthesis.—The amount of casein released by cell lines into the medium was measured by a radioimmunoassay (*14–16*). Under the conditions of the experiment with Rama cell lines, the cellular protein content of confluent cell monolayers was approximately 0.5 mg for each 5-cm petri dish. Hence the amount of casein secreted is expressed per dish. Casein remaining within the cells was less than 10% of the casein secreted into the medium (*4*). The material being precipitated in the radioimmunoassay was identified as casein as previously reported (*14, 15*).

DNA synthesis measurements were done by radioactively labeling the cultures with 3 μCi $[^3H]$dThd/ml at 1 μM for the stated time and then by processing the cultures for autoradiography as previously described (*17*). The fraction of cells with radioactively labeled nuclei was recorded from two dishes; 4 fields of about 200 cells/dish were counted.

Induction of tumors in nude mice.—Cultured cells were grown as described in protocol II, in which 600-ml flasks (Falcon Plastics, Oxnard, Calif.) containing 50 ml of medium were used. After 48 hours of exposure to Ham's medium F12, 10% FCS, 0.5 μg I/ml, 50 ng HC/ml, 2.1 mg $NaHCO_3$/ml, and various additives, the medium was removed, the cell monolayer was washed twice with PBS, incubated for 30 minutes at 37°C with 0.5 mM EDTA-disodium salt in PBS, and then removed by digestion with trypsin-EDTA solutions at 37°C, as described earlier. Cells were collected in ice-cold PBS supplemented with 10% FCS and were centrifuged at $200\times g$ for 5 minutes. (One flask yielded $\approx1.5\times10^7$ cells.) The cells were then resuspended in ice-cold Ca^{2+}- and Mg^{2+}-free PBS and centrifuged four more times, by which the FCS was removed. More than 95% of the cells excluded trypan blue after this procedure. The cells were finally resuspended at 10^7 cells/ml in the PBS, and 0.2 ml of this suspension (2×10^6 cells) was injected through the skin into the right inguinal mammary gland of 6-week-old female C57BL *nu/nu* mice [(*18*), Institute of Cancer Research, London, England]. Tumors were sized by measurement of two diameters at right angles; this procedure was repeated at about weekly intervals, and the mean diameters were recorded. Animals were usually killed after a further 6 weeks when the tumors were removed, sized, and fixed in Formol-saline for histologic examination. The right inguinal regions of mice without tumors were also dissected, and any small lumps present were subjected to histologic examination. Histologic sections were stained with H & E, mounted, and then photographed on a Reichert Polyvar automatic microscope fitted with Ilford Pan F film and a blue-green filter.

RESULTS

Isolation of DMSO-Resistant Cell Variants

Variant cell lines were isolated either from Rama 29 or from Rama 25 (fig. 1A, text-fig. 1). Isolates from Rama 29 were obtained by passage of Rama 29-32 eight times at high cell densities; then the cultures were plated sparsely and spindly, crisscross cells (frequency <1/1,000) were picked by means of a ring clone (*3, 4*). These variant cells were grown up and were subsequently single-cell cloned (*3*) (cloning efficiency, 75%). One such line was called "Rama 521" (fig. 1B), and cell stocks from it were frozen at passage 43. The variants from Rama 25 were obtained by growing Rama 25-25 for a further six passages in RM containing 1.8% (vol/vol) DMSO. Cultures were then plated sparsely, and a ring clone of cuboidal epithelial cells was picked and grown in CLM containing 1.8% DMSO. This ring clone was single-cell cloned in CLM containing 1.8% DMSO (cloning efficiency, cuboidal cells: 10%; elongated cells: 4%). Thereafter, cultures were initiated in RM without DMSO. All cuboidal epithelial cell lines so produced (Rama 250–Rama 259) were relatively resistant to the effects of DMSO in enhancing the rate of dome formation in confluent cultures, although the cell lines still yielded elongated cells and droplet cells–doming cultures without DMSO in the same frequency range as that of Rama 25 (table 1). The most resistant to DMSO was Rama 259, which was selected for subsequent use, and cell stocks were frozen at passage 37 (fig. 1C). Cuboidal epithelial cell lines which were cloned from Rama 25-25 in the absence of DMSO (Rama 25-Cl.37 and Cl.38) converted to droplet cells (fig. 1d) and domes at higher rates with DMSO (table 1).

PG and Differentiation of Rama Cell Lines in Culture

Confluent 7-day cultures of Rama 25 were initiated according to protocol I ("Materials and Methods"). Increasing concentrations of PGE_1 (50–500 ng/ml), when added to such cultures with fresh 10% FCS and the hormones Pr, HC, E, and I, increased the rate of formation of domes (text-fig. 2). The kinetics showed two distinct phases. Initially, there was a lag phase of 6–8 hours, the duration of which was independent of the concentration of PGE_1 added. Thereafter, there was an abrupt change to a new rate of formation of domes; the new rate was dependent on the concentration of PGE_1 up to a maximum of about 500 ng/ml (text-fig. 2). Above this concentration the rate was relatively independent of the concentration of PGE_1; this observation was true up to 5 μg PGE_1/ml (text-fig. 3). After about 2 days' exposure to the higher concentrations of PGE_1 (≥500 ng/ml), the numbers of domes per field also started to decline (text-fig. 2). By comparison, the maximum effect with the optimum concentrations of DMSO (1.8%) was observed after 24 rather than after 48 hours and was roughly double (30 domes/field) than with the optimum concentration of PGE_1 (15 domes/field).

However, if the cultures were maintained at confluence for a further 2 days with fresh serum and hormones before the inducers were added (protocol II), both the basal and PGE_1-stimulated numbers of domes per microscopic field were increased, but those with DMSO remained unchanged. The effect with 500 ng PGE_1/ml was then close to that observed with 1.8% DMSO after 48 hours (table 2). PGE_2 and $PGF_{2\alpha}$ were both about half as effective as PGE_1 in stimulating doming when they were added to 9-day cultures of Rama 25 (table 2). PGE_1 with the four hormones and FCS caused maximum production of domes and immuno-

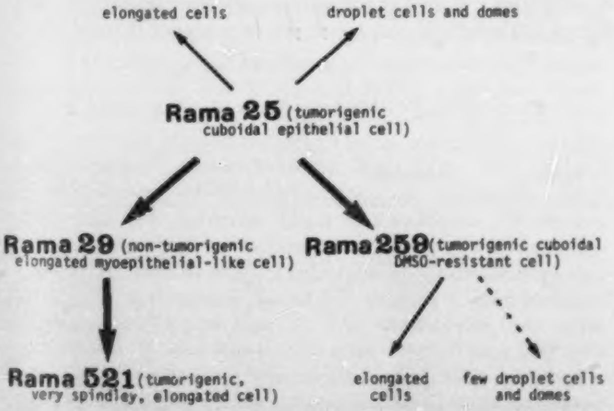
[a] Cultures were plated and grown as described in protocol II ("Materials and Methods"), and the No. of domes per 14-mm^2 microscopic field was estimated.

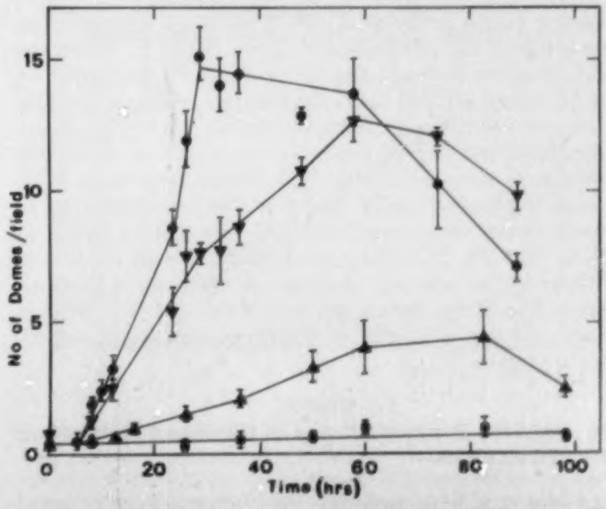
[b] Cultures were plated at 2,000 cells/9-cm dish, and the fraction as the percent of colonies containing elongated cells was scored after 1 wk.

[c] Those estimations that were recorded at 5 days are marked with an *asterisk*. CD=cell detachment; —=not done.

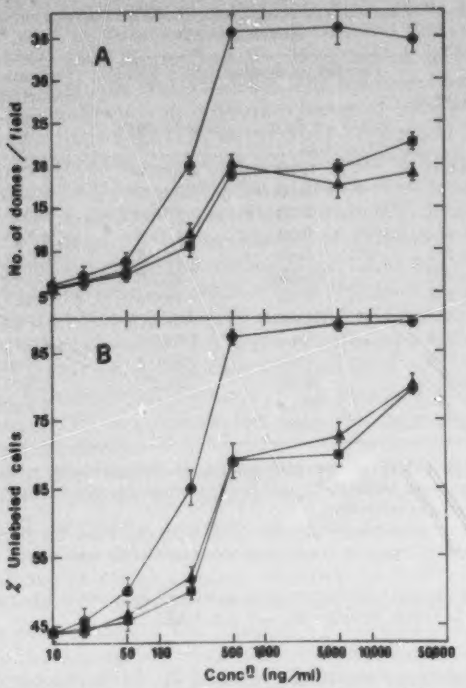


elongated cells
droplet cells and domes
Rama 25 (tumorigenic cuboidal epithelial cell)
Rama 29 (non-tumorigenic elongated myoepithelial-like cell)
Rama 259 (tumorigenic cuboidal DMSO-resistant cell)
Rama 521 (tumorigenic, very spindley, elongated cell)
elongated cells
few droplet cells and domes

TEXT-FIGURE 1.—Summary of the isolation of clonal cell lines and their cellular interconversions. Cell lines isolated from Rama 25 are shown by *thick arrows*; cellular interconversions of the individual cell lines are shown by *thin arrows*. *Hatched arrow* indicates that, although droplet cells and domes can be formed by Rama 259 cells, this process is not accelerated with DMSO, unlike the acceleration in Rama 25.



TEXT-FIGURE 2.—Kinetics of doming after additions of PGE_1. Rama 25 cultures were grown to confluence according to protocol I ("Materials and Methods"). On day 7, the medium was replaced with fresh medium containing HC, I, Pr, E, and 500 ng (●), 200 ng (▼), 50 ng (▲) PGE_1/ml. Fresh medium without PGE_1 but with the hormones was also added (■). The number of domes per 14-mm^2 field was observed with time.



TEXT-FIGURE 3.—Effects of varying concentrations of different PG on Rama 25 cells in culture. Cultures were grown for 9 days according to protocol II ("Materials and Methods"). Varying concentrations (Conc^{n}) (ng/ml) of the PG [PGE_1 (●), PGE_2 (▲), or $PGF_{2\alpha}$ (■)] were added with fresh medium containing HC, I, Pr, and E. In A) the number of domes per 14-mm^2 field formed after 48 hr ± SEM and in B) the percentage of cells remaining unlabeled after a 48-hr exposure to [^3H]dThd (percent unlabeled cells) ± SEM were recorded. Control cultures with no additions and no medium change yielded 89±1% unlabeled cells.

reactive casein, whereas removal of Pr or E resulted in inhibition of the production of casein (table 2). There was little effect on doming when the hormone I was omitted for 24 hours, but after 48 hours the numbers of domes per field were reduced (table 2). PGE_1 or DMSO and the hormones stimulated the rate of formation of domes in serum-free medium at about 50% (table 3) of the rate observed in FCS-containing medium (table 2). There was little production of casein under these conditions. The stimulatory effects of PGE_1 (figs. 2A, 2C), $PGF_{2\alpha}$, or DMSO on both markers of differentiation were not observed in confluent cultures of Rama 29 and the variant cell lines Rama 521 (fig. 2B) and Rama 259 (fig. 2D) (table 4) when they were grown according to protocol II.

PG and DNA Synthetic Rates of Confluent Cultures of Rama Cell Lines

Addition of fresh medium, 10% FCS, and Pr, HC, and I to confluent cultures of Rama 25 caused an acceleration of the rate of DNA synthesis as measured by the incorporation of [^3H]dThd into DNA or by the fraction of [^3H]dThd-labeled cells for fixed periods of 4 hours. The rate remained constant for 6–8 hours and then reached a maximum after 16–18 hours (*5*). When PGE_1 was added with FCS and hormones, the enhanced [^3H]dThd LI due to FCS and hormones alone was reduced after 48 hours (table 2). The optimum concentration (500 ng/ml) required to reduce the 48-hour [^3H]dThd LI was the same as that required for promoting the increase in doming rate as measured in parallel cultures (text-fig. 3). This reduction was about the same as that caused by 1.8% DMSO. PGE_2 and $PGF_{2\alpha}$ at 500 ng/ml were about half as effective as PGE_1 in reducing the [^3H]dThd LI. PGE_1 and DMSO also inhibited the [^3H]dThd LI in confluent cultures of Rama 25 maintained in serum- and hormone-free media. There was little effect for the first 5 hours, but thereafter this LI was greatly reduced (table 3). PGE_1, $PGF_{2\alpha}$, and DMSO failed to reduce the LI in confluent cultures of the variant cell lines Rama 259 and Rama 521 when grown according to protocol II (table 4).

TABLE 2.—*PG or DMSO and Rama 25 cells in serum-supplemented medium*

Additions[a]	No. of domes/field ± SEM[b,c]	Casein secreted, ng ± SEM[b]	Labeled nuclei, % ± SEM[b,d]
None	7±1	0.4±0.5	51±4
PGE_1	32±1	16.4±0.9	13±1
PGE_2	16±2	1.2±0.2	25±6
$PGF_{2\alpha}$	18±1	0.1±0.0	32±5
DMSO	34±1	23.2±0.1	14±5
PGE_1–HC	17±2	0.0±0.4	—
PGE_1–Pr	30±2	0.0±0.4	—
PGE_1–E	31±1	0.0±0.4	—
PGE_1–I	16±1	0.4±0.4	—
PGE_1–HC, I, and Pr	12±1	0.4±0.4	—
PGE_1–FCS	16±1	0.4±0.6	—

[a] Rama 25 cultures were plated and grown as described in protocol II ("Materials and Methods"). On day 9, the medium from the confluent cultures was changed when different agents were omitted and 500 ng PGE_1, PGE_2, or $PGF_{2\alpha}$/ml or 1.8% DMSO was added as indicated.

[b] The number of domes per 14-mm^2 microscopic field, the total immunoreactive casein released into the medium, and the fraction of cells in parallel cultures having [^3H]dThd-labeled nuclei in 48 hr were recorded.

[c] A combination of PGE_1 and DMSO yielded 61±8 domes/field.

[d] —=not done.

TABLE 3.—*PGE_1 or DMSO and Rama 25 cells in serum-free medium*

Time, hr	Additions[a]	No. of domes/ field ± SEM	Labeled nuclei, % ± SEM
5	None	0±0	5±1
	PGE_1	1±0	5±1
	DMSO	0±0	5±1
24	None	1±1	25±2
	PGE_1	12±2	18±4
	DMSO	14±2	10±3
48	None	1±1	44±2
	PGE_1	13±2	16±2
	DMSO	17±1	13±2

[a] Rama 25 cultures were grown as described in protocol II in serum-free medium. On day 9 the medium was replaced when the hormones HC, I, Pr, and E were added back (none) together with either 500 ng PGE_1/ml or 1.8% DMSO. The number of domes per 14-mm^2 field and the percentage of cells with [^3H]dThd-labeled nuclei were recorded after 5, 24, and 48 hr.

TABLE 4.—*PG or DMSO and the variant cell lines*[a]

Cell line[b]	Additions[c]	No. of domes/field ± SEM[d]	Casein secreted, ng ± SEM[d]	Labeled nuclei, % ± SEM[d]
Rama 259	None	0±0	0.0±0.02	53±4
	PGE$_1$	0±0	0.0±0.02	58±6
	PGF$_{2\alpha}$	0±0	0.0±0.01	52±5
	DMSO	0±0	0.0±0.01	44±5
Rama 521	None	0±0	0.0±0.01	33±2
	PGE$_1$	0±0	0.0±0.01	32±4
	PGF$_{2\alpha}$	0±0	0.0±0.04	29±3
	DMSO	0±0	0.0±0.01	20±1

[a] This experiment was done at the same time as that reported in table 2; PGE$_1$ and DMSO were seen to cause increased doming, increased casein secretion, and a reduced [^{3}H]dThd LI in Rama 25 cultures.

[b] Rama 259 and 521 cultures were grown according to protocol II ("Materials and Methods").

[c] On day 9, 500 ng PGE$_1$ or PGF$_{2\alpha}$/ml or 1.8% DMSO was added to the medium that contained FCS and HC, I, Pr, and E.

[d] After 48 hr the number of domes per 14-mm^2 field, the amount of casein secreted per dish, and the percentage of cells with [^{3}H]dThd-labeled nuclei in parallel cultures were recorded.

TABLE 5.—*PG or DMSO and the formation of tumors in* nu/nu *mice*

Cell line injected	Treatment in vitro[a]	No. of survivors	Tumor incidence, % ± SEM[b]
Rama 25	None	20	95±5
	Hormones	20	80±9
	PGE$_1$ − hormones	19	74±10
	PGE$_1$ + hormones	18	17±9
	PGE$_2$ + hormones	19	42±12
	PGF$_{2\alpha}$ + hormones	19	47±12
	DMSO − hormones	20	70±11
	DMSO + hormones	19	11±7
Rama 259	None	20	90±7
	PGE$_1$ + hormones	19	89±7
	DMSO + hormones	21	91±7
Rama 521	None	19	84±9
	PGE$_1$ + hormones	20	90±7
	DMSO + hormones	19	89±7

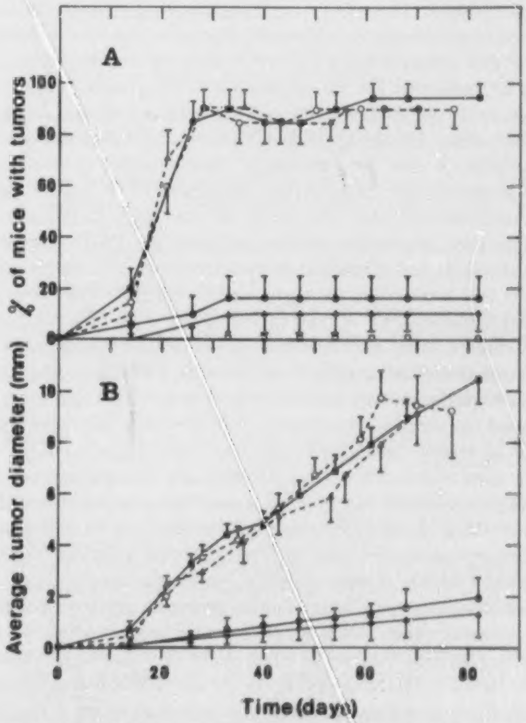
[a] Cultured cells that had been grown to confluence according to protocol II had their medium changed to that containing I and HC (none) or to that containing I, HC, Pr, and E (hormones) with 0.5 μg PG/ml or 1.8% DMSO as indicated. After 48 hr, cells were inoculated into *nu/nu* mice.

[b] Tumor incidence ± SEM was recorded after 6 wk.

Previous Exposure of Confluent Cultures to PG and DMSO and the Incidence of Cell-Induced Tumors in Nude Mice

Confluent cultures of Rama 25 were incubated with fresh medium, FCS, Pr, HC, I, E, and 500 ng PGE$_1$/ml or 1.8% DMSO (protocol II) and were then tested for neoplastic potential by injecting them into *nu/nu* mice. The number of tumors formed in 6 weeks was only 18% of the tumors obtained when cells were incubated without PGE$_1$ and hormones; this new incidence of tumors was approximately the same as the incidence with DMSO and hormones (table 5). This fractional decrease was maintained for animals kept as long as 3 months; both the fraction of mice bearing a tumor (text-fig. 4A) and the average size of the tumor (text-fig. 4B) showed a similar decrease. Previous treatment of Rama 25 cultures both with hormones and inducer (PGE$_1$ or DMSO) was required for maximum reduction in the yield of tumors (table 5). The optimum concentration of PGE$_1$ for reducing the incidence of tumors was 500 ng/ml (data not shown), and PGE$_2$ and PGF$_{2\alpha}$ were only about 60% as effective at this concentration (table 5). Rama 259 and Rama 521 formed tumors in *nu/nu* mice just as readily as did Rama 25 itself (table 5). Both PGE$_1$ and DMSO failed to reduce the incidence of tumors caused by either variant cell line (table 5). Rama 25 and Rama 259 formed histologically identical tumors in which two structures predominated: circular rings of cells typical of adenocarcinoma and spindle cell regions. Rama 521 formed tumors containing only spindle cells (fig. 3). The few tumors that arose from Rama 25 and those that arose from Rama 259 and Rama 521 that had all been treated with PGE$_1$ were histologically identical to those tumors obtained with untreated cultures. The normal elongated cell converts from Rama 25, including Rama 29, failed to induce tumors in the same period (Rudland PS, Gusterson B, Hughes C, Ormerod EJ, Warburton MJ: Manuscript in preparation).

To exclude the possibility that PGE$_1$ may be selectively



TEXT-FIGURE 4.—Kinetics of tumor formation in *nu/nu* mice. Cultured cells were inoculated into *nu/nu* mice and A) the percentage of mice with a tumor ± SEM and B) the average diameter of the tumor in mm ± SEM were followed with time in days. Cell lines Rama 25 (—, ●, ▲, ■) and Rama 259 (---, ○, △) were grown to confluence according to protocol II; then they were changed to medium containing I, HC, E, or Pr with either 1.8% DMSO (▲, △) or 0.5 μg/ml PGE$_1$ (●, ○) for 2 days before they were inserted into the mice. Rama 25 cultures with hormones but without inducers were also included (■), and injection of PBS alone is also shown (□).

killing Rama 25 but not Rama 259 or Rama 521 cultures, we performed the following controls: 1) The medium containing PGE_1 was removed, and the Rama 25 cell monolayers were washed twice with fresh medium containing serum and hormones; incubation was continued in this medium for a further 2 days until no domes or casein was detectable. When the resultant cells were injected into *nu/nu* mice, 85–95% of the mice developed tumors within 6 weeks. 2) Cell suspensions from PGE_1- and hormone-treated and untreated cultures were analyzed for viable cells by single cell cloning assays in fresh medium. In both treated and untreated cultures removed after extensive (10×) washings, the cloning efficiencies were the same. 3) Time-lapse cinematography of confluent cultures in which individual cells were continuously monitored showed that few cells (<5%) died and detached from the dish during the 48-hour exposure to PGE_1. Upon removal of PGE_1 and its replacement by fresh serum and medium (dedifferentiation), 25–30% of the cells had divided after 48 hours, and most (≥80%) went on to divide over 14 days.

DISCUSSION

The major area in which the effects of the PG on cell proliferation and differentiation have been investigated is in hematopoiesis. However, the PG effects are obscure because the early precursor or stem cells that give rise to the various blood cell lineages have not been isolated and therefore can only be recorded by the appearance of colonies of differentiated cells. In such mixed cell cultures of mouse hematopoietic cells, PG of type E (PGE_1 and PGE_2) are potent inhibitors of the production of neutrophilic granulocytes and mononuclear phagocytes, whereas PG of type F series are stimulatory, and the effect of the type E PG can be reversed by a specific growth factor (*12*). PGE_1, however, also stimulates erythroid colony formation (*12*). With established cell lines of certain precursor cells, the Friend erythroleukemia cells, PGA_1 can induce both their differentiation and reduce their proliferation rates (*19*). Moreover, treatment of these cells with 16,16-dimethyl-PGE_2 methyl ester in vitro before they were injected into DBA/2J mice increased the median survival time of the mice compared with mice in which untreated cells had been injected (*20*). We have now shown that near-physiologic concentrations of a natural hormonal agent, PGE_1, and the mammotropic hormones Pr, E, I, and HC can increase the rate at which a rat mammary stem cell line differentiates to alveolar-like cells in vitro, which makes possible molecular analysis of this differentiation step. There is also a corresponding reduction in the stem cells' DNA synthetic rate and in their tumor-forming abilities in *nu/nu* mice after this differentiation to alveolar-like cells. However, the exact relationship between these three processes is more complicated than if the relationship were simply linear. Tumorigenic cell variants that are resistant to the action of PGE_1 or DMSO in accelerating this differentiation step also show little or no reduction in their DNA synthetic rates or in their incidence of tumors in nude mice. However, the naturally occurring PG are not unique in their ability to stimulate mammary stem cells to differentiate because agents other than the synthetic DMSO behave similarly (*5*).

Whether the PG ever naturally induce differentiation and cause cessation of tumor growth in vivo is unclear. Nevertheless, PG are produced by many diverse cells including those from murine breast (*21*) and human breast (*22, 23*) tumors at concentrations sufficient to elicit the changes reported in our rat mammary system. Thus various PG could possibly influence the progression of a tumor not only by increasing (*24*) or decreasing (*25*) rates of cell replication of the mammary tumor cells themselves (*4*), but the various PG could also promote differentiation of the tumor stem cells to new cell types having an altered neoplastic potential. There is some evidence that PG may be involved in the development of certain animal tumors because the PG synthetase inhibitors aspirin and indomethacin inhibit osteolytic tumor deposits and hypercalcemia in rats with Walker carcinosarcomas (*26*), but in human breast disease there is no evidence that these inhibitors have any anticancer activity (*27*). It is also unlikely that systemic therapy in which more stable analogues of the PG are used would be considered appropriate in the treatment of disseminated breast disease in humans because the wide spectrum of PG activities in various organs and tissues would probably preclude their use. Moreover, our stem cell lines, which can be induced to differentiate, have been obtained from the early carcinogen-induced tumors of the rat, and these tumors pathologically resemble the benign breast lesions in humans rather than the truly malignant ductal adenocarcinomas (*28*). The malignant metastasizing lesions of the human breast usually contain cells with an apparently lower capability to differentiate, as judged from their histologic appearance (Gusterson B, Warburton MJ, Mitchell D, Rudland PS: Manuscript in preparation), and therefore it may be anticipated that the PG would be much less efficient in promoting their differentiation.

The mechanism of action of the PG on Rama 25 stem cells is unclear. Two extremes may be considered. Either the PG behave rather nonspecifically acting as lipophilic agents that are dissolvable to varying degrees in the plasma membrane (*29*) or they act through specific receptors (*30*). Either mechanism may then trigger changes in such phenomena as the plasma membrane enzyme systems, ion fluxes, or cyclic nucleotide concentrations as reported for $PGF_{2\alpha}$ and PGE_1 on cultured Swiss mouse 3T3 cells (*31*). The fact that diverse agents including DMSO in addition to the PG accelerate the rate of differentiation of Rama 25 stem cells without affecting the rate of the DMSO-resistant stem cell line Rama 259 may favor the nonspecific mechanism. However, because the effects of the PG can be achieved with near physiologic concentrations (*11, 32*), the fact that in freshly confluent cultures DMSO and PGE_1 are synergistic in promoting doming (table 2 legend) and the fact that another inducer, retinoic acid, is also synergistic with DMSO (*5*) suggest that the initial interaction of the PG with the cells may be different from the interaction of DMSO and the cells and that the initial reaction is more closely akin to that of the retinoids. Whatever the mechanism, the differentiation of Rama 25 cells is reversible within a few days of the removal of the PG from the culture medium. Thus differentiated Rama 25 cells when injected into nude mice probably fail to establish themselves within this time. If the differentiated Rama 25 cells survive for longer times, then presumably they would revert to the original stem cells and produce tumors at the original frequency.

Although the cause of breast cancer in humans is not known, epidemiologic surveys suggest that the hormone status of the female may influence the likelihood of this disease *(33)*. Among the protective factors are a first full-term pregnancy before 25 years of age and a late menarche. In the rat, the incidence of mammary tumors induced by chemical carcinogens *(34, 35)* can be reduced by previous exposure of the gland to those hormones that induce lobuloalveolar development *(36–38)*. The mammary adenocarcinomas arise predominantly from undifferentiated terminal end buds and terminal ducts of young, virgin rats *(39)*. With the onset of pregnancy and lactation, the terminal end buds and terminal ducts are gradually replaced by more differentiated structures, the alveolar buds and lobules. This developmental change is also accompanied by a reduction in the average proliferation rate of the cells within these structures *(40, 41)*. Of the three ultrastructurally distinct epithelial cell types described by Russo et al. *(42)* in the normal mammary gland, our stem cell line Rama 25 most closely resembles the intermediate type *(3)*. This intermediate type is also the predominant type found in DMBA-induced adenocarcinomas *(43)* and in terminal end buds (Russo J: Personal communication). We have also isolated from normal glands clonal cell lines that are similar to Rama 25 in their capability of converting to droplet and doming cultures with DMSO, PGE$_1$, and the mammotropic hormones *(44)*. Thus the protective effect of the mammotropic hormones and other agents in vivo against carcinogenic attack could be exerted by promoting differentiation of stem cells of the mammary gland into cells with lower proliferation rates. These differentiation-inducing agents could then act either at an early stage, converting normal stem cells to less susceptible differentiated cells, or at a later stage in the carcinogenic process, converting neoplastic stem cells to differentiated cells of lower neoplastic potential. Therefore, it may not be surprising that alterations in the environment of breast tissues that favor differentiation of quickly to slowly proliferating cells also confer a degree of protection against the formation of carcinomas in rats and humans *(33)*.

Immunotherapy by Intralesional Injection of BCG Cell Walls or Live BCG in Bovine Ocular Squamous Cell Carcinoma: A Preliminary Report[1,2]

Wim R. Klein,[3] **E. Joost Ruitenberg,**[4] **Peter A. Steerenberg,**[4,5] **Wim H. de Jong,**[4,6] **Wim Kruizinga,**[4] **Wim Misdorp,**[7] **Jürgen Bier,**[8] **Rudy H. Tiesjema,**[9] **Johan G. Kreeftenberg,**[10] **Jacob S. Teppema,**[4] *and* **Herbert J. Rapp**[11,12,13]

ABSTRACT—Cows of the Dutch Frisian and Maas-Rijn-IJssel breed with histologically confirmed ocular squamous cell carcinoma showed complete regression of the primary tumor in 70 or 60% of the cases after intralesional injection of a BCG cell wall or live BCG vaccine, respectively. Recurrence of the tumor was observed in 57% of the animals treated with BCG cell walls and in 25% of the animals treated with live BCG vaccine. Spontaneous regression was seen in 20% of the untreated cows. In a second control group, radical surgery, the most successful treatment for primary stage I tumors in humans, resulted in a 90% cure. Influence of immunotherapy on metastases could not yet be fully evaluated. White blood cell counts were not changed after therapy. It was not possible to link a favorable response to BCG therapy with the intensity of the delayed type hypersensitivity (DTH) reaction to purified protein derivative of mycobacteriae (PPD) or the formation of antibodies to BCG as determined by a micro-enzyme-linked immunosorbent assay. However, in animals that showed tumor regression, the DTH reaction to PPD had a tendency to persist for a longer period of time. It was concluded that 1) block resection was the best method of treatment for this tumor, 2) a single intralesional injection of a BCG cell wall vaccine was as effective as live BCG vaccine in the induction of complete regression of the primary tumor, 3) in this preliminary study BCG cell wall vaccine was less effective than live BCG vaccine in the prevention of recurrence, and 4) this naturally occurring tumor model is well suited for the study of the influence of BCG immunotherapy in a primary stage I tumor.—JNCI 1982; 69: 1095–1103.

BCG immunotherapy by intralesional injection has been shown to be successful in various chemically induced tumors in laboratory animals (*1–3*) as well as in naturally occurring tumors, such as canine venereal tumors (*4*), eye carcinomas in cattle (*5–7*), and sarcoids in horses (*8*).

Intralesional immunotherapy with BCG is based mainly on the results of studies in a syngeneic guinea pig model in which a 7-day-old intradermally growing hepatocellular carcinoma can be cured and micrometastases are eliminated (*9*). The regression of the primary tumor is followed by induction of specific immunity (*10*). In this model similar results were obtained with both live BCG (*1, 9*) and a non-living BCG cell wall preparation emulsified in mineral oil (*11*).

In studies with naturally occurring bovine ocular squamous cell carcinoma stage I, intralesional therapy with BCG cell walls also induces tumor regression in significant numbers of animals (*5–7*). Bovine ocular squamous cell carcinoma might be considered a relevant analogue for human carcinoma. The similarities observed for this type of human and bovine tumors are local destructive growth with bone involvement, which is seldom found in experimentally induced tumors, and spread of tumor cells into the draining lymph nodes, which in the advanced stage leads to generalized metastases preferentially in the lungs (*12*). Before the application of intralesional immunotherapy in human patients whose disease has not exceeded clinical stage I, further confirmation of the results with the bovine "cancer eye" could be of great importance.

In the present trial a comparison was made between immunotherapies with BCG cell walls and live BCG. The effect of immunotherapy was compared to an untreated control group and to a group that underwent radical surgery that is similar to the clinical situation in humans. During this trial the WBC counts, DTH reactions to PPD and to *Candida albicans* antigen, and the antibody production against BCG measured with ELISA were studied.

MATERIALS AND METHODS

Animals.—Fifty tumor-bearing cows of the Dutch Frisian and Maas-Rijn-IJssel dairy breed, 4–13 years of age, 400–600 kg body weight, were purchased during 3 years from farmers all over The Netherlands. During the experiment

[12] Deceased September 25, 1981.

[13] We thank Dr. J. S. M. M. van Dieten for conducting the anesthesia during surgery, Mr. F. A. Blok for photography of the tumors, Ms. M. I. J. A. Polak and Mr. J. Bolhuis for the white blood cell differentiation, and Mr. P. S. Ursem and Mr. H. Ettekoven for their excellent technical assistance.

the pregnant cows calved, lactated 8–10 months, and were not newly inseminated. Food was composed of grass, hay, and fattening fodder. Only animals in good physical health with tumor sizes between 1×1 and 3×4 cm were accepted. Animals with a positive Mantoux reaction to PPD and those suspected of metastases after palpation of the regional lymph nodes were not accepted in the trial.

Tumors.—The biology of the disease in Dutch dairy cattle is described elsewhere (*13*). The incidence of ocular squamous cell carcinoma in Dutch cattle is approximately 0.04% (own observations based on 35,000 examined animals), which is much lower than the incidence reported for the Hereford breed in various geographic areas (*12, 14–17*). For histologic confirmation of the carcinoma diagnosis, biopsy specimens were taken from the base of the tumor, fixed in 10% buffered Formalin, and embedded in Paraplast, and 5-μm sections were stained with hematoxylin and eosin. Biopsies and intralesional injections were performed under local anesthesia with 2% lidocaine. Forty-eight tumors were located on the membrana nictitans and 2 on the bulbus oculi. Not one of the membrane nictitans of the affected eyes of the 50 cows was pigmented.

BCG preparations.—The BCG cell wall preparation (lot #236) was obtained from the National Cancer Institute, Bethesda, Md. The final preparation contained 3 mg BCG cell walls/ml, 3% mineral oil (Drakeol 6VR), and 0.2% Tween-80 in physiologic saline solution and was emulsified by ultrasound. BCG lots #048 and #060 were produced in the National Institute of Public Health, Bilthoven, The Netherlands, as concentrated preparations, especially intended for experimental immunotherapy. The bacteria were grown in homogeneous culture under continuous stirring in Ungar medium with 0.05% Tween-80, harvested by centrifugation, resuspended in a stabilizing medium (containing 83 g Haemaccel/liter, 50 g D-glucose/liter, and 50 mg Tween-80/liter), filled in 2-ml portions, and lyophilized (*18*). One vial of BCG lot #048 contained 160×10^6 CP in 0.2 mg dry weight (800×10^6 CP/mg), and one vial in lot #060 contained 36×10^6 CP in 0.3 mg dry weight (120×10^6 CP/mg). Each vial was resuspended in 2 ml physiologic saline solution shortly before use. Depending on the size of the tumor, 2–8 ml vaccine was injected so the whole tumor would be saturated with vaccine.

Experimental design.—All accepted cows were randomly divided into 5 groups of 10 animals each: group 1, no treatment; group 2, intralesional application of BCG cell walls; group 3, intralesional application of live BCG 048; group 4, intralesional application of live BCG 060; group 5, radical surgery, i.e., extirpation of the primary tumor (enucleatio bulbi et adnexa), the subparotoid lymph node, the parotid gland, and the retropharyngeal lymph node (*19*).

Tumor measurements and photography were done before the animals entered the trial, then 1 week later, then monthly during the first 6 months, and then every 3 months for the next 1.5 years. Tumor size was expressed as the product of two perpendicular measurements.

Blood was collected before treatment, and at 1, 3, 6, 12, 18, and 24 months after treatment for WBC differentiation. Sera for measurement of antibodies to BCG were stored at −20°C.

The presence of DTH reactions was tested before treatment, and at 3, 6, 12, 18, and 24 months after treatment by intradermal injection of 1.0 mg PPD (Centraal Diergeneeskundig Instituut, Rotterdam, The Netherlands) in 0.1 ml phosphate-buffered saline, and 0.9 mg *Candida albicans* antigen in 0.1 ml phosphate-buffered saline. Skin swelling was measured at 20 minutes and at 72 hours.

To determine the production of antibodies to BCG, investigators developed a micro-ELISA (*20, 21*). In this assay, which will be reported in detail elsewhere (Klein WR et al.: Manuscript in preparation), twofold serum dilutions were incubated in microtiter plates coated with PPD antigen. To determine the antigen-antibody complex, we used rabbit antibovine IgG conjugated with horse-radish peroxidase, which was visualized after oxidation of 5-aminosalicylic acid and H_2O_2. We measured the reaction product with a multichannel spectrophotometer at 449 nm; the product was expressed as the extinction value. All serum samples taken at various time intervals were investigated on the same day. An animal was considered to react positively when the extinction value increased during the first 3 months by at least 0.200 in comparison with the pretreatment value at a serum dilution of 1:16.

During the experiment animals were under regular clinical observation. Animals were killed when the tumor showed progressive growth (exceeding ≈7×7 cm) or after 2 years of observation. Besides gross examination, draining lymph nodes, lungs, spleen, and liver were examined microscopically for the presence of metastases.

RESULTS

Effect of Treatment on Tumors

In the untreated group, 2 of 10 animals showed spontaneous regression of the primary tumor 1–6 months after randomization. Autopsies were performed on 9 animals: Four showed metastases in the regional lymph nodes, and 2 of these had metastases in the lungs.

Seven of the 10 cows treated by intralesional injection of BCG cell walls showed complete regression of the primary tumor between 2 and 7 months. In 4 of these animals the tumor recurred 1–13 months after regression. Autopsies on 10 animals revealed that 3 had metastases in the regional lymph nodes, and 2 of these 3 animals also had metastases in the lungs. Thus 30% of the animals treated with BCG cell walls were clinically and histologically tumor-free after the 2-year observation period (text-figs. 1, 2; table 1).

For the evaluation of the results with live BCG, the groups treated with BCG 048 and BCG 060 were pooled. Complete regression of the primary tumor was seen in 11 of 20 animals between 2 and 8 months; regression occurred in 1 at approximately 20 months. In 3 of these 12 animals the tumor recurred 4–16 months after regression. Autopsy was performed on 9 animals: 5 (55%) were clinically and histologically tumor-free. One of the 4 tumor-bearing animals (cow 142) showed metastases in the regional lymph node (text-fig. 1).

After radical surgery in 1 animal a tumor developed at the site of the subparotid lymph node. The animal was

Treatment	Regression of primary tumor[a]	Recurrence[b]	Intercurrently killed animals[c]	Metastases at autopsy[d]
BCG cell walls	7/10	4/7	5/10	3/10
BCG 048 + BCG 060	12/20	3/12	2/20	1/9
Surgery	—	0/10	1/10	1/5
Control	2/10	0/2	6/10	4/9

[a] No. of animals with tumor regression/No. of animals >3 mo in trial.

[b] No. of animals with tumor recurrence/No. of animals with previous tumor regression.

[c] No. of animals intercurrently killed/No. of animals >3 mo in trial.

[d] No. of animals with histologically confirmed metastases (regional lymph node and/or lungs)/No. of animals killed intercurrently or after 2 yr in trial.

killed at 7 months because of the growing tumor. Four animals killed at 24 months were free of metastases. The other 5 cows that underwent surgery are in good health and are clinically tumor-free.

Reactions After Injection of BCG Vaccines

During the 2–4 days after intralesional injection of BCG cell walls or live BCG, we observed a swelling of the tumor in all the animals. As shown in figure 2, in some animals enlargement of the tumor was observed before regression started. Ulceration was not more severe than it was before injection or in untreated animals. We have not seen clinical signs of discomfort or temperature elevations after injection of the BCG vaccines.

Monitoring During the Experiment

During the observation period no differences were observed in WBC counts between either the BCG-treated groups and the control group (table 2) or between animals with tumors in regression and those with progressively growing tumors (table 3).

All BCG-treated animals developed a palpable skin swelling after tuberculination except 1 animal treated with live BCG. The diameters of the skin reactions measured after 72 hours varied between 1 and 20 mm. In animals with tumor regression, the DTH reactions to PPD showed a tendency to persist for a longer period of time. Recurrence of the tumor had no effect on the persistence of the DTH reaction (table 4). *Candida albicans,* used in humans as a recall antigen, was applied as a non-BCG-related antigen. Seven of 50 animals showed weak positive (<5 mm) skin reactions. Five of these animals already showed positive reactions before the start of the experiment.

Besides the DTH reaction to PPD, antibody formation against BCG might also give an impression of the immune reactivity of the patient after BCG administration. The extinction values measured in the ELISA ranged from 0.200 to 1.000 before BCG treatment. These relatively high extinction values were probably caused by previous injections of PPD as part of a program to monitor the absence of bovine tuberculosis in The Netherlands. Fifteen of 24 animals treated with BCG antigen (live BCG or BCG cell walls) and 2 of 19 untreated animals developed positive reactions as shown by the ELISA (table 5). No correlation was found between tumor regression and the presence of BCG antibodies (table 6).

DISCUSSION

The incidence and localization of ocular squamous cell carcinoma (cancer eye) in Dutch cattle differ from those found in Hereford cattle from various geographic areas (*12, 14-17*). We found that the great majority of tumors were located on the membrana nictitans. Furthermore, the membrana nictitans of the affected eyes of all 50 cows in this trial were nonpigmented. Anderson et al. (*22, 23*) found that lack of pigmentation is a contributing factor in the development of eye carcinoma. The validity of this observation for the Dutch cattle will be further explored and included in the final evaluation of our experiment. No evidence was found that cancer eye occurred more frequently in one geographic area of The Netherlands than in another.

It was clearly shown for this tumor that (radical) surgery is the best method of treatment. In veterinary practice surgical treatment of this tumor is limited to the extirpation of the membrana nictitans or to enucleatio bulbi et adnexa. In this study, radical surgery was chosen *a*) to compare immunotherapy with the best possible surgical method of treatment and *b*) because radical surgery is the therapy of choice in humans. At this time it is not yet possible to evaluate the influence of surgery on metastasis.

Tumor sizes, ranging from 1 to 14 cm^2, had no correlation with the response to treatment. This observation was probably due to the dosage of vaccine used in this experiment; i.e., each tumor was saturated with vaccine. Furthermore, complete regression was obtained in 60–70% of the animals after one single intratumoral vaccine injection, regardless which of the vaccines was used. This fact is in keeping with the guinea pig model (*1, 9, 11*) in which similar results were obtained with the use of either vaccine.

With regard to recurrence rate, we found a difference between the animals treated with the live BCG vaccine (3/12) and the BCG cell wall vaccine (4/7). This difference could not be found in the guinea pig model, because in guinea pigs recurrences are prevented by the induction of a specific antitumor immunity. Recurrences in the live BCG-treated animals occurred only in those treated with BCG 060, which could be attributed to the lower number of CP administered. The maximum dose based on the number of CP for BCG 060 was approximately equal to the number of CP in the lowest dose for BCG 048. However, no differences were present between the two batches when dosage was expressed in milligrams. Another explanation for the difference in recurrence rates could be the higher rate of dead versus live bacteria in the BCG 060 batch that might interfere with the BCG adjuvant activity (*24, 25*). Whether this is also true for the induction of tumor immunity is not yet known.

In general, if an animal was responding to the BCG immunotherapy, complete tumor regression occurred during the 2d to 7th month. Thus a time limit might be set for response to treatment, after which repeated injections might be considered as it was reported for sarcoids in horses (*8*). This consideration is also applicable to the animals that show tumor recurrence. In the guinea pig model nonspecific stimulation by intralesional BCG injection induced specific immunity toward the tumor (*10*). Since tumor recurrence is not expected in immune animals, the relatively high recurrence rate in our cow study is probably due to the lack of a sufficient degree of specific immunity after regression of the primary tumor. When complete tumor regression occurs, tumor antigenic material becomes available for immunologic triggering. However, in some cases immunity is not induced as indicated by recurrence of the tumor. Presumably the adjuvant activity of a single intralesional BCG injection was not strong enough to induce specific immunity. Therefore, the effect of repeated BCG injections will be studied in a follow-up trial with regard to the induction of specific immunity.

From the spontaneous regression observed in 2 untreated animals, it seems likely that the bovine cancer eye has immunogenic properties that might be partially responsible for the relatively high response rate of 60–70% after BCG treatment. Also, the observed tumor regression obtained after a single im injection of a saline-phenol tumor extract (*28*) indicates immunogenicity and even the existence of common antigens for the bovine cancer eye (*26–29*).

In nonresponding animals (8/20 treated with live BCG and 3/10 treated with BCG cell walls) no indications were found for tumor growth enhancement; none of the tumors grew more rapidly than those of the control group (text-fig. 2).

Contradictory results were reported with regard to the correlation between Mantoux conversion and tumor regression (*30–32*). In our experiment DTH reactions to PPD could not be used as a prognostic value since all BCG-treated animals, except 1, showed a conversion. However, reactions to PPD showed a tendency to persist for a longer period of time in animals with a favorable response to immunotherapy. This might suggest that these animals were more immunocompetent at the time of therapy. With regard to *C. albicans*, our results clearly show that this antigen cannot be used as "recall" antigen in cows.

With regard to the results obtained in the ELISA, it should be kept in mind that besides a cellular reaction to PPD, the induction of antibodies as a reaction to PPD administration is also possible (*33*).

Block resection was found to be the best method of treatment for this tumor. However, our preliminary data show that the cow model is also suited for the study of the effect of BCG immunotherapy on a primary stage I tumor. Therefore, studies in the cow model might be used as a guide for the application of BCG immunotherapy in primary tumors in humans. We shall examine the effect of repeated BCG applications in a follow-up study.

Expression of Fibronectin and Laminin in the Rat Liver After Partial Hepatectomy, During Carcinogenesis, and in Transplantable Hepatocellular Carcinomas[1,2,3]

Stewart Sell[4,5] *and* Erkki Ruoslahti[6,7]

ABSTRACT—The distribution in the F344 rat liver of two extracellular matrix and basement membrane components, fibronectin and laminin, was studied by immunofluorescence. Fibronectin was found diffusely in normal liver lining the sinusoids and in connective tissue surrounding blood vessels and bile ducts; laminin was present predominantly in the basement membranes of blood vessels and bile ducts and was only inconsistently seen lining the sinusoids. After partial hepatectomy (PH), there was a transient decrease of fibronectin in the central and midzone sinusoidal hepatic areas. This decrease was most marked on day 3 after the PH. Carcinogens caused marked changes in the distribution of fibronectin. Large extracellular deposits of fibronectin were seen in areas of oval cell proliferation in livers of rats treated with *N*-2-fluorenylacetamide (2-FAA) while being fed a choline-deficient diet. In contrast, the nodules that developed in these livers were almost completely devoid of fibronectin staining. Neoplastic nodules produced in rats by cyclic feedings of 2-FAA or by injections of diethylnitrosamine also contained little or no fibronectin. Laminin staining did not change markedly during these treatments, but increased staining was seen associated with the newly formed ductlike structures and oval cells in livers of rats treated with carcinogens. Transplantable hepatomas varied in their fibronectin staining from fibronectin-negative hepatomas to ones with fibronectin staining within or around every tumor cell. Laminin was only found around the vascular structures within the tumors. The presence or absence of fibronectin in hepatomas did not show an obvious correlation to growth rate or metastatic potential of the tumors studied.—JNCI 1982; 69:1105–1114.

Fibronectin is a high-molecular-weight glycoprotein present in extracellular matrices, at cell surfaces, and in the blood (*1, 2*). Fibronectin binds to collagen (*3*) and mediates attachment of cells to collagen matrices and other surfaces in vitro (*4–8*). Fibronectin is frequently absent from the surface of malignantly transformed cells (*9–11*), and this absence is thought to play a role in the ability of such cells to grow invasively and to metastasize (*12, 13*).

Laminin is a newly discovered basement membrane glycoprotein (*14–16*) somewhat similar to fibronectin but biochemically and immunochemically distinct from it (*15–17*). Laminin also appears to be involved in cellular adhesion but with a specificity different from that of fibronectin (*18–20*).

Although fibronectin has been studied extensively, the function of this protein is not known. The liver provides a unique model for studies on a number of processes involving carcinogenesis and tissue remodeling inasmuch as this tissue has been extensively studied with regard to cellular events that take place during such processes (*21–24*). We thought that useful information about the role of fibronectin and laminin in normal and malignant tissues might be obtained by studying the distribution of these proteins during liver regeneration and carcinogenesis, and we thought that such information might also be useful for interpreting the cellular changes during these processes. We report here that marked changes take place in the distribution of fibronectin and lesser changes take place in the distribution in laminin during treatment of the liver with carcinogens. We also find that transplantable hepatomas may or may not contain fibronectin, suggesting that no simple relationship exists between the expression of fibronectin and the malignant phenotype.

MATERIALS AND METHODS

Tissue blocks from the livers of F344 rats that had been prepared as components of a number of earlier experiments (*25–32*) were fixed in a cold 95% ethanol–1% acetic acid solution and were dehydrated, cleared, and embedded in low-melting-point paraffin. Before fixation, the livers were perfused with saline via the inferior vena cava, which flushed out serum proteins (*33, 34*).

Rabbit antisera to rat fibronectin (*35*) and rat laminin (*18*) and affinity-purified antibodies from such sera (*35–37*) were used at 1:5–1:20 dilutions as the first antibodies.

Microscopic sections cut from the blocks were deparaffinized at 56°C, flooded with 1:5–1:20 dilutions of the first antiserum for 30 minutes at room temperature, were washed in cold phosphate-buffered saline, and were then labeled by addition of FITC-conjugated polyvalent goat IgG anti-rabbit Ig (*27*). Controls included unlabeled sections, normal serum dilutions as the first antibody, and the FITC-labeled goat IgG anti-rabbit Ig only.

Transplantable hepatocellular carcinomas 7777, 8994, and 9098 were obtained from Harold Morris of Howard University, Washington, D.C.; tumors FB 56, 252, and 311

ABBREVIATIONS USED: AFP=α-fetoprotein; CD=choline-deficient; DDPMN =*p,p'*-diaminodiphenylmethane; DENA=diethylnitrosamine; 2-FAA=*N*-2-fluorenylacetamide; FITC=fluorescein isothiocyanate; PH=partial hepatectomy.

were obtained from Frederick F. Becker, M. D. Anderson Hospital, Houston, Tex. These tumors were maintained by intramuscular passage in the thigh muscle as described (*32*).

RESULTS

Normal and regenerating liver.—In agreement with earlier results (*17, 18, 38*), the normal liver showed staining for fibronectin in the sinusoidal, blood vessel, and bile duct walls (fig. 1). Liver regeneration induced by PH caused a transient decrease in the fibronectin staining in the sinusoidal areas, particularly in the central and midzones. Livers were studied from animals in three different experiments, and in each experiment, a decrease of fibronectin staining was observed between days 2 and 4 after the PH. A representative series of such staining results is shown in figure 1. Laminin was found prominently surrounding the blood vessel and bile duct walls of the normal liver (fig. 2). Staining of laminin lining hepatic sinusoids was inconsistently seen, but it was faintly visible in some sections (fig. 2A). It was not possible to determine if a decrease or increase in laminin labeling occurred during regeneration.

Carcinogenesis.—Focal increases and decreases in the intensity of fibronectin and laminin labeling occurred after exposure to hepatocarcinogens (figs. 3, 4). A marked increase in fibronectin was associated with "oval cell" proliferation in the portal zone after the rats were fed 2-FAA in a CD diet (*29, 31, 39*). In the same tissue, a decrease in fibronectin labeling was seen in the central zone of the liver. Newly forming, ductlike structures were surrounded by intensive labeling for fibronectin. Labeling for laminin was increased in zones of oval cell proliferation (fig. 3D), resulting in delineation of cords and ductlike structures formed by oval cells. A variable distribution of fibronectin occurred after DENA exposure, with intensively labeled areas alternating with lightly labeled areas (fig. 4). A few liver cells also stained intensely for fibronectin. In hyperplastic (nonnodular) zones seen after cyclic feeding of 2-FAA, fibronectin labeling remained in the sinusoids (fig. 4E). In neoplastic nodules, intensity of labeling was weak (fig. 4F). Laminin was not seen in nodules.

Transplantable hepatocellular carcinomas.—Six transplantable hepatocellular carcinomas were examined for fibronectin and laminin (figs. 5, 6). Laminin was only found around vascular structures (figs. 5C, 5D). The distribution of fibronectin was different with each tumor. Three locations were apparent: around vascular structures and in connective tissue within the tumor, surrounding individual tumor cells, and within individual tumor cells. A summary of the labeling patterns and a comparison with other properties of the tumors are given in table 1. In 2 tumors, 7777 and 8994, abundant fibronectin was found to be associated with the surface of tumor cells. Each cell in these 2 tumors was surrounded by fibronectin (figs. 5, 6). Hepatoma 252 showed a similar staining pattern, but it was weaker (fig. 6). One tumor (311) had intracellular fibronectin fluorescence, but it had no cell surface-associated fibronectin (fig. 6). The distribution of fibronectin did not correlate with growth rate, because the 3 Morris hepatomas (7777, 8994, and 9098) are all fast growing (*30*) and the Becker hepatomas (311, 252, and FB 56) have similar growth rates (Becker F: Personal communication). In addition, no clear correlation with other properties was apparent. Although intense fibronectin labeling was generally seen in the high-AFP-producing tumors, not enough tumors were studied to permit a definite conclusion on the association of serum protein production and fibronectin.

TABLE 1.—*Correlation of properties of transplantable hepatocellular carcinomas*

Hepatoma	Serum AFP, μg/ml	Immunofluorescence labeling intensity[a]				
				Fibronectin		
		AFP	Albumin	Connective tissue	Extracellular	Intracellular
7777	5,000	++++	+++	+++	++	0
8994	3,000	+++	++++	+++	+++	0
FB 56	50	++	ND	++	0	0
311	13	++	+++	+	+	+++
252	<0.05	0	++	++	+	+
9098	<0.05	0	ND	0	0	0

[a] ND=not done; 0 to ++++ are relative degrees of immunofluorescence.

DISCUSSION

The main findings in this work are that the amount of fibronectin is reduced in regenerating liver, that areas of oval cell production show a marked increase in fibronectin in the associated connective tissue, that neoplastic nodules show a decrease of fibronectin, and that hepatomas have different patterns of fibronectin distribution. Under these experimental situations there is less change in laminin distribution, but laminin was increased in zones of oval cell proliferation.

Extracellular matrix degradation and synthesis are thought to be important in tissue remodeling. A decrease of fibronectin in the liver during the peak of the regenerative response is found in central and midzones of the liver. Increased amounts of laminin can be demonstrated in mouse liver during regeneration following carbon tetrachloride poisoning and also to some extent after PH (*18*). In the present work, we did not see an increase in laminin after PH. This may depend on a species difference or technical differences. Frozen sections were used for laminin evaluation in the previous work, and subtle differences in laminin concentration may have been more easily detected in the frozen sections than in the fixed tissues used in this study. In any event, these results show that changes in the extracellular matrix components accompany the regenerative process.

The relationship between the marked differences in tissue distribution of fibronectin and the cellular changes during carcinogenesis is intriguing, but it is not readily interpretable at the present time. The increase in fibronectin associated with oval cell proliferation is marked. In these areas, the degree of connective tissue involvement suggests deposition of collagen associated with oval cells. Early investigators interpreted this as a form of cirrhosis (*40*), but there is no evidence of progressive fibrosis as a result of the rat's being fed 2-FAA. In areas of disorientated liver cells that are not nodular, fibronectin is present in normal intensity, but fibronectin is markedly decreased in well-delineated neoplastic nodules. Thus nodules were found to resemble normal regenerating liver cells in that both of these areas had decreased amounts of fibronectin.

The normal distribution of laminin changed little during carcinogenesis, but the distribution during carcinogenesis did give us further insights. The ductlike structures that arise in association with oval cells as a result of carcinogen exposure (tubuloform degeneration) are faintly delineated by laminin, whereas normal bile ducts and the new ducts induced by feeding the noncarcinogenic agent DDPM, which produces marked bile duct proliferation, are highlighted by a much more visible surrounding layer of laminin (*41*). The ductlike structures that appear during carcinogenesis frequently contain AFP and/or albumin in contrast to normal and DDPM-induced ducts which do not (*27, 31*). These findings may be relevant to conclusions regarding the lineage of cellular changes in the liver. A number of investigators have suggested that oval cells are ductal in origin because the development of these ductlike structures is associated with oval cell proliferation (*22, 42*). However, these newly appearing ducts have properties more consistent with a hepatocyte origin than with a bile duct origin (*24*).

The distribution of fibronectin in transplantable hepatocellular carcinomas is quite variable and does not support a relationship between tumor growth and metastatic potential and contrarily fibronectin content. Although the number of tumors studied is not large enough for definitive conclusions, it appears that the presence of fibronectin shows some relationship to the ability of these tumors to produce other proteins (*43*). However, at this time, the fibronectin seen cannot be concluded to have actually arisen from tumor production. Fibronectin is present in the circulation at a relatively high concentration (300 μg/ml) (*44*). The origin of the circulating fibronectin is not known. It could be that it is made in the liver and that its synthesis is coupled to that of other serum proteins. Because it has been shown that circulating fibronectin can become insolubilized in tissues (*45*), the fibronectin surrounding the hepatoma cells could be of the type that arises from plasma fibronectin.

It is not possible at this time to differentiate plasma fibronectin from other fibronectins. A monoclonal antibody that reacts more strongly with fibronectin from fibroblasts than with fibronectin from plasma has been reported (*46*), but this difference is not large enough to allow distinction by immunofluorescence in tissue (Hynes RO: Personal communication).

Fibronectin is often absent from the surface of malignant cells cultured in vitro (*10*), and a correlation has been found between the amount of cell surface fibronectin expressed in vitro and the tumorigenic (*12*) and metastatic potential (*13*) of such cells. Relatively few studies have explored the expression of fibronectin in tumors in vivo. Labat-Roberts et al. (*47*) and Asch et al. (*48*) found fibronectin expressed at reduced levels compared to normal tissues in human and mouse mammary carcinomas at early stages, whereas Stenman and Vaheri (*49*) could not demonstrate any fibronectin in human epithelial tumors. Because the series of Stenman and Vaheri did not include human liver cancers, we do not know whether hepatomas in humans would also be fibronectin-positive. However, at least one human hepatoma cell line (*50*) has fibronectin in vitro (Ruoslahti E: Unpublished observations).

Because each of the hepatomas we studied is relatively fast growing (*30*) and the fibronectin-distribution is quite different, a correlation between cell surface fibronectin as expressed in vivo and the rate of tumor growth in this system is not apparent. A similar conclusion has recently been reached from studies with rat mammary tumors growing in vivo (*51*) and in a number of in vitro studies (*52–55*).

The metastatic potential for each of the hepatomas used in this study is not known. However, after amputation of the transplant site of hepatoma 7777, pulmonary metastases regularly occur (*32*). Thus the presence of fibronectin surrounding each tumor cell is not associated with a low metastatic potential of at least this tumor. The profound effects of fibronectin on cellular adhesion, including adhesion of hepatocytes (*5, 6, 18*), and on cellular motility (*56*) suggest that cell surface fibronectin is one of the factors that affects tumorigenicity and metastasis, but a simple relationship such as that proposed in earlier studies seems unlikely.

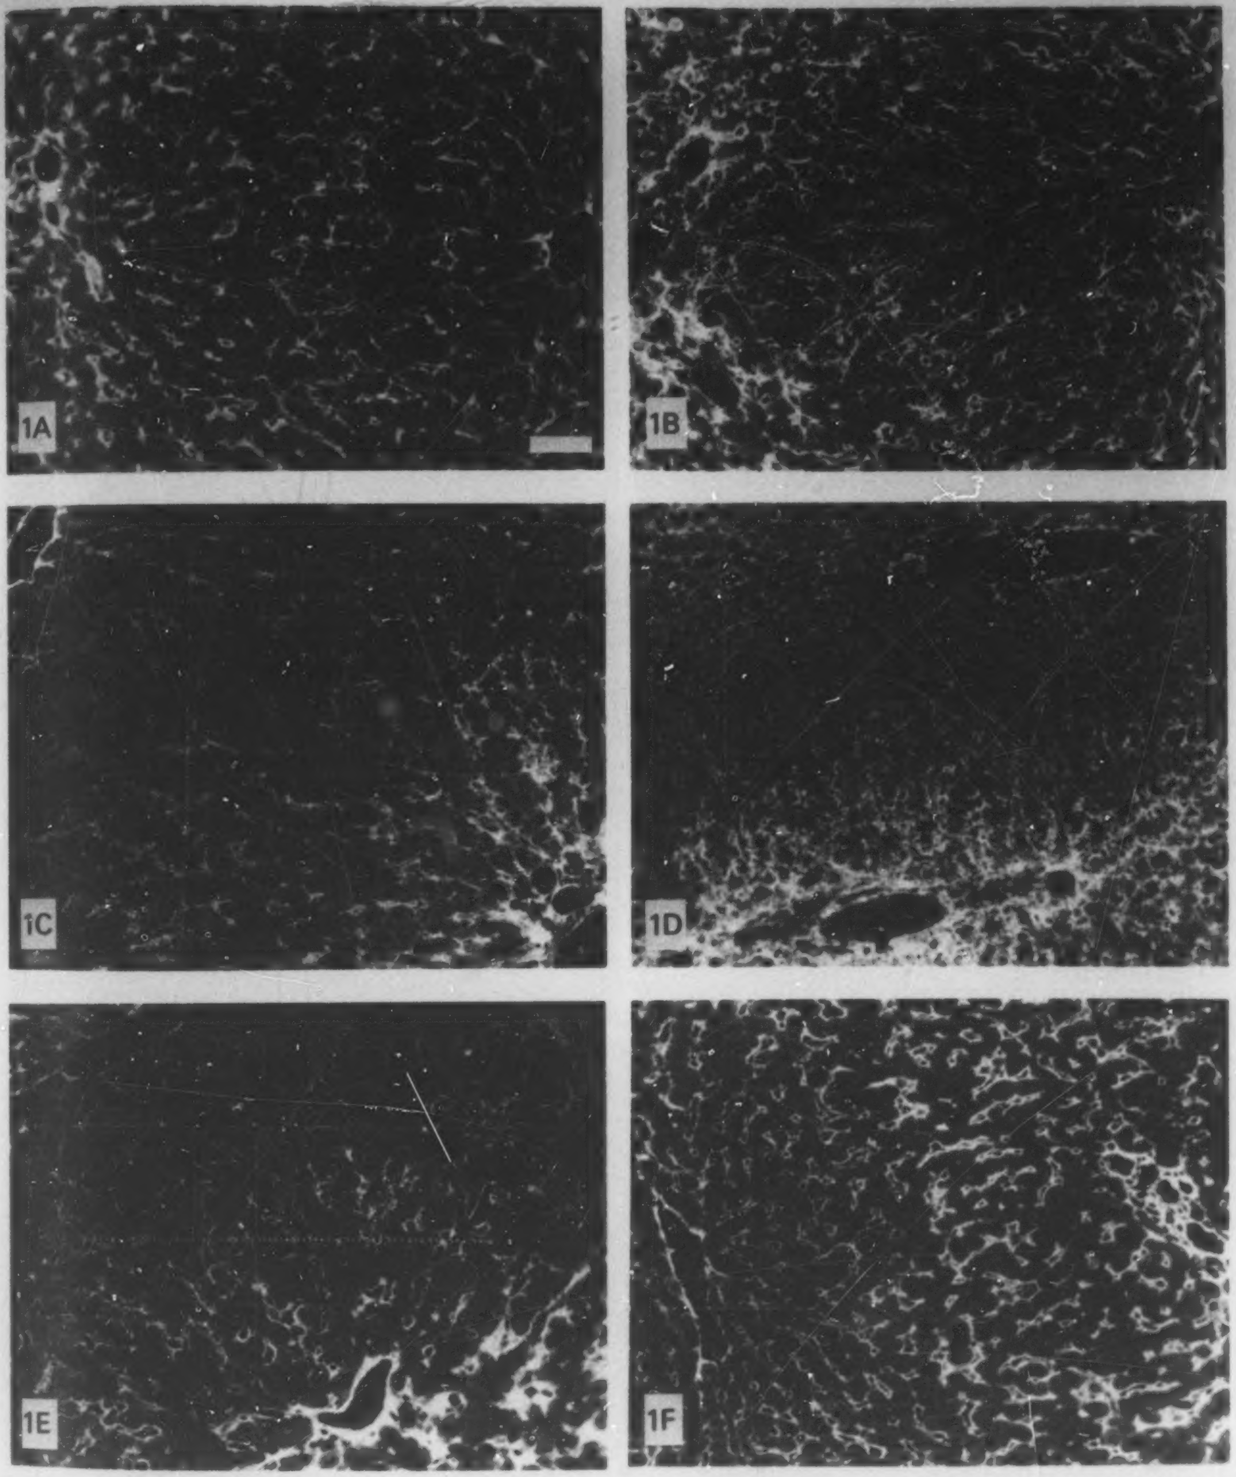

FIGURE 1.—Immunofluorescent localization of fibronectin in A) normal liver and in regenerating livers obtained at B) 1, C) 2, D) 3, E) 5, and F) 7 days after PH. Each picture includes an area of liver containing all three lobular zones (central, midzone, and portal). In normal liver and by 7 days after PH, fibronectin is uniformly distributed in all zones of the liver. At 1 day after PH, staining of fibronectin in the midzone is slightly reduced. This reduced staining is more pronounced on days 2 and 3, when some reduction is also present in the central zone. *Note* decreased staining intensity and loss of linearity in (C) as compared to that in (A) and (F). By 5 days, midzone staining has increased, and by 7 days, normal staining is evident in all three zones. The changing pattern of fibronectin staining was seen in three experiments. *Bar*=50 μm. × 180.

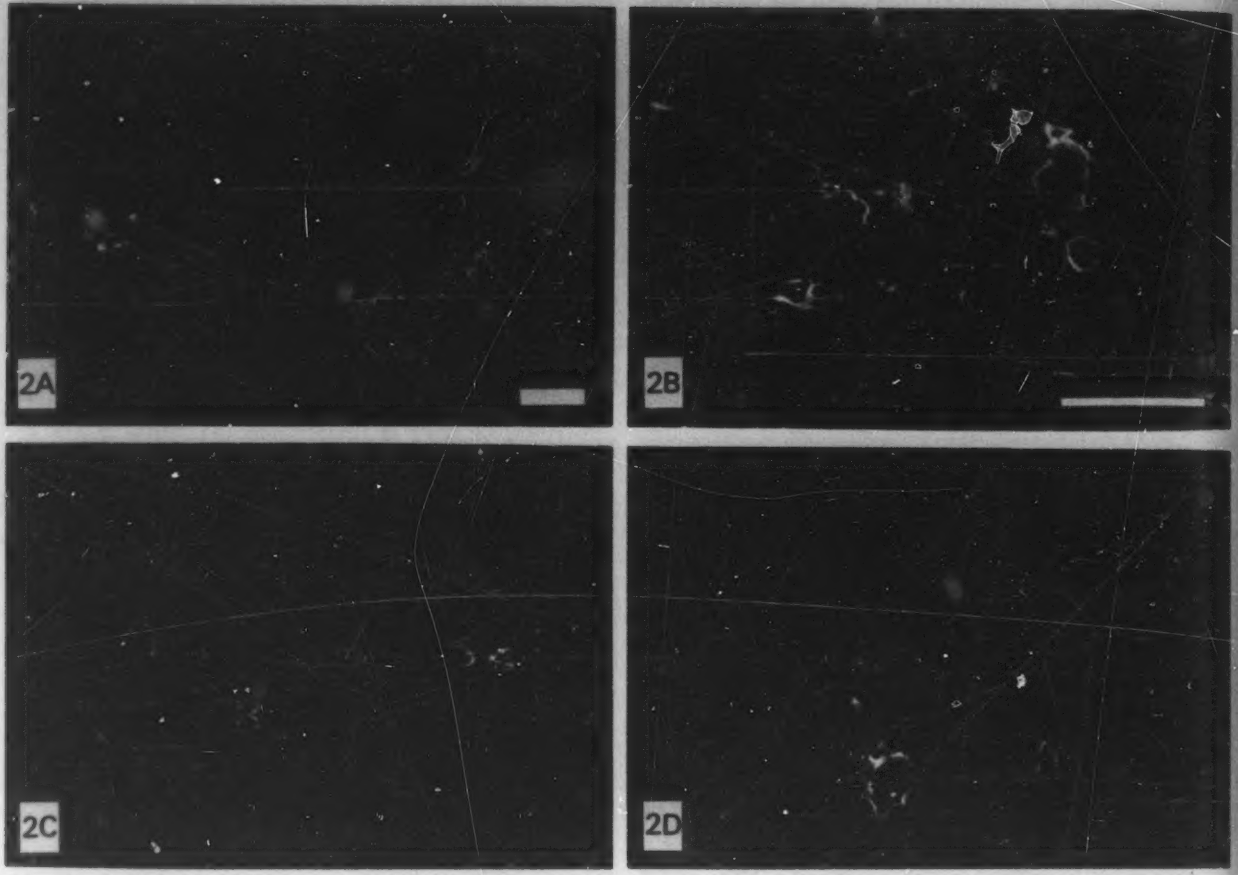

FIGURE 2.—Laminin in normal liver (A, 180 ×; B, 450 ×) and in regenerating rat liver obtained 1 day (C, 180 ×) and 3 days (D, 180 ×) after PH. Laminin is present mainly around bile ducts and hepatic arteries with lesser fluorescence around portal veins. Central veins are not stained, and sinusoids (A) in the liver lobule are very faintly and inconsistently labeled. *Bars* = *50 µm.*

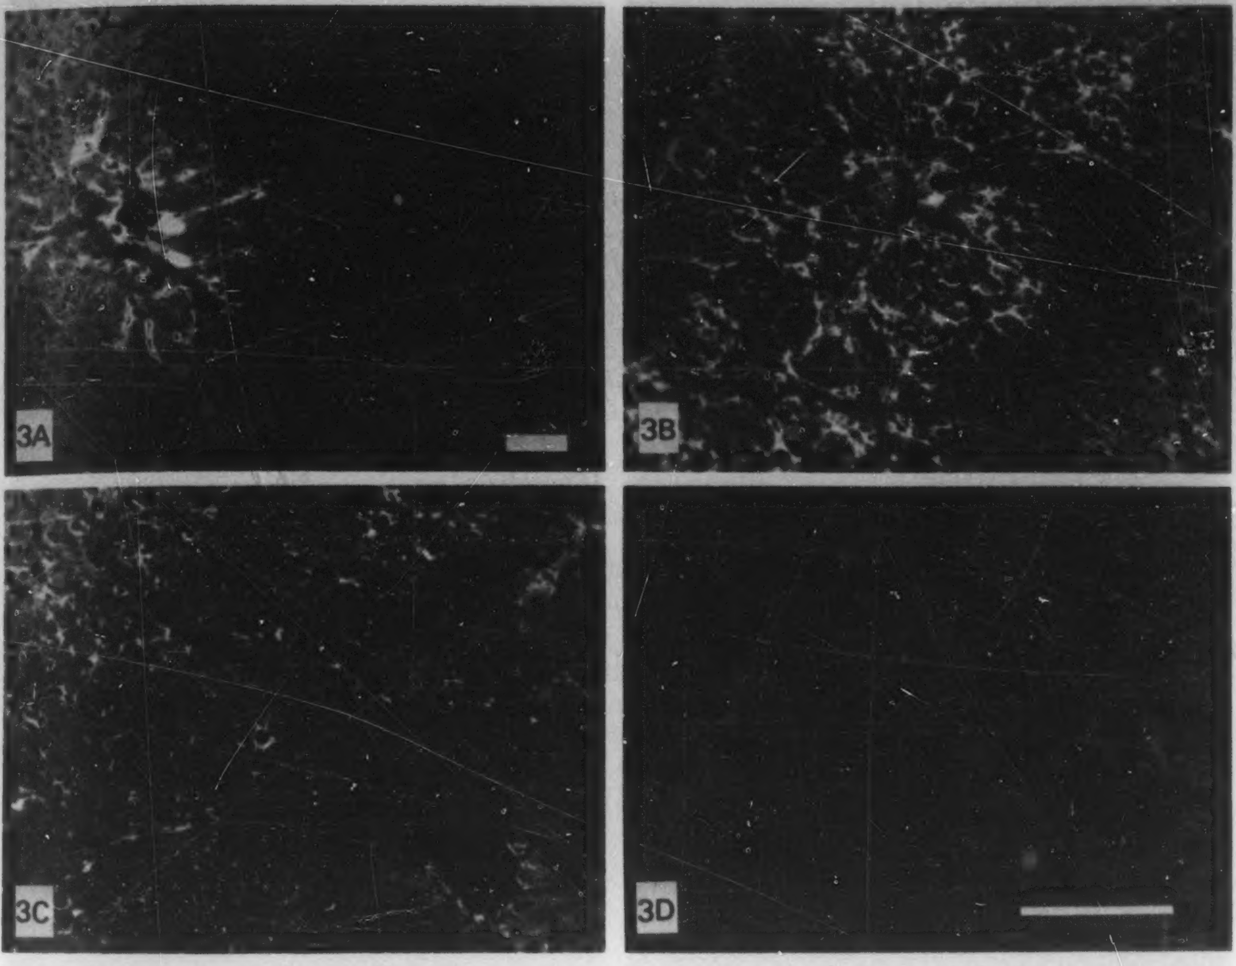

FIGURE 3.—Immunofluorescent localization of fibronectin in livers of rats fed 2-FAA in a CD diet for A) 6, B) 16, and C) 28 days (180 ×), and laminin in a liver of a rat 1 wk after having been fed E) 2-FAA in a CD diet for 13 days (450 ×). After F344 male rats were fed 2FAA in a CD diet, oval cells extending from the portal triad rapidly proliferated. Fibronectin staining increased in the portal zones after 6 days of 2-FAA feeding in a CD diet (A) and later extended from the portal zone through the midzone (B, C) (180 ×). Laminin staining in zones of oval cell proliferation increased, with ductlike structures and cords of oval cells being partially outlined (E). *Bars*=50 µm.

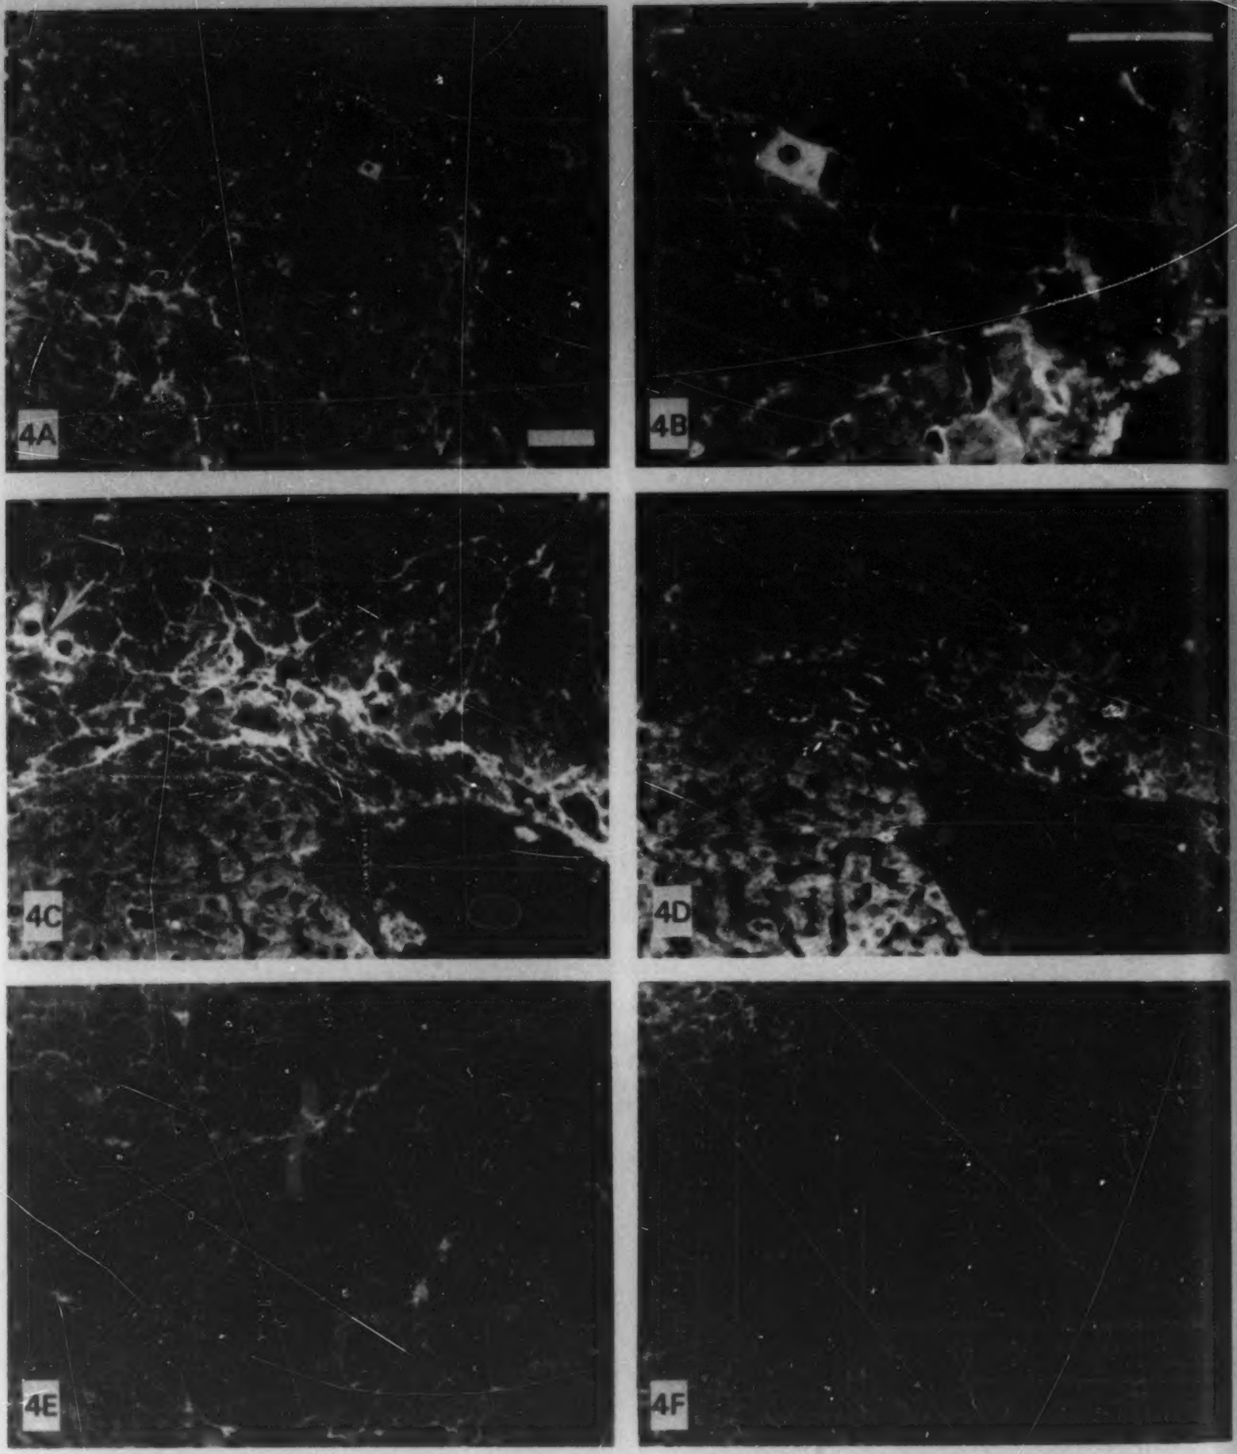

FIGURE 4.—Immunofluorescent localization of fibronectin (A–C, E, F) and laminin (D) in livers of rats treated with DENA (A–D) or fed diets containing 2-FAA for four 2-wk cycles (E, F). A (180 ×) and B (450 ×) illustrate variable distribution of fibronectin in livers after DENA, with the cytoplasm of a large cell staining for fibronectin. Areas of increased and decreased staining for fibronectin are seen. C and D (180 ×) illustrate fibronectin and laminin staining, respectively, of serial sections of a portal area. Staining of extracellular areas for fibronectin is increased irregularly, as are two cells staining for fibronectin (*arrow*). Laminin staining is limited to portal triads, where it is localized around ductules and arteries. E and F (180 ×) illustrate areas of hyperplasia and nodularity, respectively, seen in rats fed four cycles of 2-FAA. Neoplastic nodules consistently and definitely had decreased fibronectin staining. *Bars*=50 µm.

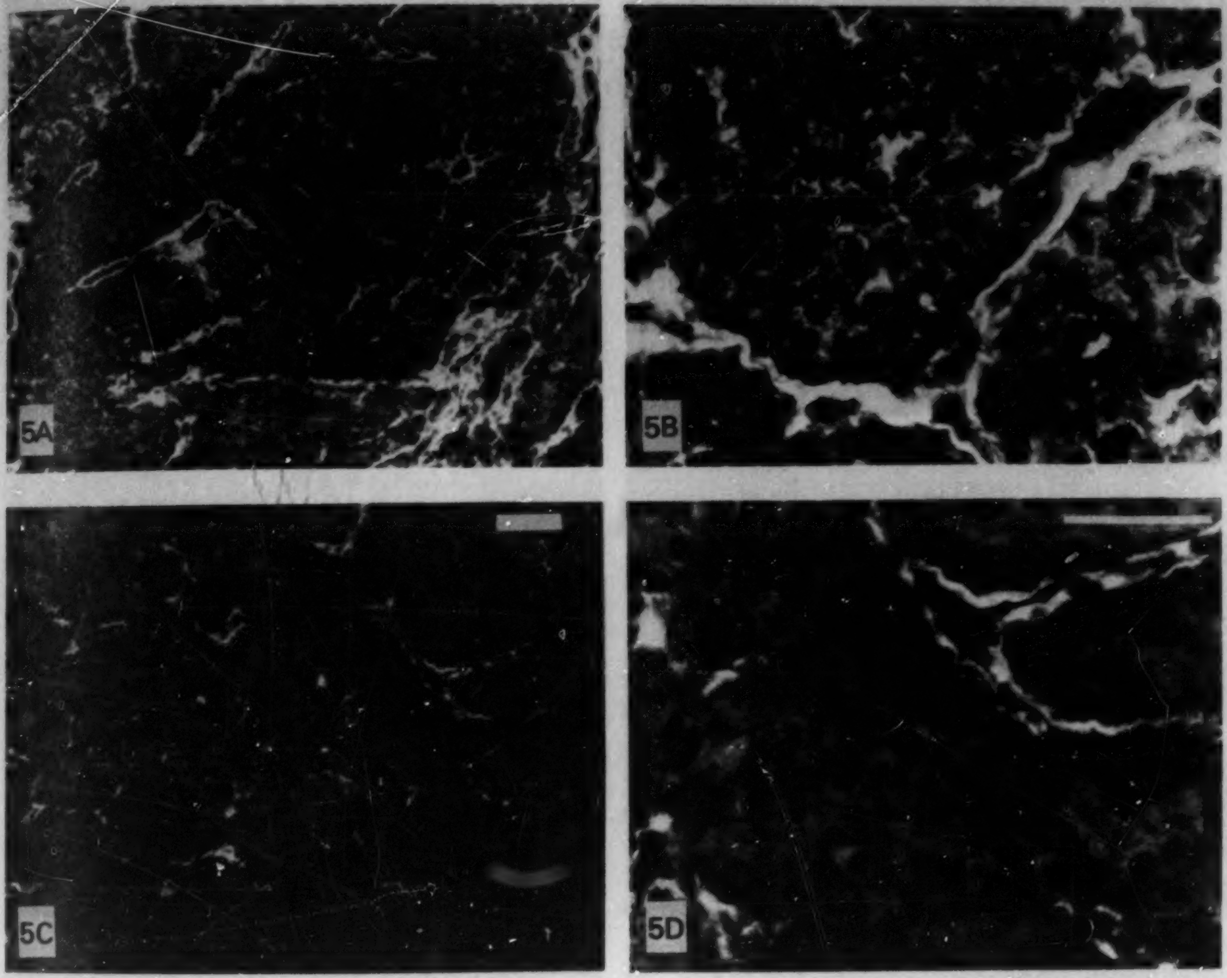

FIGURE 5.—Immunofluorescent localization of fibronectin (A, 180 ×; B, 450 ×) and laminin (C, 180 ×; D, 450 ×) in transplantable Morris hepatoma 7777. Intense fluorescence of fibronectin is seen in vascular areas and in connective tissue stroma as well as around each individual cell. Laminin is also present in stromal tissue but is not seen around individual cells. The appearance of the cells in (D) does not represent specific fluorescence but is due to background yellow fluorescence of the tumor cells. *Bars*=50 µm.

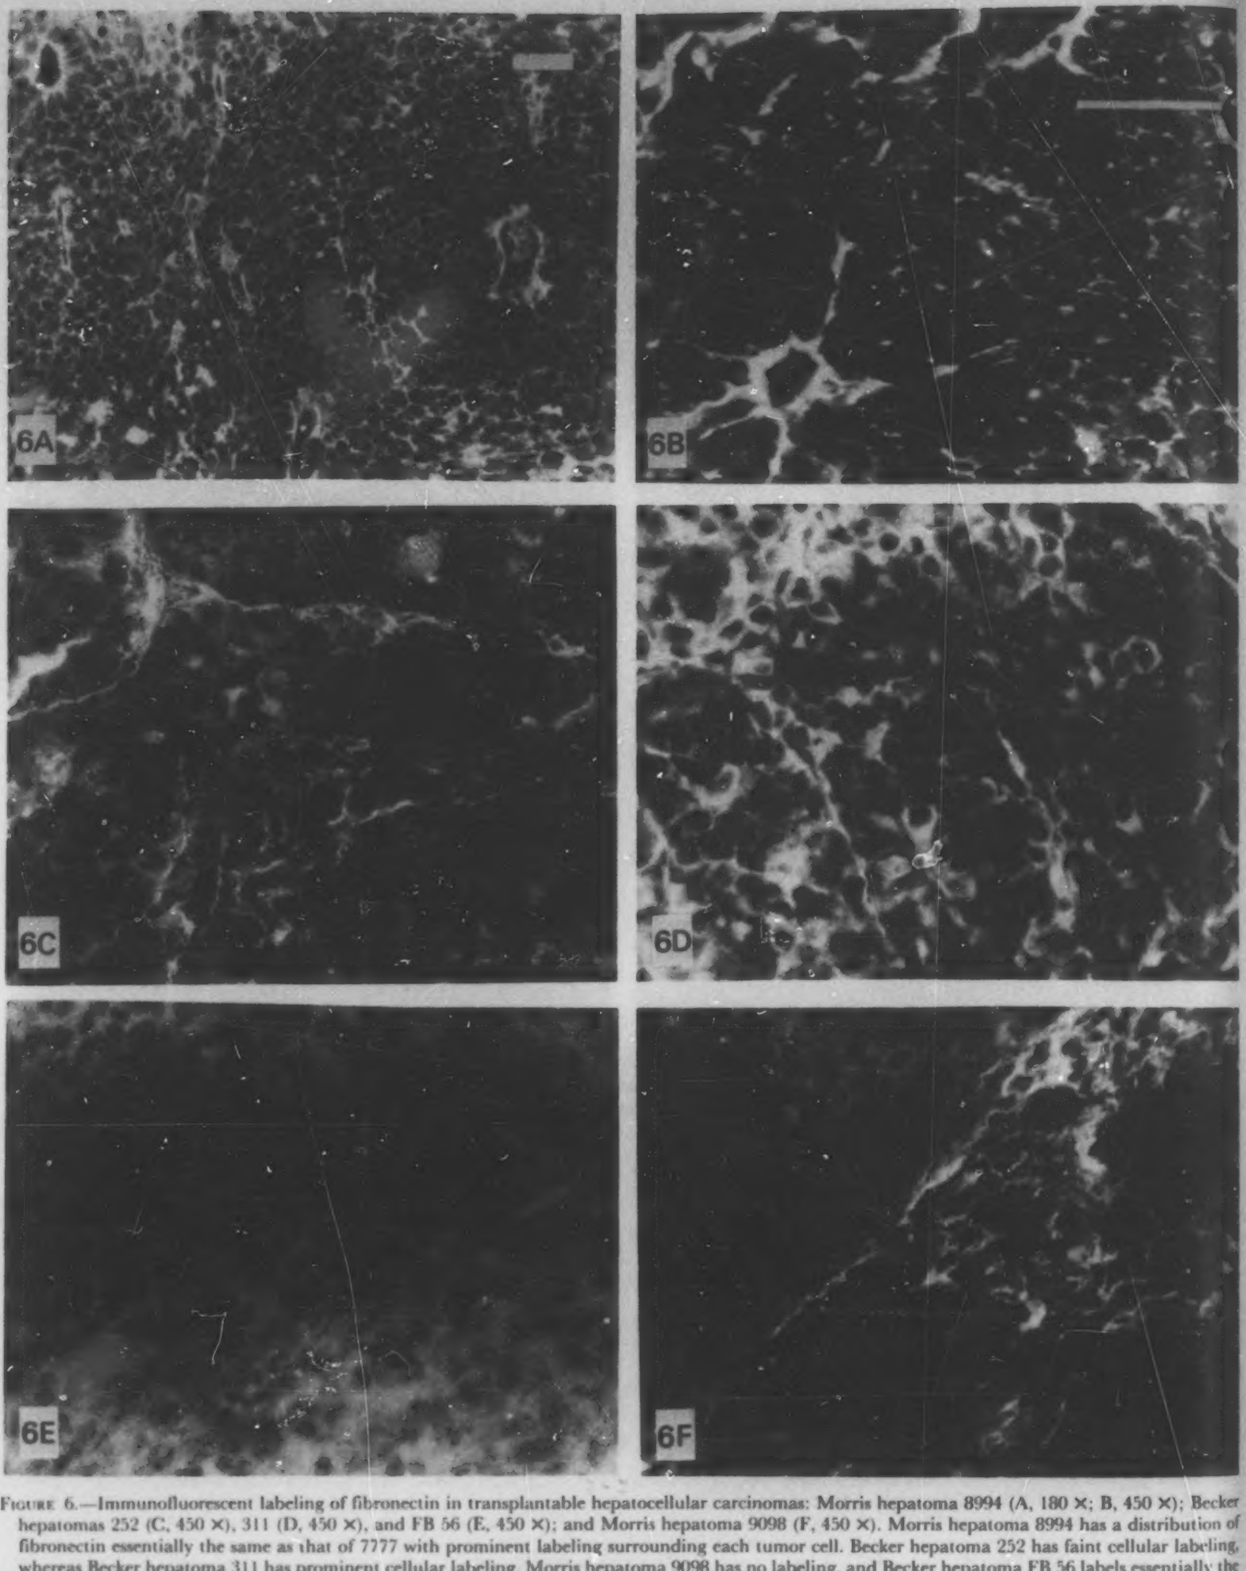

FIGURE 6.—Immunofluorescent labeling of fibronectin in transplantable hepatocellular carcinomas: Morris hepatoma 8994 (A, 180 ×; B, 450 ×); Becker hepatomas 252 (C, 450 ×), 311 (D, 450 ×), and FB 56 (E, 450 ×); and Morris hepatoma 9098 (F, 450 ×). Morris hepatoma 8994 has a distribution of fibronectin essentially the same as that of 7777 with prominent labeling surrounding each tumor cell. Becker hepatoma 252 has faint cellular labeling, whereas Becker hepatoma 311 has prominent cellular labeling. Morris hepatoma 9098 has no labeling, and Becker hepatoma FB 56 labels essentially the same as Morris hepatoma 252. *Bars*=50 μm.

Effects of Isoproterenol on Mammary Gland Tumors Induced by *N*-Nitroso-*N*-Methylurea and Salivary Gland Tumors Induced by 7,12-Dimethylbenz[*a*]anthracene[1,2,3]

Tibor Barka[4,5,6]

ABSTRACT—The effect of isoproterenol (IPR) (20 mg/kg, twice per wk) on mammary gland tumors induced by *N*-nitroso-*N*-methylurea (NMU) (40 or 77 mg/kg, iv) was studied. Within 18 weeks 50–60% of the noninbred female Sprague-Dawley rats that received a single injection of NMU developed carcinomas of the mammary gland. In addition, a malignant lymphoma was observed. There was no change in the incidence of tumors if NMU was administered at the time that DNA synthesis was stimulated in the submandibular glands by two injections of IPR (160 mg/kg, ip) given 24 hours apart. Tumors of unequivocal salivary gland origin were not observed, irrespective of whether NMU was given at the peak of stimulated DNA synthesis or without pretreatment with IPR. However, in 10% of the tumor-bearing rats, tumors were found in the neck region. These tumors could be separated from the salivary glands by dissection and were of mammary gland origin. Chronic treatment with IPR caused marked enlargements of the parotid and submandibular glands with hypertrophy of the acinar cells and degeneration of the duct system. Such a treatment caused a high death rate but no change in the incidence of the tumors. The effect of chronic IPR treatment (10 mg/kg twice per wk or 5 mg/kg three times per wk) on submandibular gland tumors induced by 7,12-dimethylbenz[*a*]anthracene (DMBA) was also studied. With the intraglandular injection of 100 or 200 μg of DMBA, the incidences of squamous cell carcinomas in the glands were 6.8 and 38.6%, respectively. Chronic administration of IPR after the instillation of DMBA caused a high death rate but no statistically significant change in the incidence of salivary gland tumors—JNCI 1982; 69:1115–1120.

DNA synthesis of the acinar cells in the parotid and submandibular glands of rats and mice can be stimulated by the administration of the beta-adrenergic agonist IPR. Repeated administration of this drug leads to hyperplastic and hypertrophic enlargements of the glands (*1–11*). IPR thus provides a means to study the effects of induced cell proliferation and hyperplastic and hypertrophic growth on the induction and development of tumors of the salivary glands. Specifically, this study was concerned with two related problems: 1) the role of cell replication in the induction of salivary gland tumors and 2) the possible promoting effect of IPR in chemical carcinogenesis of the salivary glands.

The rationale of the experiments to analyze the first problem was as follows: The rate of DNA synthesis and cell replication in the parotid and submandibular glands of adult rats is very low (>0.1%). Both DNA synthesis and cell replication can be stimulated greatly by IPR. It was established previously (*3*) that two injections of 160 mg IPR/kg, given 2 hours apart ip to female rats, maximally stimulate DNA synthesis in the parotid and submandibular glands; the peak of DNA synthesis occurs 24 hours after the second injection of the drug. At that time, a significant proportion of acinar cells in the parotid and submandibular glands are in the S-phase of the cell cycle. By selection of an appropriate carcinogen, which acts during the time of induced DNA synthesis, the role of cell replication in the initial step of carcinogenesis in the glands could be studied. I have selected NMU as the carcinogen because it fulfills the following criteria: It is a potent carcinogen capable of producing tumors in a wide variety of organs, even as a single injection given systematically (*12*); it does not require metabolic activation (*13*); and it is quickly metabolized and eliminated (*14*). Hence the initial interactions of NMU with its target molecules are restricted for a short period of time. Of the large number of diverse tumors induced by NMU, Druckrey et al. (*12*) have reported the occurrence of only 1 parotid gland tumor. However, Parkin and Neale (*15*) described a 10% incidence of salivary gland tumors induced by NMU in female Wistar rats pretreated with IPR. Our findings, reported in this communication, are at variance with those of Parkin and Neale. Since the single injection of NMU produced a high incidence of mammary gland tumors, our observations bear also on the possible effect of adrenergic stimulation on the development of mammary gland tumors.

For the study of the possible tumor-promoting effect of IPR, rats were treated chronically with IPR following the instillation of DMBA in doses that produced carcinomas in less than 50% of the animals.

MATERIALS AND METHODS

Six-week old, female Sprague-Dawley rats (Zivic-Miller Laboratories, Allison Park, Pa.), weighing approximately 150 g, were used. The rats were housed in air-conditioned (20–22°C, 50% relative humidity) quarters, 3/cage, and had

free access to rat chow and water. The number of animals in the various experimental groups, the doses of carcinogens, and treatment with IPR are given in table 1.

A 2% solution of NMU (ICN Pharmaceuticals Inc. Plainview, N.Y.) in saline was given iv into the femoral vein of rats under light ether anesthesia. DMBA (Eastman Kodak Co., Rochester, N.Y.) was dissolved in liquid petrolatum (4 or 8 mg/ml) and was injected (25 µl) into the left lobe of the submandibular gland disposed by a midline incision under aseptic conditions. The skin incision was closed with metal clips. Isoproterenol-HCl (Winthrop Laboratories, New York, N.Y.) was dissolved (8 or 1%) in 0.1% sodium metabisulfite and was given ip.

Autopsies, excluding the brain, were performed on all rats that were killed or died. Routinely, the submandibular, sublingual, and parotid glands, the cervical lymph nodes, and the tumors were examined microscopically. Histologic examinations were extended to other organs if pathologic lesions were suspected on the basis of gross examinations. The tissues were fixed in Formalin and embedded in paraffin. The sections were stained with hematoxylin and eosin.

Statistical analyses of tumor rates and death rates were performed according to Peto (*16*).

RESULTS

Table 1 summarizes the experiments and results. Text-figure 1 shows the death rates in all experimental groups.

Experiment I

Experiment I was designed to test two hypotheses: *a*) NMU, a short-lived carcinogen, induces tumors of the parotid and/or submandibular glands in high incidence in rats only if DNA synthesis is stimulated (by IPR) concomitantly in these organs (groups 1, 2, and 3). *b*) The development of salivary gland tumors induced by NMU is promoted by the chronic administration of IPR, which causes marked hyperplastic and hypertrophic enlargements of the parotid and submandibular glands (groups 4 and 5).

To test the first hypothesis, I gave rats two injections of IPR (160 mg/kg) 24 hours apart, followed by MNU (40 or 77 mg/kg) 24 hours after the second injection of IPR. Female animals were used because stimulation of DNA synthesis by IPR is more pronounced in female than in male rats (17).

Of the 46 rats that received 40 mg NMU/kg following the two injections of IPR (group 1), 40 survived 18 weeks when the experiment was terminated. Six rats died shortly after the IPR–NMU injections and were excluded. In this group, 23 (50%) rats developed 36 mammary gland tumors. The tumors were adenocarcinomas, most showing a high degree of differentiation. One rat had a tumor in the neck region, which adhered to and partially surrounded the parotid and submandibular glands but could be separated from them by a careful dissection with the aid of a stereomicroscope. Histologically, this tumor was also an adenocarcinoma (fig. 1).

Of the 40 rats given 77 mg NMU/kg following two injections of IPR (group 2), 24 (60%) had developed tumors within 22 weeks when the experiment was terminated. There was no death within this time period. In 1 rat a diffuse, histiocytic malignant lymphoma, involving lymph nodes, spleen, mesentery, liver, kidney, and salivary glands, was found. All remaining tumors were adenocarcinomas of the mammary glands, 1 invading the skin (fig. 2). Three tumors were located in the neck region, but they did not originate from or involve the salivary glands.

Of the 43 rats that were given 40 mg NMU/kg only (group 3), 23 (53%) had a total of 35 tumors. These tumors were also carcinomas of mammary glands, 4 in the neck region, but not involving the salivary glands.

I concluded from these experiments that: 1) A single iv injection of NMU induced no tumors of the salivary glands, even if it was given at the peak of stimulation of DNA synthesis in the glands by IPR. 2) More than 50% of rats given a single injection iv of NMU in a dose of 40 or 77 mg/kg developed single or multiple mammary gland tumors. These tumors grew large, frequently causing ulceration of the skin, but did not produce distant metastases. 3) Of the

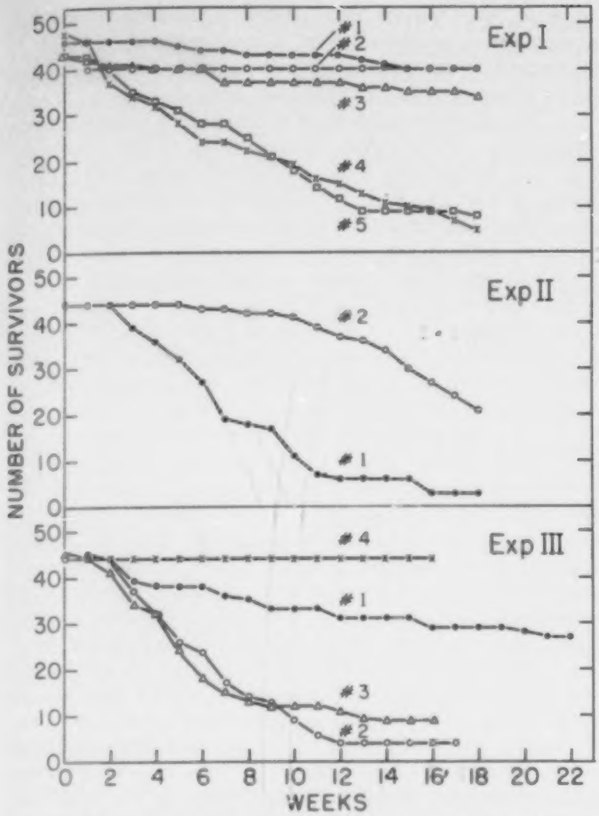
[a] Details of the experiments are given in "Materials and Methods." NMU (2% in saline) was injected iv as a single dose. DMBA was dissolved in liquid petrolatum and injected intraglandularly. IPR (8 or 1% solution in 0.1% sodium metabisulfite) was given ip. In expt I, group 2, a malignant lymphoma was found. The rest of the NMU-induced tumors were adenocarcinomas. All the DMBA-induced tumors were squamous cell carcinomas.

[b] + = IPR given; – = IPR not given.



TEXT-FIGURE 1.—Survival of rats in the various experimental groups. Experimental groups and the treatment of rats in each group are given in table 1. The *graphs* show the number of rats alive at the end of each week.

69 rats that developed tumors, 1 (1.4%) had a malignant lymphoma. The rest of the tumors were adenocarcinomas. 4) Eight of the tumors were located in the ventral neck region. Those tumors were also adenocarcinomas and most likely originated in mammary glands. 5) Administration of IPR prior to the injection of NMU had no effect on the incidence of mammary gland tumors.

To test the second hypothesis, I treated rats chronically with IPR; these rats had received NMU, either after 2 injections of high doses of IPR (group 4) or without preceding administration of IPR (group 5) (20 mg/kg, twice per week).

The animals that were treated with IPR chronically had a high rate of death (text-fig. 1). This high death rate was unexpected since in several previous studies this dose of IPR was found to be well tolerated by rats. The cause of the high incidence of death is unknown. Of the 48 rats chronically treated with IPR following IPR and NMU injections (group 4), 4 rats developed mammary gland tumors, detected on 64, 64, 76, and 88 days after the administration of NMU, respectively. Of the 43 rats that received the same dose of NMU (40 mg/kg) followed by the chronic administration of IPR (group 5), 7 developed mammary gland tumors. In 2 rats the tumor was located in the neck region without involving the salivary glands. All tumors were carcinomas showing different degrees of differentiation. No tumor of salivary gland origin was observed.

As described previously (*6–11*), the parotid and submandibular glands of rats chronically treated with IPR were markedly enlarged. In these glands the acinar cells were enlarged and were filled with secretory material. The ratio of ducts to acini was decreased, with frequent degenerative changes of the duct system. In the submandibular glands the granular convoluted duct (or tubule) cells were devoid of secretory granules. The sublingual glands were not affected or only minimally affected by the treatment with IPR.

The incidence of mammary gland tumors induced by NMU appeared to be greatly reduced by the chronic administration of IPR (group 3 vs. group 5 and group 4 vs. group 1). However, the lower incidence of tumors in IPR-treated rats was probably caused by the high death rate; death prevented the development of the tumor in some of the animals. A statistical analysis of these data from the point of view of a possible effect of IPR on the incidence of mammary gland tumors is not feasible, since these experiments were set up to study possible effects of the drug on salivary gland tumors and not on tumorigenesis in the mammary gland. Thus rats in which mammary gland tumors were detected during the life of the animal were not killed to allow for possible tumor development in the salivary glands. Hence the mammary gland tumors were neither "incidental" findings nor diagnosed during the life of the animal (*16*).

Experiment II

Experiment II was set up to study the possible effect of chronic IPR treatment on the development of mammary gland tumors induced by NMU. NMU (40 mg/kg) was given to 88 rats, which then were divided into 2 groups of equal size. Rats in group 1 were given injections twice weekly of 20 mg IPR/kg; rats in group 2 were given the solvent (sodium metabisulfite). Ten rats in group 1 and 31 rats in group 2 bearing mammary gland tumors were found. Morphologically, these neoplasma were similar. Statistical analysis of these data indicated, however, that treatment with IPR had no significant effect on the incidence of mammary gland tumors.

Experiment III

Experiment III was designed to test whether chronic administration of IPR, which produces enlargements of the submandibular and parotid glands, has an effect on the induction of tumors by DMBA. DMBA (groups 1 and 2, 100 μg; groups 3 and 4, 200 μg) was injected into the submandibular glands of rats that were then divided into groups treated with IPR (group 1, 10 mg/kg, twice weekly; group 3, 5 mg/kg, three times a week) or with the solvent (sodium metabisulfite) (groups 2 and 4).

Animals that died or were killed were autopsied, and the parotid glands, the injected and uninjected submandibular glands, and adjacent lymph nodes were examined histologically.

As in previous groups, IPR, even in the lower dose of 5 mg/kg, caused a high incidence of death (text-fig. 1). Of the 44 rats that received injections of 100 μg DMBA (group 2), 3 (6.8%) developed squamous cell carcinomas in the submandibular gland at the site of injection. Two of these tumors were found in rats that died after 16 weeks, and 1 was found in a rat killed at the end of the 22d week, when the experiment was terminated. Of the 45 rats that were treated with 10 mg IPR/kg after the injection of DMBA (group 1), only 4 were alive at the end of the 17th week, when they were killed. In this group no tumors were found.

In view of the low number of tumors found in the control group after the injection of 100 μg DMBA and because of the high rate of mortality in the IPR group, the experiment was repeated with the use of 200 μg DMBA and reduction of the dose of IPR to 5 mg/kg.

Of the 44 rats receiving injections of the higher dose of DMBA (group 4), tumors were observed in the submandibular glands of 17 (38.6%) rats at the end of the 16th week, when all animals were killed. All these tumors were squamous cell carcinomas developed at the injection site. At the end of the 16th week, only 9 of the 45 rats that were treated with IPR (5 mg/kg, three times a week) were alive. In this group (group 3), 3 squamous cell carcinomas were found. The earliest of those was found in the submandibular gland of a rat that died 6 weeks after the instillation of DMBA. The other 2 tumors were detected after the 13th and 16th weeks, respectively. Statistical analysis indicated that treatment with IPR had no significant effect on the induction of tumors by DMBA. The injected glands in which tumors were observed were infiltrated frequently with lymphoid cells. Such glands consisted mostly of ducts with few islands of remaining acini. In the glands of the rats in which no tumors were observed, large cysts lined with squamous epithelium and varying degrees of chronic inflammation were present. The uninjected submandibular gland and the parotid glands of the rats treated with IPR chronically were enlarged and showed hypertrophy, hyperplasia, and degenerative changes of the duct cells, as described above.

DISCUSSION

Neoplasms of rodents' salivary glands are readily induced by intraglandular, but not by systemic, administration of chemical carcinogens (*18–26*). Hence the report of Parkin and Neale (*15*) on the induction of salivary gland tumors in rats by NMU given iv is of considerable interest. These authors described that with a single injection of NMU, salivary gland tumors developed in animals *a*) in which DNA synthesis in the glands was stimulated by IPR (*1*) and *b*) that received the carcinogen at the peak of DNA synthesis. The findings of Parkin and Neale imply that DNA synthesis is a critical factor in NMU-induced carcinogenesis of the salivary glands and, as a corollary, that the low rate of cell replication is, at least in part, responsible for the lack of tumor induction in these organs by systemic carcinogens.

In our series of experiments, a single iv injection of NMU induced mammary gland tumors in about 50% of the rats. Most of these tumors were well-differentiated adenocarcinomas, which in the absence of metastases are difficult to distinguish from polymorphic adenomas. Induction of mammary gland tumors by NMU has been described (*12, 27–29*). The incidence of tumors is dependent on the species, strain, dose, and schedule of application of the carcinogen (*12, 30*). Parkin and Neale (*15*) have found that 17% of female Wistar rats given 77 mg MNU/kg developed mammary gland tumors within 12 weeks and that the percentage of tumor-bearing rats and the average number of tumors were increased if the carcinogen was given at the peak of DNA synthesis induced by IPR.

At variance with the findings of Parkin and Neale (*15*), I have observed no tumors of unequivocal salivary gland origin, irrespective of whether NMU was given at the peak of stimulated DNA synthesis or without pretreatment with IPR. There were, however, 4 of 47 tumor-bearing rats in the IPR–NMU groups (expt. I, groups 1 and 2) and 3 of 23 tumor-bearing rats in the NMU group (expt I, group 4) that developed tumors on the ventral neck region. These tumors could be separated by careful dissections from the parotid and/or submandibular glands. These adenocarcinomas probably originated in mammary glands encountered not infrequently both in rats and mice (*31*) in the subcutaneous tissue adjacent to the parotid gland. Although some mammary gland tumors are difficult to distinguish from sweat gland tumors, sweat glands apparently are not found in the neck region in the rat. The salivary gland tumors described by Parkin and Neale were "pleomorphic adenomas" with the exception of 1 tumor that arose "from keratinized squamous epithelium of salivary duct." One of the 6 salivary gland tumors observed by Parkin and Neale originated from the sublingual gland. This is of interest because DNA synthesis is not stimulated significantly by IPR in the sublingual gland.

Further experiments are required to explain the discrepancy between the findings of Parkin and Neale (*15*) and mine. Strain differences may account for the induction of salivary gland tumors by NMU in Wistar rats and the lack of induction in Sprague-Dawley rats. It is conceivable, however, that the tumors observed by the British authors did not originate in the salivary glands either but that they surrounded or perhaps invaded these glands.

The conspicuous enlargement of the parotid and submandibular glands has been well characterized since its first description by Selye and his co-workers (*6*). Chronic administration of IPR seemed to reduce the incidence of mammary gland tumors induced by NMU, but it also caused an unexpected high rate of death. By taking into account the high death rate, which "prevented" tumor development in some animals, I could detect no statistically significant effect of chronic IPR administration on tumor development of the mammary gland.

DMBA and other polycyclic hydrocarbon carcinogens instilled into the submandibular gland produce tumors in a dose-dependent manner (*23*). With two doses of DMBA (100 and 200 μg) I have observed a 6.8 and 38.6% incidence, respectively, of tumors in the submandibular glands. All these tumors were squamous cell carcinomas. These doses of DMBA were chosen to investigate possible tumor-promoting effects of IPR. Chronic treatment with IPR caused a high mortality rate. In several previously published and in my unpublished experiments, it was found that rats tolerated well much higher doses of IPR than those used in this study. The cause of this unexpected high death rate is not known, but it may be related to an exacerbation of a subclinical (pulmonary) infection. A statistical analysis of the data according to Peto (*16*), which accounts for the death of experimental animals not caused by the tumors, indicated that chronic administration of IPR had no significant effect on the induction of tumors by DMBA. According to Shklar and Cataldo (*24*), chronic administration of IPR, commencing with the implantation of 5 mg DMBA into the submandibular gland, reduced both the size and number of tumors. Since such a high dose of DMBA induces tumors in 100% of the animals, the interpretation of the data of Sklar and Cataldo is difficult. The dose (200 μg) used in this study seems optimal for detection of inhibitory or promoting effects on tumorigenesis. Since IPR can produce marked hyperplastic and hypertrophic enlargements of the salivary glands even in much smaller doses than those used in this study, further experiments with low doses of IPR in combination with DMBA (200 μg) are warranted. Such experiments should provide a definite answer on the effect of IPR on the induction of salivary gland tumors by a polycyclic hydrocarbon carcinogen.

Immunotherapeutic Effects of Partially Purified Tumor-Specific Transplantation Antigens on Pulmonary Metastases of a 3-Methylcholanthrene-Induced Sarcoma in Mice: A Preliminary Report[1,2,3]

Tsuguo Tanaka,[4] Neal R. Pellis,[4] *and* Barry D. Kahan[4,5]

ABSTRACT—Tumor-specific transplantation antigens (TSTA), which were partially purified by preparative isoelectric focusing of 3-*M* KCl extracts of a fibrosarcoma MCA-F induced in inbred female C3H/HeJ mice with 3-methylcholanthrene and previously shown to display immunotherapeutic activity against subcutaneous neoplasms, were effective against pulmonary metastases. Weekly sc injections of 25 μg fraction 15 decreased the number of pulmonary colonies after iv injection of tumor cells into syngeneic, virgin C3H/HeJ mice. The effect was immunologically specific; the immunoprotective fraction from the heterotypic, antigenically distinct MCA-D tumor did not affect the number of pulmonary MCA-F tumor colonies. Because fraction 15 treatment did not alter the number of extrapulmonary tumor colonies, the survival rates of hosts challenged iv with MCA-F cells were unaffected. The variant cell line MCA-F-4 was selected to detect prolonged host survival as a result of a therapeutic effect against pulmonary metastases. This line was selected for its proclivity for lung colonization and low propensity for growth in extrapulmonary sites. Cross-immunoprotection tests demonstrated that MCA-F-4 shares a TSTA with the parent tumor. Therapeutic administration of fraction 15 prolonged the survival of hosts in two settings: 1) after artificial iv injection of MCA-F-4 cells and 2) as treatment for hosts resected of 1-cm subcutaneous MCA-F-4 primary tumors and at high risk for spontaneous pulmonary metastases. Therefore, fraction 15 displayed therapeutic effects on both artificially induced and spontaneous pulmonary metastases.—JNCI 1982; 69:1121–1126.

TSTA have been extracted from MCA-induced guinea pig hepatomas (*1, 2*), virus-induced tumors (*3*), and MCA-induced murine sarcomas (*4–6*) with the use of hypertonic potassium chloride (3*M* KCl). Pretreatment of syngeneic murine hosts with 0.5–1.0 mg protein of crude 3-*M* KCl extracts of MCA-induced fibrosarcomas induces specific resistance against sc challenge with one hundredfold the lethal dose of the homotypic tumor (*4, 7, 8*). Fiftyfold purification of the active principle was obtained by isoelectric focusing (*9*): 10–25 μg fraction 15 (pI 5.8–6.0) specifically protects syngeneic hosts. The focused material evokes delayed-type hypersensitivity in syngeneic hosts immunized with irradiated cells or with purified plasma membranes and does not contain H-2 alloantigenic activity (*10*). Weekly injections of fraction 15 enhance host resistance against subcutaneous primary tumors, supralethal challenges after complete tumor excision, and residual neoplastic cells following partial resection (*11*).

In clinical practice, however, therapeutic failures tend to occur when there has been intravenous, rather than local, dissemination of tumor cells. In many cases, patients succumb to micrometastases that have occurred prior to surgery. The present studies were designed to investigate the therapeutic effects of fraction 15 on neoplastic progression after hematogenous dissemination of tumor cells produced artificially or spontaneously. Weekly administration of fraction 15 decreased the number of pulmonary, but not extrapulmonary, tumor colonies following artificial, iv injection of MCA-F cells into virgin C3H/HeJ mice or into hosts resected of 1-cm MCA-F tumors. Using a cell variant MCA-F-4, which displays selectivity for the lung and spontaneous pulmonary metastases after resection of subcutaneous primary tumors, we demonstrated that fraction 15 therapy prolongs host survival. Thus therapeutic administration of fraction 15 at weekly intervals stimulates host immunity to resist hematogenously disseminated cells capable of forming metastatic deposits in the lung.

MATERIALS AND METHODS

Tumors.—Several antigenically distinct tumors induced in inbred female C3H/HeJ mice (The Jackson Laboratory, Bar Harbor, Maine) by injection of 179 μg MCA have been characterized (*7*). The present studies used 2 fibrosarcomas, MCA-F and MCA-D, which were serially passaged sc in 4- to 6-week-old female syngeneic C3H/HeJ mice. All experiments used cells from the fourth to sixth transplant generation.

Extraction and purification of TSTA.—Freshly excised 1.5-cm tumors were minced with scissors and treated three or four times with 0.25% trypsin in Hanks' solution for 20 minutes at 37°C. The cell suspension was washed three times with EMEM. TSTA was extracted by the 3-*M* KCl method

ABBREVIATIONS USED: EMEM=minimum essential medium; MCA=3-methylcholanthrene; MTD=minimum tumorigenic dose(s); PBS=phosphate-buffered saline; pI=isoelectric point; TSTA=tumor-specific transplantation antigen(s).

(*7, 12*): Tumor cells were suspended in a solution of 3 *M* KCl in 0.15 *M* PBS (pH 7.2). After 16 hours at 4°C, the insoluble cell debris was sedimented at 165,000×*g* for 60 minutes. The supernatant was concentrated by dialysis against 50% sucrose in PBS and then dialyzed against 200 volumes of PBS to remove sucrose and KCl. Precipitates formed during dialysis were removed by a second 165,000×*g* ultracentrifugation for 60 minutes. The protein content in the final supernatant, designated "crude" antigen, was measured with the use of the Lowry assay with albumin as a standard (*13*).

The crude extract was fractionated by preparative isoelectric focusing by means of a modification of the method of Radola (*14*), described in detail previously (*9*). The pI-5.9 zone (fraction 15), previously demonstrated to bear immunoprophylactic and immunotherapeutic activities (*9*), was first demonstrated to induce immunoprophylaxis, i.e., to protect syngeneic hosts against challenge 10 days later with 100 MTD of the corresponding MCA-induced tumor (*9*). Fraction 15 was injected sc into the flanks on a weekly schedule at a dose of 25 μg protein, the optimal amount in the immunoprotection test that was assumed to be the best therapeutic dose, beginning 1 day after challenge or resection of a primary tumor.

Experimental intravenous metastasis.—C3H/HeJ mice anesthetized by ether inhalation were given injections via the femoral vein of a variable number of viable tumor cells suspended in 0.2 ml Hanks' solution. The mice were killed 21 days later for enumeration of extrapulmonary and pulmonary tumor colonies. Extrapulmonary tumor colonies, located primarily in subcutaneous tissues, skeletal muscles, kidney, mediastinum, and/or mesentery, were counted macroscopically at autopsy if they were greater than 1 mm in diameter. The intracranial space was not examined. Pulmonary tumor colonies were enumerated with the use of the india ink insufflation method of Wexler (*15*) with the aid of a dissecting microscope. The size of individual metastases was not measured; therefore, one cannot be assured that the observed numerical differences do not reflect a shift to a size below that visible with a dissecting microscope.

Immunologic specificity of fraction 15.—For evaluation of immunologic specificity, groups of 10 mice given injections iv of 10^5 MCA-F cells were treated weekly on three occasions with 25 μg MCA-F fraction 15 or with 20 μg MCA-D fraction 15. At 21 days after injection, the number of pulmonary colonies counted in the 2 therapy groups was compared with the number in an untreated, control group.

Selection of the metastatic variant MCA-F-4.—The variant cell line MCA-F-4 was selected from the parent MCA-F tumor by the method of Fidler (*16*). A single cell suspension of the MCA-F tumor, which had been prepared from a 1.5-cm neoplasm in the sixth in vivo passage with the use of sequential treatments with 0.25% trypsin in Hanks' solution, was inoculated iv at a dose of 10^5 trypan blue-excluding viable cells in 0.2 ml Hanks' solution. Three representative pulmonary tumor colonies were aseptically isolated 21 days later. The cells dissociated from the lung lesions were suspended in EMEM supplemented with 10% fetal calf serum, 100 U penicillin/ml, 100 μg streptomycin/ml, and 2 m*M* L-glutamine and incubated in 5% CO_2 at 37°C (10^6 viable cells). After growth to confluence, these cells denoted "MCA-F-1" were dissociated from tissue culture flasks and injected iv into virgin C3H/HeJ hosts. Three weeks later, the mice were killed and pulmonary tumor colonies were isolated and grown in tissue culture for a second cycle (MCA-F-2 cells). This procedure was repeated four times. The daughter cell line designated "MCA-F-4" was thereafter maintained by in vivo passage. In addition to its propensity to form pulmonary nodules upon iv injection, the MCA-F-4 cell line displays spontaneous lung metastases following excision of 1-cm primary subcutaneous tumors.

*Immunoprotection test with the use of 3-*M *KCl extracts from MCA-F and MCA-F-4 tumors.*—Cross-immunoprotection tests were performed to investigate the antigenic relationship between MCA-F and its variant MCA-F-4. Groups of 10 mice were immunized with 3-*M* KCl extracts prepared from either MCA-F or MCA-F-4. Ten days later, immunized as well as nonimmunized hosts were challenged sc with 10^4 (100 MTD) MCA-F or MCA-F-4 cells. Tumor diameters were serially measured, mean tumor diameters were computed, and the differences between immunized and nonimmunized groups were compared by means of Student's *t*-test.

Protocol design.—Effect of fraction 15 on the formation of pulmonary and extrapulmonary tumor colonies: Five groups of 30 mice received injections iv of 10^2, 10^3, 10^4, 10^5, or 10^6 MCA-F cells. One day later, 15 mice in each group were treated with three weekly sc injections of 25 μg fraction 15. In addition, 15 mice were not treated. At 21 days after iv challenge, all mice were killed; pulmonary tumor colonies were enumerated, and the groups were compared by means of the Wilcoxon two-sample rank sum test.

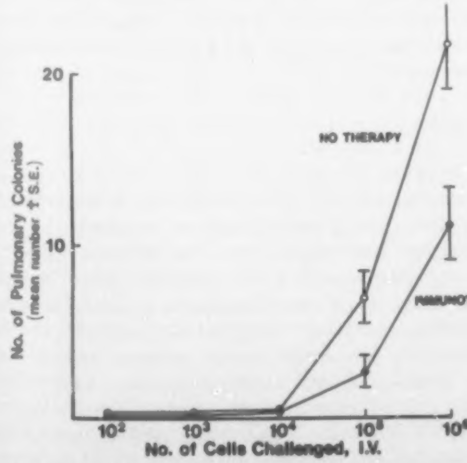
Effect of fraction 15 on the survival rates of hosts challenged iv with MCA-F or MCA-F-4 cells: Groups of virgin C3H/HeJ mice received injections iv of varying numbers of MCA-F cells—10^3 (10 MTD; No. of mice=30), 10^4 (100 MTD; No. of mice=40), 10^5 (1,000 MTD; No. of mice=30), or 10^6 (10,000 MTD; No. of mice=30). Separate groups of virgin mice received injections of MCA-F-4 cells at a dose of either 10^4 (100 MTD; No.=40) or 10^5 cells (1,000 MTD; No.=40). One day later, half the members of each group were treated with weekly sc injections of 25 μg fraction 15; the other half were not treated. Differences in survival rates among animals in these groups as computed by the 50% survival time were analyzed by means of the chi-square method, previously described (*7*).

Effect of fraction 15 on spontaneous pulmonary metastases: The therapeutic effect of fraction 15 on spontaneous pulmonary metastases was investigated with the use of a metastatic variant MCA-F-4. Two groups of 25 mice were inoculated sc in the flanks with 10^5 MCA-F-4 cells. Mice were resected of 1.0- to 1.5-cm tumors at 14 days after the inoculation. One group of 25 mice was treated with weekly injections of 25 μg fraction 15; the other group of 25 mice was not treated. At 21 days after resection, all mice were killed and pulmonary metastases were enumerated. The incidence of metastases, i.e., the proportion of hosts displaying nodules, in the 2 groups was compared by the chi-square test. The number of metastases per mouse was compared by means of the Wilcoxon two-sample rank sum test.

RESULTS

Effect of immunotherapy on tumor colonies in pulmonary and extrapulmonary tissues.—Pulmonary tumor colonies were enumerated 21 days after iv inoculation of 10^2, 10^3, 10^4, 10^5, or 10^6 MCA-F cells into syngeneic, virgin C3H/HeJ mice. Mice given injections of 10^2, 10^3, or 10^4 MCA-F cells displayed only rare colonies in the lungs, presumably due to the low incidence of cell variants capable of forming pulmonary metastases. As the inoculum dose increased, an effect of therapy was apparent. The average number of pulmonary tumor colonies in mice challenged iv with 10^5 cells was 6.8±1.7 in untreated hosts and 2.5±0.7 in treated animals ($P<0.05$). Untreated mice given injections iv of 10^6 cells showed 21.6±3.0 (mean ± SE) pulmonary colonies, whereas the treated group displayed 11.0±2.2 pulmonary colonies ($P<0.01$) (text-fig. 1). Therefore, three weekly injections of fraction 15 after iv challenge with MCA-F cells significantly decreased the number of pulmonary tumor colonies. A second experiment confirmed the original one: The number of nodules in each afflicted animal was reduced, but the incidence of mice with pulmonary metastases was unaffected (table 1). Furthermore, fraction 15 had no therapeutic effect on metastases in extrapulmonary sites (table 1). Although not statistically significant, there appeared to be an increased incidence and number of extrapulmonary metastases in treated hosts.

Immunologic specificity.—To ascertain immunologic specificity, we treated groups of C3H mice with fraction 15 prepared from either MCA-F or MCA-D tumors following iv challenge with 10^5 MCA-F cells. Whereas MCA-F fraction 15 decreased the number of pulmonary tumor colonies produced by homotypic MCA-F cells, the immunoprotective fraction from the antigenically distinct MCA-D tumor, which was demonstrated to display specific immunoprophylaxis against 100 MTD of MCA-D [data not shown but similar to those in (*7*)], had no effect on the formation of MCA-F pulmonary tumor colonies. Thus the effect of fraction 15 on pulmonary tumor colonies is immunologically specific (table 2).



TEXT-FIGURE 1.—Effect of fraction 15 on the formation of pulmonary tumor colonies. A group of 30 mice were given injections iv of 10^6 MCA-F cells. One day later, 15 mice received either three weekly injections of 25 µg fraction 15 (●——●) or were not treated (○——○). At 21 days all mice were killed, and pulmonary tumor colonies were enumerated.

TEXT-FIGURE 2.—Cross-immunoprotection test. Groups of 10 mice were immunized with 3-*M* KCl extracts from MCA-F (○) or MCA-F-4 tumor (□). Ten days later, immunized as well as nonimmunized hosts (●) were challenged sc with 10^4 (100 MTD) MCA-F cells (*left panel*) or MCA-F-4 cells (*right panel*). Tumor diameters were serially measured, and mean tumor diameters were computed.

lung passage in vivo. The variant displays greater avidity for pulmonary, compared to extrapulmonary, tissues. Not only was the number of pulmonary nodules decreased but also the length of host survival was prolonged in hosts treated with fraction 15 after iv injection of 10^4, but not of 10^5, cells (table 3). The slightly prolonged survival of animals inoculated with MCA-F-4 may have been due to the reduced incidence of lethal extrapulmonary metastases, which apparently escape the immunotherapeutic effect of fraction 15 (data not shown).

MCA-F-4 cells implanted sc spontaneously metastasize to the lung during early stages of tumor growth. Treatment with 25 μg fraction 15 reduced the incidence of pulmonary metastases in treated hosts (table 4): 61% of untreated but only 28% of fraction 15-treated mice displayed pulmonary metastases 21 days after resection of 1-cm MCA-F-4 flank tumors. The average number of metastatic foci in afflicted mice was not significantly different between treated and untreated groups (data not shown). The benefit of immunotherapy was most evident in mice bearing local recurrences of the MCA-F-4 tumor; 82% of untreated hosts displaying a local recurrence bore pulmonary metastases. In contrast, three weekly injections of 25 μg fraction 15 significantly decreased the incidence of pulmonary metastases in the recurrence group to 23% ($P<0.01$). The results demonstrate that fraction 15 treatment reduces the incidence of spontaneous hematogenous metastases following resection of a primary tumor, particularly in hosts at high risk for disease recurrence.

Common TSTA between unselected MCA-F and variant MCA-F-4 tumors.—Text-figure 2 shows the outgrowth of MCA-F and MCA-F-4 tumors after immunoprophylaxis with 3-*M* KCl extracts. Mice immunized with crude tumor extracts, either from the original MCA-F tumor or from MCA-F-4, were protected against challenge with either the parent MCA-F or the variant MCA-F-4 tumors. Since the tumors share a cross-reactive TSTA, a major antigenic modulation during the process of selection of the metastatic variant is excluded. These findings are consistent with the suggestion that the therapeutic effects of MCA-F fraction 15 are due to the induction and/or potentiation of host resistance against a TSTA shared with MCA-F-4.

DISCUSSION

Immunotherapeutic application of a tumor extract demands antineoplastic effects not only against local recurrences but also against hematogenous metastases. The investigations described herein extend our previous report (*11*) of therapeutic effects against subcutaneous growths of the MCA-F sarcoma to therapeutic effects against hematogenous pulmonary metastases induced artifically by iv injection or naturally by dissemination from a subcutaneous neoplasm. Weekly administration of fraction 15 decreased the number of pulmonary tumor colonies 3 weeks after iv injection of MCA-F cells. The protection was immunologically specific: MCA-D fraction 15 had no effect on pulmonary nodules following iv inoculation of the heterotypic MCA-F tumor. These findings demonstrate that pulmonary metastases bear at least one common surface antigen present on subcutaneous MCA-F tumors from which fraction 15 was prepared, in addition to any distinctive markers that have been suggested in previous reports (*17–20*).

Fraction 15 treatment did not prolong the survival of hosts challenged iv with MCA-F cells. Although the therapeutic regimen reduced the number of MCA-F lung colonies, it had no effect on extrapulmonary tumor metastases that displayed unimpeded progression leading to death. The differential susceptibility of pulmonary, but not extrapulmonary, metastases to fraction 15 may reflect 1) unique properties of the induced systemic immune response that favor the elimination of cells bearing specific surface properties leading to proclivity for pulmonary colonization, 2) a possible effect of fraction 15 to promote natural killer activity eliminating intravascularly disseminated cells destined to be pulmonary metastases, 3) redirection of cells potentially capable of implanting in the lung to extrapulmonary sites, 4) differential activation of pulmonary host defense mechanisms by fraction 15 therapy, and 5) loss of the TSTA on extrapulmonary metastases. Failure to affect extrapulmonary metastasis is distinctive of fraction 15 therapy, because treatment with crude butanol extracts of MCA-F is equally effective against pulmonary and extrapulmonary metastases (*21*). Therefore, it is most likely that the differential effect of the immunity induced by fraction 15 reflects either a unique susceptibility of variants forming pulmonary metastases or host defenses resisting neoplastic cells destined for, or resident in, the lung.

To demonstrate an effect of fraction 15 immunotherapy on the survival of hosts artificially challenged iv with tumor cells, we used the method described by Fidler for B-16 melanoma in C57BL/6 mice (*16*) to isolate the MCA-F-4 cell variant, which displayed a propensity to form pulmonary, but not extrapulmonary, metastases. Fraction 15 immunotherapy prolonged the survival of hosts inoculated iv with MCA-F-4, presumably due to the aversion of the tumor to grow in subcutaneous sites. Of greater importance as a model for metastatic neoplastic disease was the tendency of MCA-F-4 implanted sc to disseminate hematogenously as spontaneous lung metastases; 61% of mice showed spontaneous pulmonary metastases 21 days after the resection of exponentially growing 1-cm subcutaneous tumors. Conversely, mice bearing 2-cm MCA-F neoplasms display only an 8.7% incidence of pulmonary metastases (data not shown). Furthermore, the 82% incidence of pulmonary metastases in mice with local recurrences of MCA-F-4 after resection of 1-cm tumors was almost twice the incidence in animals free of a local recurrence. The greater immunotherapeutic effect of antigen in hosts at high risk for disease recurrence may be due to the necessity to potentiate their weak resistance (*22–27*), which is otherwise insufficient to overcome residual neoplastic cells, particularly when reactivity is dampened by surgical procedures (*28–32*). These findings are consistent with our recent observations that tumor extract therapy yields superior results in hosts with low concomitant immunity (Inabass S, Pellis NR, Kahan BD: Unpublished observations).

The effect of immunotherapy on the number of lung metastases is critically dependent on the antigen dose and the tumor burden at the time of treatment (*17, 33*). Administration of excess soluble TSTA (*34*) or irradiated tumor cells (*35*) has been shown to impair the expression of concomitant immunity after surgery, to antagonize host resistance, and to increase the number of metastases. These effects may be due at least in part to the presence of antigenic determinants stimulating immune responses that facilitate neoplastic outgrowth (*36*). Contrarily, the results presented herein demonstrate that separation of the immunogenic fraction 15 from antigens facilitating tumor growth provides an effective stimulus to boost host resistance against hematogenous metastases. These effects of fraction 15 compel further evaluation of the potential of tumor extracts as tools for adjuvant immunotherapy of human cancer.

Dose-Response Studies With Nitrosoheptamethyleneimine and its α-Deuterium-Labeled Derivative in F344 Rats[1,2,3]

W. Lijinsky,[4] M. D. Reuber,[4] T. S. Davies,[4] *and* C. W. Riggs[4]

ABSTRACT—A dose-response study of the carcinogenicity of nitrosoheptamethyleneimine (N-HEP) in inbred F344 male and female rats was performed by administration of the nitrosamine at several concentrations in drinking water to groups of 20 rats. The concentrations differed by a factor of nearly 2.5 and ranged from 1.0 to 100 mg/liter. The duration of treatment was 13, 25, 50, or 100 weeks, after which the animals were allowed to die naturally of tumors induced. In most treated groups the incidence of tumors of the upper gastrointestinal tract approached 100%. However, at the higher doses there was an inverse relationship between total dose and survival time of the rats. Matched treatment of groups of rats with N-HEP labeled with deuterium in the alpha positions resulted in longer survival. The slower action of the deuterium-labeled compound, as measured by a lower rate of death from tumors, suggests that cleavage of a carbon–hydrogen bond at an alpha position is a rate-limiting step in carcinogenesis by N-HEP in rats.—JNCI 1982; 69:1127–1133.

Experiments in which deuterium-labeled nitrosomorpholine, nitroso-2,6-dimethylmorpholine, and nitrosoazetidine have been used have shown that, in rats, replacement of hydrogen at the α-carbon atoms with deuterium reduces carcinogenic potency (*1–3*). A similar observation was made with deuterium-labeled nitrosodimethylamine (*4*) and suggested that, in both cyclic and open-chain nitrosamines, oxidation at the α-carbon atom was a rate-limiting step in carcinogenesis. Analysis of the effects of deuterium substitution was more difficult for the asymmetric nitrosomethylethylamine (*5*), nitrosomethyl-2-phenylethylamine (*6*), and nitrosomethyl-*n*-butylamine (*7*). All of the foregoing compounds induced tumors either in the liver or esophagus of rats, and some compounds induced tumors in both locations. To expand our understanding of the role of alpha oxidation in carcinogenesis by nitrosamines, we examined the effect of deuterium substitution on the carcinogenic potency of N-HEP in rats. This compound has been reported to induce lung tumors in rats (*8, 9*). Because several dose rates must be used to establish the effect of deuterium substitution with some certainty, a dose-response study of N-HEP was done and is reported here.

MATERIALS AND METHODS

Chemicals.—N-HEP was prepared as described previously (*8, 9*).

N-HEP-d_4 was prepared by exchange of 8 g of N-HEP with 60 ml of deuterium oxide in the presence of 30 g of sodium ethoxide, the reaction mixture being boiled under reflux for 4 hours. After cooling, 100 ml methylene chloride was added to the dark brown reaction mixture, followed by 100 ml water. The mixture was shaken gently, and after the layers were allowed to separate, the lower, pale yellow solution was separated off and the upper layer was discarded. The lower (methylene chloride) layer was washed twice with 30 ml water, after which the methylene chloride was distilled off, leaving a light brown oil. This was then exchanged with deuterium oxide and sodium ethoxide, exactly as described above. The procedure was repeated an additional three times (a total of five exchanges), and the product was distilled under reduced pressure, yielding 4 g of yellow liquid which had a boiling point of 98–99°C at 2 mm Hg. The mass spectrum of the product after each exchange was measured, and the spectrum showed progressive replacement of hydrogen by deuterium, as reflected by increase in the ions of mass 145 and 146 at the expense of ions of mass 142 and 143. The mass spectrum of the product after five exchanges showed that 93% of the hydrogens at the alpha positions had been replaced by deuterium and that ions of mass 146 comprised the overwhelming proportion of the molecular ions, observations consistent with a majority of the molecules being N-HEP-d_4.

Animal treatments.—Groups of 20 male F344 rats of the colony of the NCI-Frederick Cancer Research Facility were used for each treatment; they were 7–8 weeks old at the beginning of the treatment. The animals were housed four to a plastic cage with a wire-mesh bottom. Each cage of rats was given 80 ml of a solution of N-HEP as drinking water on each of 5 days/week; on the other 2 days, tap water was given ad libitum so that the animals could make up any water deficit they had incurred. After the animals became accustomed to the taste of the N-HEP solution, which took a few days, almost all of the solutions were consumed, with little spillage, so that the average dose received by the animals could be estimated reasonably well. Each treatment solution was prepared by dilution of a stock solution of N-HEP in ethanol, prepared once every 3 months, with deionized water at pH 6.8–7.2. The treatment solutions were dispensed to the animals for prescribed numbers of weeks, after which the animals were allowed to die naturally (a few were killed when moribund); each animal was given a complete necropsy and any lesions and all major organs were fixed for histologic examination.

The animals in groups 1–9, 13, and 14 (table 1) and the untreated controls were all from the same lot and were introduced to the experiment simultaneously. To assess the

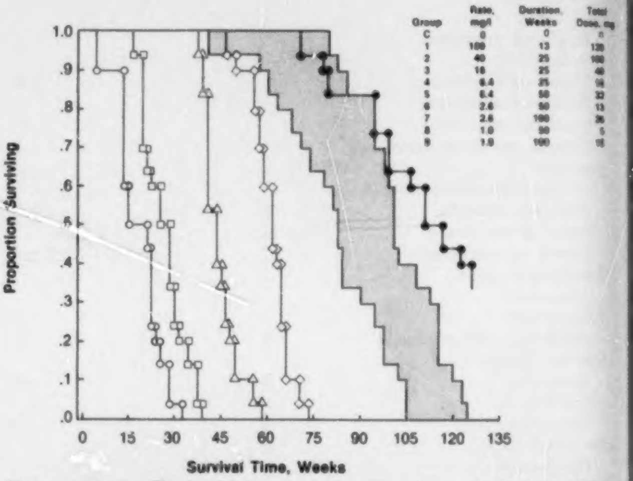
differences between male and female F344 rats in response to N-HEP and to assess the effect of deuterium substitution thereon, we began groups 10–12, each containing 20 females, later. Groups 12–14 were given the deuterium-labeled nitrosamine; all other groups received the unlabeled compound.

Statistical methods.—The survival patterns for many of the test groups were compared both graphically and analytically. The graphs of the survival curves were constructed on the basis of the Kaplan-Meier methodology (*10*), which adjusts for censored observations. The censored observations resulted from those relatively few animals that survived until the termination of the study and the several animals that were killed in one of the groups during the course of the study. The individual survival curves were comparable, pairwise, when the method of Mantel and Haenszel (*11*) was used. When the incidence of upper GI tract tumors did not differ significantly between groups of rats receiving different treatments, the only difference in carcinogenic effectiveness that could be measured easily was a difference in survival between the groups, inasmuch as the tumors lead to death of the animals. The analyses were produced with the computer program developed and described by Thomas et al. (*12*). Tumor incidences were compared by the exact test of Fisher (*13*).

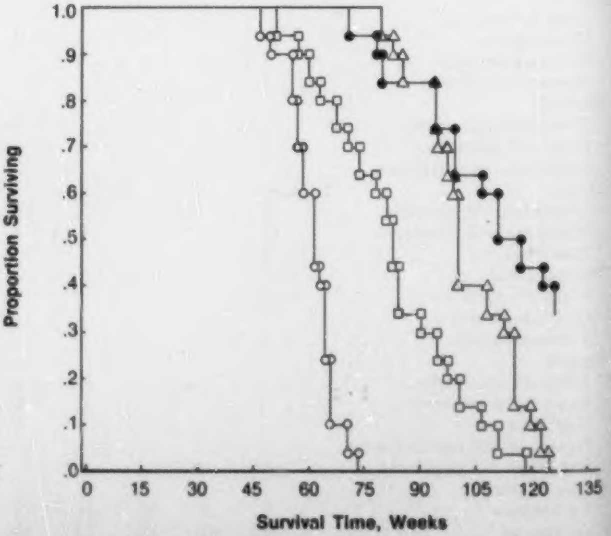
RESULTS

In table 1 is listed every tumor found in our F344 rats, according to treatment group. Among the rats given N-HEP, the commonest sites of occurrence of tumors not found in the untreated rats were in the upper GI tract (esophagus, oropharynx, tongue, and forestomach). These tumors were also not seen in a large survey of untreated F344 rats in other laboratories (*14*). A few tumors of the nasal cavity occurred, but these appeared only in certain dosage groups. In marked contrast with a previous study in F334 rats (*15*), in the present study very few tumors in the lungs developed, perhaps because in the former study N-HEP was given in oil solution by gavage.

As measured by the mortality rate from tumors of the upper GI tract in our rats (text-fig. 1), carcinogenic effectiveness of the treatment decreased from group 1 to group 4. Although we originally planned to treat all groups for a minimum of 25 weeks, this was not possible in group 1 because the animals had begun to die with tumors at the 12th week; consequently, treatment was stopped at the 13th week, which formed the rationale for stopping treatment in



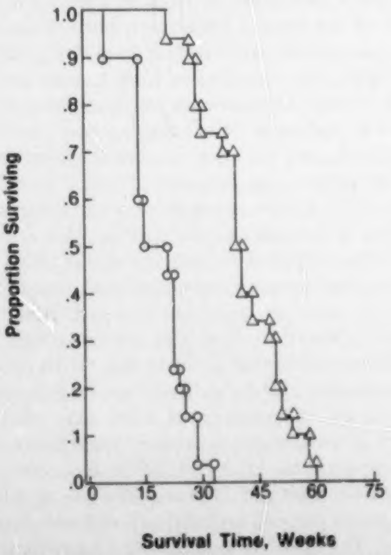
TEXT-FIGURE 1.—Kaplan-Meier survival curves for unlabeled N-HEP-treated groups, individually represented, with respect to death from all causes. Group 1, ○; group 2, □; group 3, △; group 5, ◇; and untreated control (C), ●. Curves for groups 4 and 6–9 all lie within the *shaded area*. *See* table 1 for parameters of treatment for groups C–9.



TEXT-FIGURE 2.—Survival curves with respect to death from all causes for groups receiving unlabeled N-HEP for 50 wk. Group 5, ○, received 6.4 mg N-HEP/liter; group 6, □, received 2.6 mg N-HEP/liter; group 8, △, received 1.0 mg N-HEP/liter; and the control, ●, was untreated.

all of the comparable groups at week 13. The rate of mortality in group 5 was considerably greater than that in group 4, corresponding with the longer treatment with 6.4 mg N-HEP/liter. The mortality rates in groups 4, 6, and 7 were greater than the rates in the untreated animals, although the rates were not statistically different from each other. Mortality in groups 8 and 9 was also significantly different from that of the untreated rats, but the difference in mortality between group 8 and group 9 was not significant. The number of animals in group 8 with tumors of the upper GI tract was 2, not a significant incidence if considered alone. For those groups treated for 50 weeks (groups 5, 6, and 8), significant differences in mortality rates were observed; each of the groups also differed from the untreated control (text-fig. 2).

Considering the effect of deuterium labeling on carcinogenicity, we saw no significant difference in numbers of animals with upper GI tract tumors between group 1 and group 14 both of which received 100 mg N-HEP/liter for 13 weeks, although fewer animals had malignant tumors (carcinomas) in group 1 than in group 14, presumably reflecting longer survival of group 14 animals. Examining the mortality of the rats in groups 1 and 14 (text-fig. 3), we found that rats in group 1 died considerably more rapidly than rats in group 14, the group that received the deuterium-labeled compound. At 40 mg N-HEP/liter, the effect of deuterium labeling was similar; as shown in text-figure 4A, the mortality in group 2 (given N-HEP) was much greater than that in group 13 (given N-HEP-d_4). Similarly, in females given the same concentration of N-HEP or N-HEP-d_4 for 13 weeks (text-fig. 4B), group 11 (given N-HEP) showed a higher mortality rate than did group 12 (given N-HEP-d_4). The death rate of the females given 40 mg N-HEP/liter (group 11) appeared higher than that of the males (group 2), even though the former received N-HEP for only 13 weeks (compared with 25 wk for the latter), and the higher death rate of the females was probably due to the higher dose per unit body weight which they received during the first 13 weeks, which perhaps is the crucial period for induction of tumors of the upper GI tract by N-HEP.



TEXT-FIGURE 3.—Survival curves for selected treatment groups receiving 100 mg N-HEP or 100 mg N-HEP-d_4/liter for 13 wk. Group 1, ○, was from the original, unlabeled set; group 14, △, was deuterium labeled and tested concurrently with group 1.

Table 2 shows the incidence of tumors of the upper GI tract for selected groups. For those groups receiving the lower doses of N-HEP for 50 and 100 weeks, a clear dose-response relationship emerged both for carcinomas alone and for total tumors. However, for those groups receiving the higher doses for 25 weeks, no dose-response relationship emerged for either carcinomas alone or total tumors; this is most likely a result of the highly significant inverse relationship between dose level and survival time.

Table 3 provides a comparison of tumor incidence for the N-HEP and N-HEP-d_4 groups for both males and females. Although the total tumor incidence was essentially unchanged by the addition of the deuterium label, the incidence of carcinomas was significantly greater for the groups receiving the labeled compound; the most likely explanation for this difference is the longer survival of the groups receiving the labeled compound.

TEXT-FIGURE 4.—Survival curves for groups receiving 40 mg N-HEP or 40 mg N-HEP-d_4/liter for 25 wk (males) and for 13 wk (females). Groups 2 and 11, ○, received N-HEP; and groups 13 and 12, △, received N-HEP-d_4.

DISCUSSION

An examination of the mortality rates in text-figures 1 and 2 shows a clear relationship between the dose rate of N-HEP and the carcinogenic effectiveness of the treatment as measured by higher mortality. This pattern is shown both for the groups treated for 25 weeks and for the groups treated for 50 weeks. The incidence of tumors of the upper GI tract in group 8 was small (2/20), and 1 mg N-HEP/liter for 50 weeks (a total of 5 mg) might represent the smallest effective dose of N-HEP in an animal group of this size. This observation contrasts with the findings with nitrosodiethylamine (*16*) and nitrosomethyl-2-phenylethylamine (*6*), in which total doses of less than 3 mg gave rise to highly significant incidences of tumors of the upper GI tract.

At 100 mg N-HEP/liter, the compound was quite toxic; it led to early death of many rats with pneumonia, and it possibly accelerated death of the remaining tumor-bearing rats. This might explain the small number of carcinomas of the upper GI tract in animals of group 1 as compared with the number in group 14: Not only were the animals in group 1 dying before they developed carcinomas, but also the females in group 10 largely succumbed to the toxic action of N-HEP (of the 20 group 10 animals, 13 were dead by the 12th wk and the remaining 7 animals all developed carcinomas). The fact that the smaller females received a relatively larger dose per unit body weight than the males is probably a factor.

At 40 mg N-HEP/liter, deuterium labeling had a very clear effect in reducing the carcinogenic effectiveness (as measured by increased survival) of N-HEP in both males and females (text-fig. 4). This result lends additional support to the concept that carcinogenesis by nitrosamines (at least in rats) begins with oxidation at the carbon atom alpha to the nitroso function, which is, therefore, a rate-limiting step in carcinogenesis. Hecht and Young (*17*) have recently shown that deuterium labeling at the α-carbons of nitrosomorpholine leads to a lower formation rate for those metabolites that arise from alpha oxidation, which correlates well with the diminished carcinogenicity of nitrosomorpholine when deuterium replaces hydrogen at the alpha positions (*1*). An anomaly is the enhancing effect of deuterium labeling in the alpha position on carcinogenesis by nitroso-2,6-dimethylmorpholine in Syrian golden hamsters (*18*), which suggests that induction of pancreas tumors by this nitrosamine in hamsters might proceed by a mechanism other than alpha oxidation.

One surprising result of this study is the low incidence of lung tumors in our F344 rats treated with N-HEP in their drinking water. Previous experiments in which N-HEP was given to MRC Wistar-derived rats (*8, 9*) and to Sprague-Dawley rats (*19*) in their drinking water or was even given in the form of its precursors, heptamethyleneimine plus nitrite, in the drinking water of Sprague-Dawley rats (*20*) have led to the induction of high incidences of squamous cell tumors of the lung. Likewise, in both Sprague-Dawley and F344 rats treated with N-HEP in oil by gavage or by sc injection, significant numbers of lung tumors were induced (*15*). In all of these experiments, the incidence of tumors of the upper GI tract was also high, as was true for Syrian golden hamsters, but no lung tumors occurred in the hamsters (*21*). In guinea pigs, however, N-HEP failed to induce any tumors (*22*), a rare example of a carcinogenic nitrosamine finding a nonsusceptible species. We must assume, because of these differences, that the metabolism of N-HEP in F344 rats, when given in drinking water (and therefore at relatively low rates per unit time), is such that the lung is insufficiently affected for it to give rise to tumors. Studies of the metabolism of N-HEP in F344 rats (with special attention to metabolism in lung vs. liver) are in progress and will be expanded to comparisons of F344 rats with Sprague-Dawley rats in an attempt to answer this question.

Our conclusions are that N-HEP is a potent carcinogen for the upper GI tract of F344 rats, effective at total doses of a few milligrams per rat, and shows a definite dose-response relationship. The effect of α-deuterium labeling in reducing carcinogenic potency of N-HEP (as measured by reduced time to death from tumors) indicated that oxidation of an α-carbon atom was a rate-limiting step in carcinogenesis.

Induction of Mammary Neoplasms in the ACI Rat by 430-keV Neutrons, X-Rays, and Diethylstilbestrol[1,2,3]

Claire J. Shellabarger,[4] **Danielle Chmelevsky,**[5] **Albrecht M. Kellerer,**[5] **J. Patrick Stone,**[4] *and* **Seymour Holtzman**[4,6]

ABSTRACT—Mammary tumorigenesis was studied in female ACI rats after treatment with X-irradiation or neutron-irradiation, with or without diethylstilbestrol (DES) treatment. The mortality-corrected cumulative tumor rate based on all mammary neoplasms and the mortality-corrected incidence based on the first neoplasms only have been derived. In non-DES-treated animals, at the relatively high radiation doses studied, all dose–effect relationships were consistent with relative biological effectiveness (RBE) values slightly in excess of 10. In DES-treated rats definite findings were observed at neutron doses as low as 0.01 Gy (1 rad). The dose–effect relationship in DES-treated rats showed a strong sublinearity (dose exponent <1) at low neutron doses. RBE values in DES-treated rats increased in inverse proportion to the square root of the neutron dose, and exceeded 100 at a neutron dose of 0.01 Gy (1 rad).—JNCI 1982; 69:1135–1146.

In female rats of the ACI strain, both low LET and high LET radiations induce mammary AC and mammary FA (*1, 2*). In this strain of rat, a form of synthetic estrogen, DES, induces mammary AC, but no mammary FA, when given in the form of a 20-mg pellet of 25% DES and 75% cholesterol (*3*). Furthermore, in ACI rats, the effect of DES and ionizing radiations appears to be synergistic for mammary AC formation, as shown in studies with X-rays by Segaloff (*4*) and later by Stone et al. (*2*), and in studies with neutrons by Shellabarger et al. (*5*).

The present work is primarily aimed not at the further elucidation of the synergistic effect but at the comparison of the effects of X-rays and neutrons at low doses. Therefore, graded X-ray and neutron doses were applied and only one dose of DES was utilized. The interest in this investigation is due to the theoretical prediction (*6*) and the experimental observation in various systems (*7–9*) of high-neutron RBE, which may be of considerable impact to radiation protection because they support the suggestion that the quality factor of 10, now used for neutrons, should be reconsidered (*10*). The only source of human data for neutrons, the Japanese atomic bomb survivors, may be lost due to the revision of neutron dosimetry (*11*); thus data from animal studies with low doses of neutrons have gained importance.

In an earlier experiment with Sprague-Dawley rats, very low doses of neutrons were used, and for a neutron dose of 1 mGy an RBE in excess of 100 was found (*12, 13*). However, it remained unclear whether this finding was specific to the Sprague-Dawley rats only, with the high spontaneous incidence and with a considerably larger number of FA than AC characteristic to this strain. Therefore, it appeared desirable to conduct analogous studies with ACI rats that have a very low spontaneous incidence of mammary neoplasms and show predominantly AC when treated with DES.

A second aspect of the earlier findings on Sprague-Dawley rats was of particular importance and has been an additional motivation of the present study. This was the finding of a substantial *sublinearity*, i.e., a negative curvature of the dose-effect relationship, at small neutron doses. Such a sublinearity implies that the effect per unit dose is largest at smallest doses and is therefore of evident concern in radiation protection, for which risk assessments are commonly based on the linear hypothesis. Sublinearity is also of interest because it occurs at doses that are sufficiently small that only few cells are traversed by any neutron recoil, and the probability of several recoils can be disregarded (*14, 15*). In this dose range the tendency is to postulate linear dose dependences for neutrons, because the number of cells that receive any energy deposition is merely proportional to dose. The failure to find a linear relation has therefore been interpreted as evidence of a multicellular reaction or a radiation-induced tissue factor (*15*). Examination of the linearity or nonlinearity of the dose–effect relationship for neutrons was accordingly another main goal in the present investigation.

MATERIALS AND METHODS

Rats and treatment schedules.—Approximately 800 weanling, virgin, female ACI rats were purchased from M.A. Bioproducts, Walkersville, Md. Rats were delivered to this laboratory in eight shipments of at least 50 rats at weekly intervals. From each shipment 3 rats were assigned to each of 14 groups that were to be irradiated, and 4 rats were assigned to each of 2 groups that were reserved as nonirradiated controls. This procedure was repeated with another 400 rats. Thus all 16 groups were matched closely for age both in regard to the average age and the range of ages. Neutron irradiation was given to rats with an average age of 88 days, and X-irradiation was given to rats with an average age of

89 days. All irradiations were done as described previously (*5*). DES (5 mg) was given, in pellet form, 2 days before irradiation, with methods described earlier (*4*). All data were recorded in days after the date of DES administration and, for simplicity, all ages, life-spans, and times quoted in this article refer to the date of DES administration as time 0.

All rats were kept in temperature-controlled (21–23°C) and humidity-controlled (45–65%) animal rooms with 12 hours (8 a.m.–8 p.m.) of fluorescent light. The animals were maintained on commercial rat chow and water ad libitum. Each rat was examined at least weekly for the presence of mammary tumors, and all mammary tumors were studied microscopically and given a pathologic classification of either AC or FA according to criteria consistent with those of Young and Hallowes (*16*).

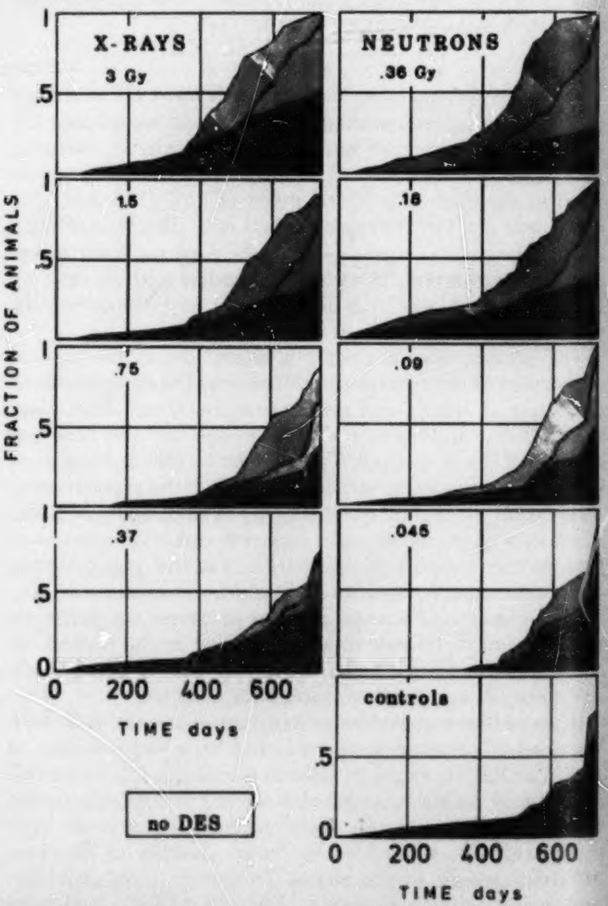
Tumor methodology.—Each rat was identified by a numbered ear tag. The anatomic location of each mammary tumor was recorded with the nipples as reference points. Because two distinct types of mammary tumor responses were found, individual or multiple, each was recorded separately. Individual mammary tumors were removed under ether anesthesia at a size of about 2 cm. If a second tumor was found at the site of a previously removed tumor, it was not recorded as a second individual tumor unless a 10-week period had elapsed between removal of the first tumor and the detection of the subsequent tumor. In the other type of mammary tumor response, which was confined to mammary AC in DES-treated rats, multiple AC were often detected within a single quadrant of mammary tissue over about 1 week. Because too many tumors existed to be counted by palpation alone, the entire quadrant was removed, fixed, defatted, stained with hematoxylin, cleared, and stored in methyl salicylate. Each quadrant was examined under a dissecting microscope at magnification 10X, and all presumed pathologic areas were removed individually for sectioning. The minimum number of these multiple AC was never less than 4 per quadrant. Even though there were often too many multiple AC per quadrant to be counted accurately, an individual quadrant was assigned a maximum number of 4 AC. Thus an individual rat could then have a maximum number of 16 AC. The multiple AC response within a single quadrant was usually found within a 1–3-week period. However, quadrants were removed not more often than twice per week. Rats were killed when they showed a multiple tumor response in all four quadrants, when they became moribund, or when tumor removal was no longer feasible. All remaining DES-treated rats were killed at days 523–525. Of the non-DES-treated rats still alive, approximately half of each treatment group was killed either on day 712 or on days 726–730. At autopsy, confirmation of DES treatment was made by locating the DES pellet. An abnormal pituitary gland was recorded as a pituitary tumor if the pituitary was hemorrhagic and fragile and exceeded a weight of 50 mg. Pituitary tumors were found in 30% of the untreated control rats, in 39% of the irradiated only rats, in 90% of the DES only rats, and in 79% of the irradiated plus DES-treated rats. The combined incidence of pituitary tumors in all nonirradiated rats was 58% compared to 52% in all irradiated rats, and the combined incidence in all non-DES-treated rats was 38% compared to 81% in all DES-treated rats. These results are in agreement with those of Stone et al. (*3*).

RESULTS

Of a total of 789 rats studied, 348 rats received DES and 441 did not receive DES. Of the rats that received DES, only 6.3% developed FA. Because of the small yield of FA in DES-treated rats (a total of 32 FA vs. 2,474 AC), the FA response in DES-treated animals was not analyzed. Among the non-DES-treated animals, 47% showed mammary neoplasms, 35% developed FA, and 26% developed AC; in view of their limited number, both types of neoplasms were pooled in the analysis.

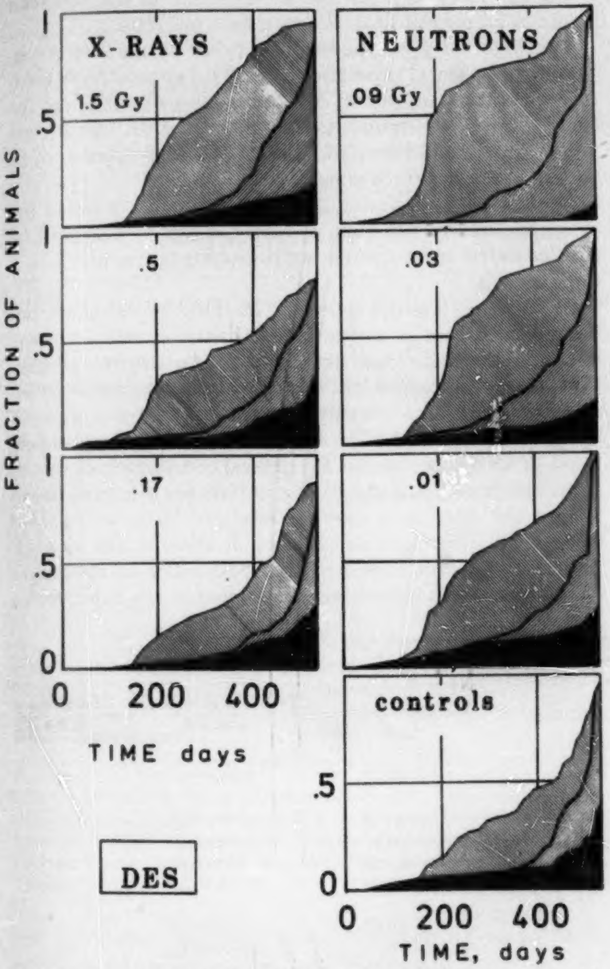
Summary of Observations

The results of this study will first be presented in elementary form; the more rigorous actuarial analysis will be given



Text-figure 1.—Fraction of the non-DES-treated animals dead or alive with and without FA and/or AC as a function of time after irradiation. Group sizes are given in table 3. ■, Fraction of animals dead without neoplasm; ▩, fraction of animals dead with at least 1 neoplasm; ▨, fraction of animals alive with at least 1 neoplasm; □, fraction of animals alive without a neoplasm.

in a second part. Text-figure 1 represents the time course of tumor incidence and mortality of the animals not treated with DES. The heavy solid lines indicate the fraction of animals dead at the specified times. The lower black areas indicate the fraction of animals dead without neoplasms; the lower shaded areas give the fraction of animals that have died with at least 1 neoplasm. The upper shaded areas give the fraction of animals alive with at least 1 mammary neoplasm. For all doses of X-rays and neutrons, the increased incidence of neoplasms is readily evident. A substantial increase of mortality is apparent only for the highest X-ray and neutron doses. The analysis of radiation-induced life shortening cannot, however, be an objective of the present study, because the surgical procedures and the killing after multiple tumor response enhance mortality.



TEXT-FIGURE 2.—Fraction of the DES-treated animals dead or alive with and without AC, as a function of time after irradiation. Group sizes are given in table 1. ■, Fraction of animals dead without AC: ▩, fraction of animals dead with at least 1 AC; ▨, fraction of animals alive with at least 1 AC; □, fraction of animals alive without AC.

Text-figure 2 is the analogous representation for the animals treated with DES. The graphs extend over a shorter period after irradiation, since the DES-treated animals have a significantly reduced life-span. In comparison to the controls in text-figure 1, the high incidence of mammary neoplasms due to DES alone is recognizable. A considerable further increase due to the irradiations is evident for the highest X-ray dose and for all neutron doses. Mortality is not substantially increased due to the irradiations in comparison to that of the control group that is treated only with DES.

Text-figures 1 and 2 are only restricted representations of the neoplastic response. In particular, multiple mammary neoplasms in an animal are not taken into account. Furthermore, no distinction is made between the two types of neoplasms, i.e., FA and AC, that occur in the non-DES-treated animals. The DES-treated animals develop almost exclusively AC.

Table 1 lists the number of animals with specified numbers of mammary AC throughout life for the DES-treated animals. In addition, it gives the mean number of AC per animal, the fraction of animals with AC, and the total number of AC. Mean lifetimes of the animals, mean AC-free lifetimes, and mean times of the first AC and of all AC are given in table 2. The analogous data for the non-DES-treated animals are given separately for FA and AC in tables 3–5.

Different types of dose–effect relationships can be derived from the raw data in the tables. Text-figure 3 gives the conventional raw incidence versus absorbed dose or the fraction of animals that develop at least 1 mammary neoplasm throughout life. The standard errors are derived from the binomial distribution. The dose scales for the X-rays

and the neutrons in this and in the subsequent text-figures differ by a factor of 10. Data for the non-DES-treated animals indicate an RBE of neutrons somewhat larger than 10. For the DES-treated animals, RBE is substantially larger and may apparently exceed 100 at the lowest dose; however, it is difficult to infer accurate values of RBE from this crude analysis.

An RBE-versus-dose relationship for neutrons will be given at the end of this paper. The curves drawn through the data in text-figure 3 correspond to this RBE–dose relationship. The same applies to the dose–effect relationships given in subsequent text-figures. These curves will not always be the best fits to the individual data, but they are always consistent with them, and they are inserted to permit a judgment of the RBE–dose relationship of the last text-figure as an overall fit to the experimental data.

Text-figure 4 gives the mean number of mammary neoplasms per animal throughout life. The approximate coincidence of the two curves for X-rays and neutrons for the non-DES-treated animals indicates again RBE values close to 10. For the DES-treated animals the RBE appears to be well in excess of 100 at small doses.

Similar conclusions can be drawn from the values of the mean tumor-free life-span in tables 2 and 5. This will be substantiated by a competing-risk-corrected analysis in a later section.

Text-figures 3 and 4 show, for the DES experiments, not only RBE values in excess of 100 but also *sublinear* dose-effect relationships (dose exponent <1) for neutron irradiation. Similarly, high RBE values and sublinear dose–effect relations were also obtained in earlier experiments with Sprague-Dawley rats (*12, 13*). In view of the evident importance of such observations for general considerations on the effects of small doses of ionizing radiations, it is essential to submit the data to a rigorous analysis. Such an analysis corrects for differences in life-span. It also permits an evaluation of the time course of the appearance of mammary neoplasms; this is particularly important in the experiments

TEXT-FIGURE 3.—Fraction of animals with mammary neoplasms as a function of the neutron or the X-ray dose. Scales for the neutron (D_N) and the X-ray (D_X) doses differ by a factor of 10. Data are given with standard errors. *Solid lines* refer to the neutron irradiations; *dashed lines*, to the X-irradiations.

with DES where the raw incidence is always close to 100% regardless of radiation dose, and where, accordingly, dose-effect curves can be constructed only on the basis of the temporal distribution of neoplasms.

Actuarial Analysis

Estimates of Cumulative Tumor Rate and Cumulative Tumor Incidence

The same basic quantities will be utilized that have been employed in the preceding article on the induction of mammary neoplasms in the Sprague-Dawley rat (*13, 17*). The tumor rate $r(t)$ is the probability per unit time interval for an animal to develop a neoplasm at time t. Because the actual time of origin of a neoplasm is unknown, it is identified with the time of first observation. The cumulative tumor rate $R(t)$ is defined as time integral of the tumor rate:

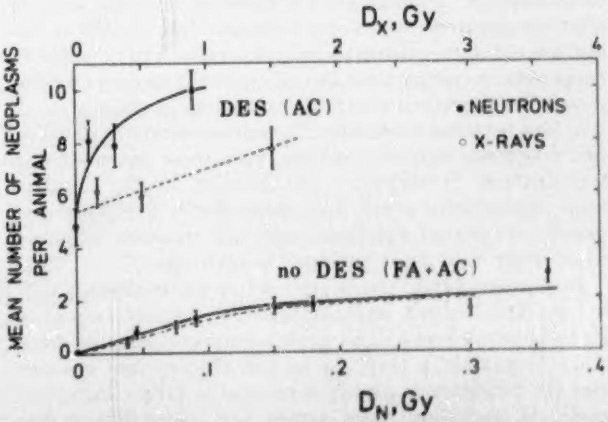
$$R(t) = \int_0^t r(t')\,dt'. \qquad [1]$$

It is difficult to estimate the tumor rate with sufficient precision, and its integral $R(t)$ is therefore a quantity more suitable to characterize the time course of the incidence of neoplasms. $R(t)$ can be considered as the expected number of neoplasms up to time t for animals that are at risk throughout the whole time period from 0 to t. However, $R(t)$ may differ from the actual mean number of neoplasms in those animals that survive up to time t; the reason is that $R(t)$ is estimated on the basis of the complete information, including tumor incidence in those animals that do not survive up to time t.

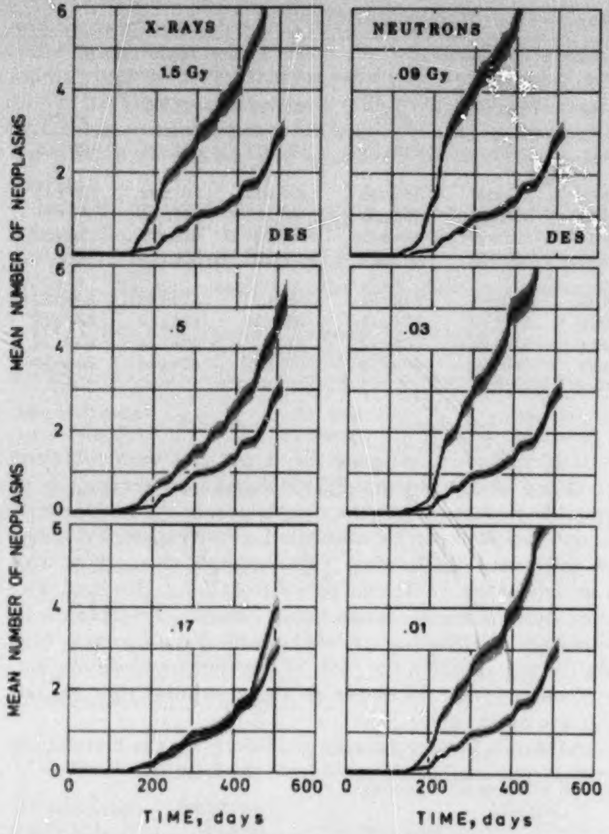
As shown in our preceding article (*13*), the cumulative tumor rate can be estimated from the formula:

$$\hat{R}(t) = \sum_i \frac{1}{N(t_i)} \pm \sqrt{\sum_i \frac{1}{N(t_i)^2}}, \qquad [2]$$

where t_i are the times of appearance of the individual neoplasms up to time t, and $N(t_i)$ are the numbers of animals still at risk at these times. The numerical values and the standard errors resulting from equation 2 are given in text-figure 5 for the DES-treated animals.



TEXT-FIGURE 4.—Mean number of mammary neoplasms as a function of the neutron or the X-ray dose. Scales for the neutron (D_N) and the X-ray (D_X) doses differ by a factor of 10. Data are given with standard errors. *Solid lines* refer to neutron irradiations; *dashed lines*, to X-irradiations.



TEXT-FIGURE 5.—Cumulative tumor rates $R(t)$ also designated as mean number of neoplasms, as a function of time after exposure to X-rays *left panels* or to neutrons *right panels* for DES-treated animals. Curves are given with their standard errors. Absorbed doses are noted in the individual *panels*. The *curve* for the unirradiated but DES-treated animals is repeated in *each panel*.

The results in text-figure 5 are obtained on the basis of all neoplasms, i.e., animals are not removed from the analysis after the occurrence of a first neoplasm but remain at risk and are not distinguished from animals that had no previous neoplasms. A comparative analysis in the subsequent section shows that the tumor rate is above average in those animals that had previous neoplasms. Therefore, estimates based on first neoplasms only will be lower than those represented in text-figure 5. Furthermore, the formula for the standard error applies strictly only to independently occurring neoplasms; the actual standard errors will therefore be somewhat larger than those indicated in text-figure 5.

A synopsis of the cumulative tumor rates at all doses both for the DES-treated and the non-DES-treated animals is given in text-figure 6. The spontaneous incidence of mammary neoplasms is very low in non-DES-treated animals, and the incidence is greatly enhanced in DES-treated animals. All radiation doses except the lowest X-ray dose enhance markedly the incidence of mammary neoplasms in DES-treated animals.

The most striking observation is the very substantial enhancement of tumor incidence due to 0.01 Gy (1 rad) of neutrons in DES-treated animals. Even without further detailed analysis, it is evident that the dose dependence for neutron irradiation of DES-treated animals is sublinear; i.e., it corresponds to a dose exponent <1. This will be substantiated in the section dealing with dose–effect relationships.

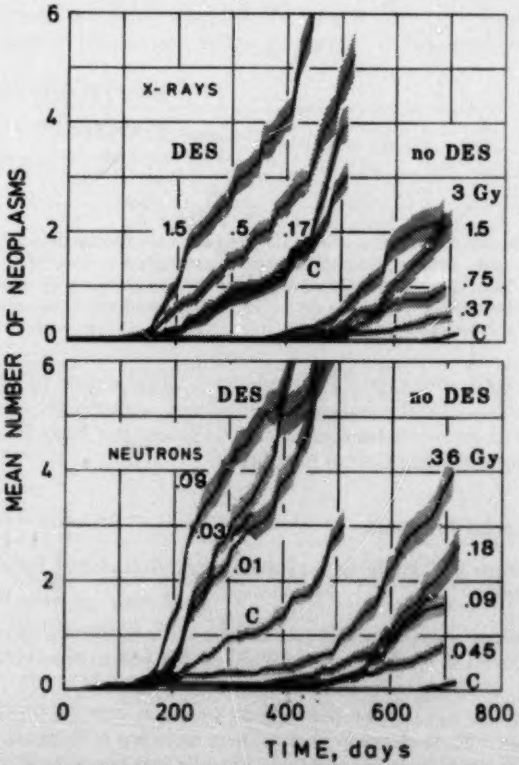
The cumulative tumor rates are not given separately for the two types of neoplasms in DES-treated animals. The absolute numbers of these neoplasms are too small to permit the identification of possible differences in the time dependence for the two types of neoplasms. Instead of the cumulative tumor rate $R(t)$, one can also derive the cumulative incidence $I(t)$, i.e., the mortality-corrected probability per animal to have at least 1 tumor. This quantity is derived by the Kaplan–Meier product limit estimate (*18*):

$$\hat{I}(t) = 1 - \prod_i \left[1 - \frac{1}{N(t_i)}\right] \pm [1 - \hat{I}(t)] \cdot \sqrt{\sum_i \frac{1}{N(t_i)^2}}. \qquad [3]$$

One may note that very nearly the same numerical values are obtained from the sum limit estimate (*see* equation 2):

$$\hat{I}(t) = 1 - \exp\left[-\sum_i \frac{1}{N(t_i)}\right]. \qquad [4]$$

In equations 3 and 4 the numbers $N(t_i)$ of animals at risk include only those animals that have not incurred an earlier



TEXT-FIGURE 6.—Cumulative tumor rates $R(t)$ also designated as mean number of neoplasms, as a function of time after exposure to X-rays *upper panel* or to neutrons *lower panel*. Curves and their standard errors are given both for DES-treated and non-DES-treated animals. Absorbed doses are noted on the *curves*. C designates controls, i.e., unirradiated animals. For non-DES-treated animals, both FA and AC are included; for DES-treated animals, only AC are included.

neoplasm. If all neoplasms were statistically independent, and if one were to deal with an entirely homogeneous population, one could include all animals and would then obtain somewhat better statistical accuracy, and, in particular, one would then have the relation:

$$I(t)=1-\exp[-R(t)]. \qquad [5]$$

However, it will be seen in the subsequent section that these conditions are not fulfilled in the present experiment. $I(t)$ is therefore determined from equation 3 by considering only those animals that had no earlier neoplasms.

Text-figures 7 and 8 represent the time course of the cumulative incidence $I(t)$ for non-DES-treated and for DES-treated animals. In both text-figures the control curve is repeated in each panel.

The difference between the estimates of $R(t)$ from all neoplasms and first neoplasms only will be considered next.

Difference of Cumulative Tumor Rates Obtained From All Neoplasms, From First Neoplasms per Quadrant, and From First Neoplasm per Animal

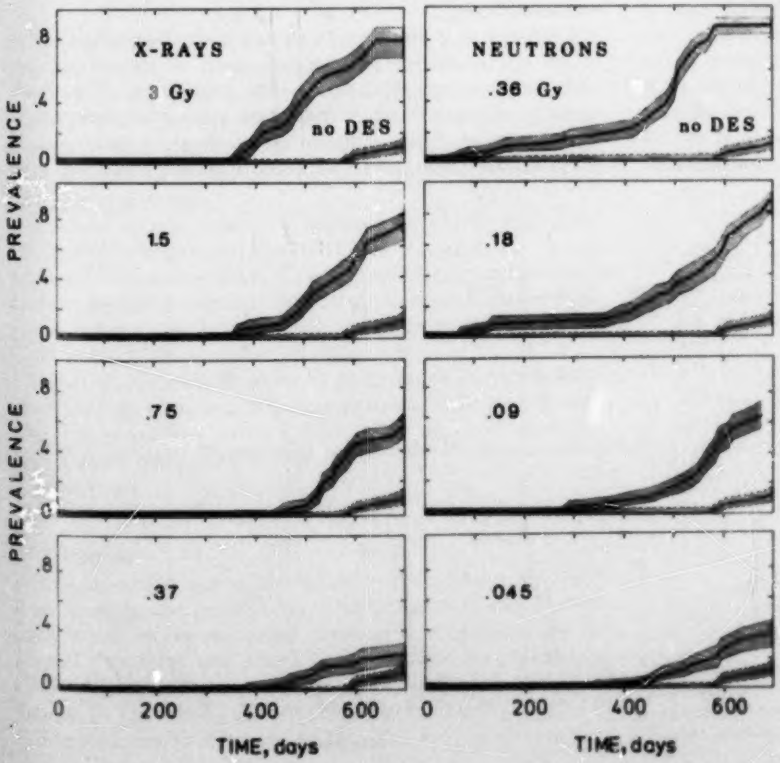
Text-figure 9 gives the estimates of the cumulative tumor rates for DES-treated animals that are obtained if all mammary neoplasms, if only the first neoplasms per quadrant of the mammary tissue, or if only the first mammary neoplasms per animal are utilized in the analysis. As stated, one should obtain essentially the same estimates if the tumor rate in the animals, or in the quadrants with previous neoplasms, were equal to the tumor rate without previous neoplasms. The difference would merely be that taking all neoplasms into account would result in a somewhat better statistical accuracy. In reality, the estimates are considerably higher if all neoplasms are included, i.e., if the animals with previous neoplasms are retained in the analysis. The estimates are much lower if only the first neoplasm per animal is taken into account, i.e., if an animal is removed from the analysis as soon as a first neoplasm has occurred. If only first neoplasms per quadrant are considered, one obtains intermediate values of the cumulative tumor rate. In this latter type of analysis, an animal is taken to be *partially at risk* according to the fraction of quadrants still unaffected.

The substantial differences in the estimates of $R(t)$ in the DES experiments indicate large differences of the tumor rates between animals with and without previous neoplasms. A similar but less substantial effect has been found in the earlier experiment with the Sprague-Dawley rats (*13*). It has also been pointed out earlier that the effect could either be due to an increase of the tumor rate after the incidence of neoplasms or, and this may be more likely, to inherent differences in sensitivity within the strain.

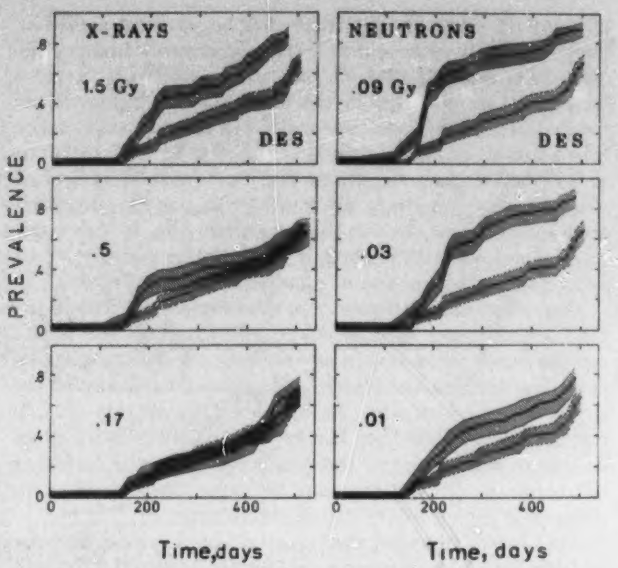
Text-figure 10 shows that there is also a certain decrease of the cumulative tumor rate in non-DES-treated animals if first neoplasms only are considered. However, the difference is smaller, and, in view of the modest size of the effect, only the curves for all neoplasms and for the first neoplasm per animal are plotted.

Dose-Effect and RBE-Dose Relationships

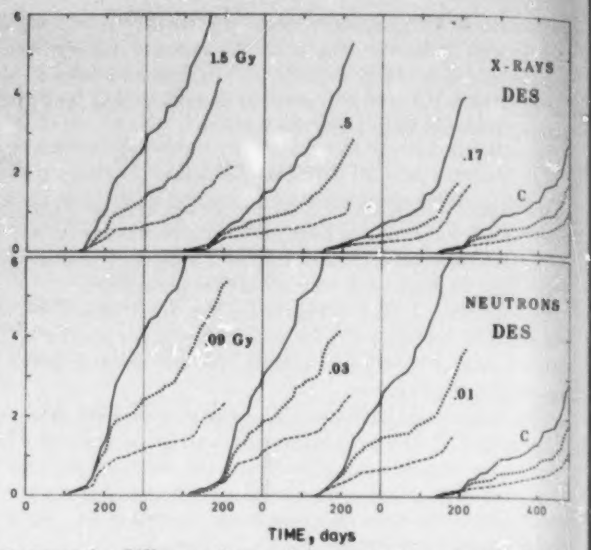
The results from the actuarial analysis can be used in several ways for the construction of dose-effect relations; it



TEXT-FIGURE 7.—Cumulative incidences $I(t)$ and their standard errors as a function of time after exposure to X-rays *left panels* or to neutrons *right panels* for non-DES-treated animals. Results are based both on AC and FA. Absorbed doses are given in the individual *panels*. The *curve* for the controls is repeated in *each panel*.



TEXT-FIGURE 8.—Cumulative incidences $I(t)$ and their standard errors as a function of time after exposure to X-rays *left panels* or to neutrons *right panels* for DES-treated animals. Results are based on AC only. Absorbed doses are given in the individual *panels*. The *curve* for the unirradiated, but DES-treated controls is repeated in *each panel*.



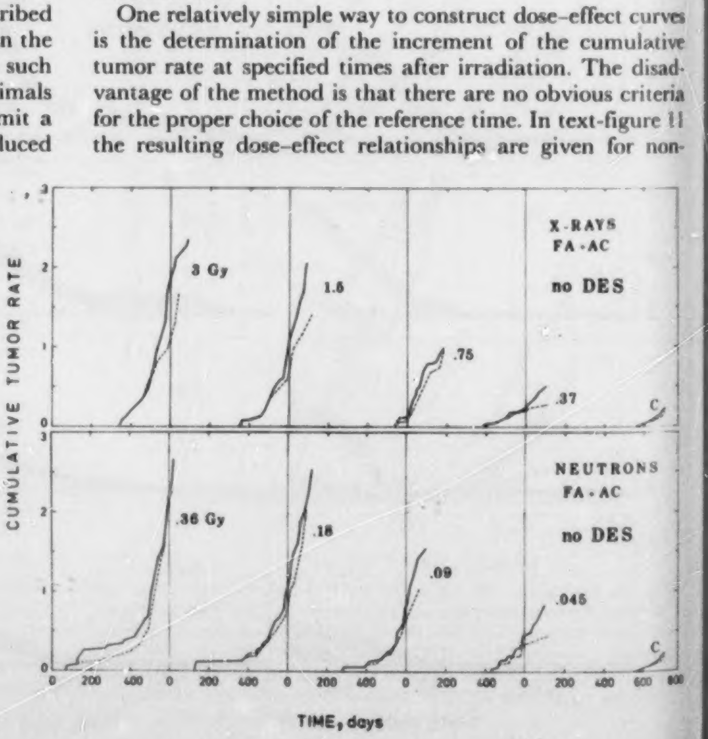
TEXT-FIGURE 9.—Different estimates of the cumulative tumor rate $R(t)$ for DES-treated animals as a function of time after exposure to X-rays *upper panel* and to neutrons *lower panel*. *Solid lines* are obtained on the basis of all AC, *dotted lines* on the basis of first AC in a quadrant, and *dashed lines* on the basis of the first AC in an animal. Absorbed doses are noted on the *curves*; *C* designates unirradiated but DES-treated animals.

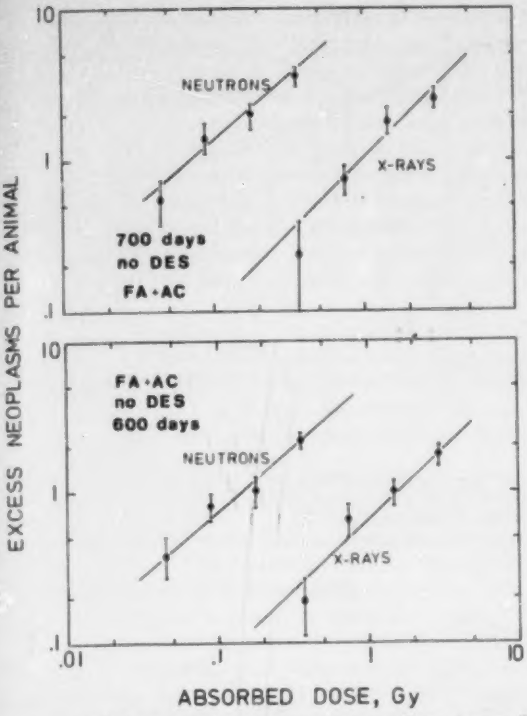
is of particular interest to examine these possibilities and to assess the consistency of their conclusions as well as those from text-figures 3 and 4 that had been based on the conventional analysis.

In the earlier experiment with Sprague-Dawley rats, it has been found that the results can adequately be described in terms of a radiation-induced forward shift in time in the occurrence of tumors. In the present experiment no such conclusion can be drawn for the non-DES-treated animals because the spontaneous incidence is too low to permit a comparison to the time course of the radiation-induced incidence. Alternatively, the neoplasms appear so early in the DES-treated animals that there can be only limited further shortening of the latent period and, accordingly, any simple linear relationship appears unlikely. The construction of dose-effect curves must therefore be based on other considerations.

One relatively simple way to construct dose-effect curves is the determination of the increment of the cumulative tumor rate at specified times after irradiation. The disadvantage of the method is that there are no obvious criteria for the proper choice of the reference time. In text-figure 11 the resulting dose-effect relationships are given for non-

TEXT-FIGURE 10.—Different estimates of the cumulative tumor rate $R(t)$ for non-DES-treated animals as a function of time after exposure to X-rays *upper panel* or to neutrons *lower panel*. Both FA and AC are taken into account. *Solid lines* are obtained on the basis of all mammary neoplasms; *dashed lines*, on the basis of first neoplasms in an animal. Absorbed doses are noted on the curves; *C* designates unirradiated animals.





TEXT-FIGURE 11.—Excess number of mammary neoplasms in non-DES-treated animals, i.e., increase of the cumulative tumor rate $R(t)$ over the control level, at 600 *lower panel* and at 700 days *upper panel* after irradiation. Data are given with their standard errors.

DES-treated animals at two different times after irradiation (600 and 700 days). An analogous plot is given in text-figure 12 for DES-treated animals; in keeping with the shorter lifespans, shorter reference times, 300 and 500 days, are chosen. Consistent with the results of the conventional analysis, the RBE appears to exceed 100 at the lowest neutron dose in the DES experiment.

It would be tempting to investigate separately the dose-effect relationships and the RBE for FA and AC in the experiments without DES. Text-figure 13 gives such a separate analysis that appears to indicate somewhat larger RBE values for the FA; however, the absolute numbers are too small to establish a confirmed difference.

Dose-effect curves also can be constructed in a somewhat more general way, and two possibilities will be considered. The first possibility utilizes $R(t)$ and a quantity that has been termed *effect period* Θ (*12, 17*):

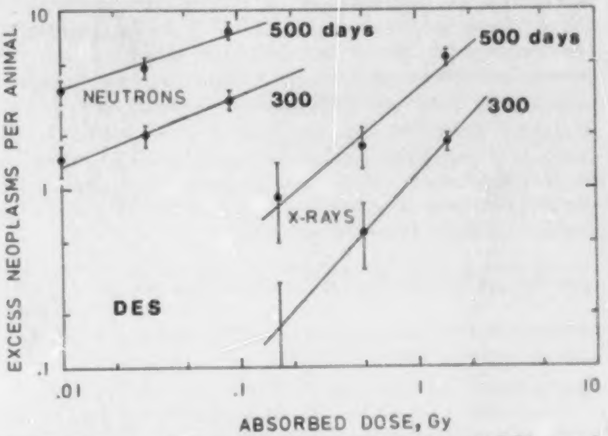
$$\Theta=\int_0^{t_{max}} R(t)\,dt. \qquad [6]$$

In this definition t_{max} is the maximum time for which $R(t)$ is obtained in the experiment. The quantity Θ can then be understood as the expected time with neoplasms for an animal that is at risk up to t_{max}; multiple neoplasms are counted with a corresponding factor so that Θ can ultimately, at high doses, exceed the period of observation.

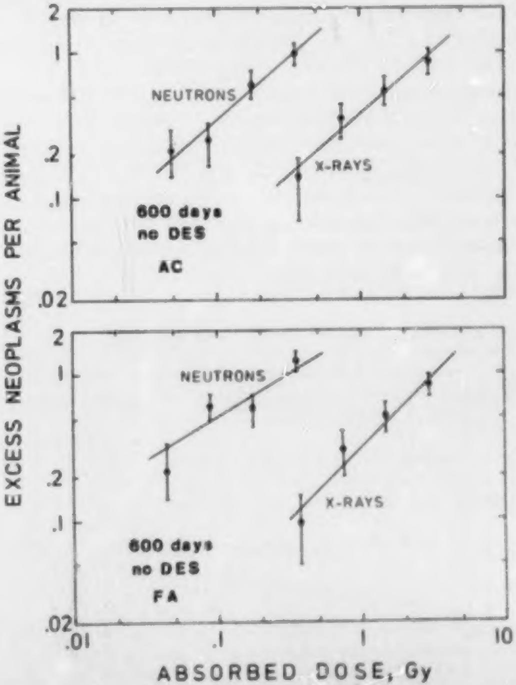
The quantity Θ is estimated by

$$\hat{\Theta}=\sum_i \frac{1}{N(t_i)}(t_{max}-t_i)\pm\sqrt{\sum_i \frac{1}{N(t_i)^2}(t_{max}-t_i)^2}. \qquad [7]$$

The summation extends over all $t_i<t_{max}$, and t_i and $N(t_i)$ have the same meaning as in equation 2. Text-figure 14 gives a plot of $\hat{\Theta}$ as a function of dose. t_{max} has been taken as 500 days in the DES experiment and as 700 days in the experiment without DES.



TEXT-FIGURE 12.—Excess number of mammary neoplasms in DES-treated animals, i.e., increase of the cumulative tumor rate $R(t)$ over the control level at 300 and 500 days after irradiation. Data are given with their standard errors.



TEXT-FIGURE 13.—Excess number of mammary neoplasms in non-DES-treated animals, i.e., increase of the cumulative tumor rate $R(t)$ over the control level, separately for FA *lower panel* and AC *upper panel* at 600 days after irradiation. Data are given with their standard errors.

An alternative construction of a dose–effect plot is based on a quantity that is similar to Θ but differs from it in depending on first neoplasms only. Hoel and Walburg (*19*) have defined a quantity

$$\mu = \int_0^\infty [1 - I(t)/I(\infty)]dt \qquad [8]$$

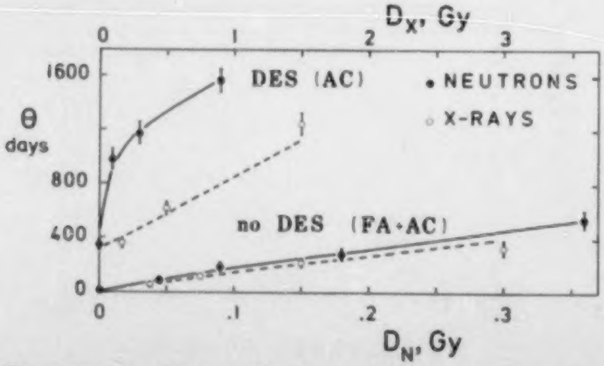
that is frequently applied in studies of life shortening, i.e., in the analysis of lethal diseases (*20, 21*). In these studies it is called "mean age at death," and $I(t)$ is either the overall cumulative mortality or the cumulative mortality due to a particular risk. However, it is evident that the quantity proposed by Hoel and Walburg can also be applied in the analysis of nonlethal diseases. In the present case $I(t)$ is the cumulative incidence of mammary neoplasms (*see* equation 5), $I(\infty)$ is set equal to 1 and, as in the determination of Θ, the integration is terminated at t_{max}=500 or 700 days. The formula for the estimation of μ is then:

$$\hat{\mu} = \Sigma[\hat{I}(t_i) - \hat{I}(t_{i-1})]\cdot t_i \pm \sqrt{\{\Sigma t_i^2[-\hat{I}(t_i)]/N(t_i) - \hat{\mu}^2\}/(n-1)} \qquad [9]$$

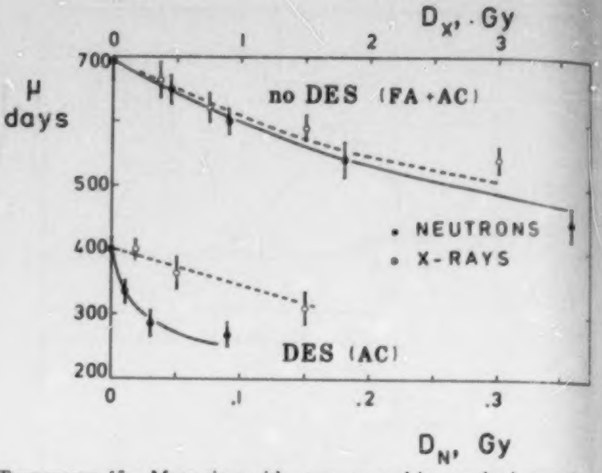
(summation over all t_i up to t_{max}; n is the number of animals with neoplasm). The standard error in equation 9 corresponds to the formula given by Hoel and Walburg (*19*).

The symbol μ stands for a competing-risk-corrected mean time without mammary neoplasm for the animals. The influence of the correction is substantial, as seen from a comparison of text-figure 15 with the mean tumor-free lifetimes in tables 2 and 5. The dose dependence of μ in text-figure 15 is yet another confirmation of the sublinearity in the DES experiment at small neutron doses; it also confirms the high RBE values in excess of 100 for the DES experiment and close to 10 for the experiment without DES.

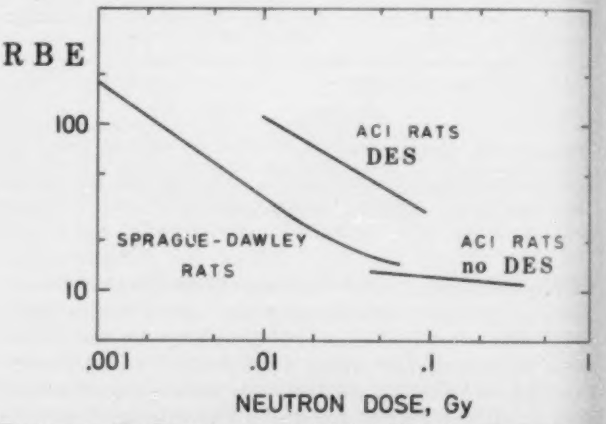
Text-figure 16 gives, both for the experiments with and without DES, the RBE of neutron irradiation as a function of dose. These curves have been derived from the mortality-corrected results, i.e., from text-figures 11, 12, 14, and 15. The curves inserted in text-figures 3 and 4 are in agreement with these RBE–dose relationships. The RBE–dose relationship from the earlier experiment with Sprague-Dawley rats (*13*) is inserted for comparison.



TEXT-FIGURE 14.—*Effect period* Θ and its standard error (*see* equation 7) for DES-treated and non-DES-treated animals. Scales for the neutron (D_N) and the X-ray (D_X) doses differ by a factor of 10. *Solid lines* refer to neutron irradiations; *dashed lines*, to X-irradiations.



TEXT-FIGURE 15.—Mean time without tumor and its standard error (*see* equation 9) for DES-treated and non-DES-treated animals. Scales for the neutron (D_N) and X-ray (D_X) doses differ by a factor of 10. *Solid lines* refer to neutron irradiations; *dashed lines*, to X-irradiations.



TEXT-FIGURE 16.—Dependence of the RBE of 430-keV neutrons on dose for the induction of mammary neoplasms. Results for the Sprague-Dawley rats are from an earlier study (*13*) (rats were not treated with DES). Results for ACI rats are from the present investigation. Line segments for ACI rats correspond to the curves in text-figs. 3, 4, 11, 12, 14, and 15.

DISCUSSION

Previous experiments (*12, 13*) with female Sprague-Dawley rats had led to the conclusion that the RBE of neutron irradiation for the induction of mammary neoplasms exceeds 100 at an absorbed dose of 1 mGy (0.1 rad). In agreement with earlier microdosimetric considerations (*6*), it had also been found that the RBE of neutron irradiation increases in inverse proportion to the square root of the neutron dose. A further finding was a strong sublinearity (dose exponent ≈0.5) of the dose–effect relationship at small neutron doses. In view of the potential implications of such findings for radiation protection, it seemed desirable to inquire whether similar results are obtained in other strains. The present experiment has been designed for this purpose.

The incidence of mammary neoplasms in control female ACI rats is low. However, the mammary carcinogenic response of non-DES-treated ACI rats to irradiation is relatively small, thus requiring relatively high doses of X-rays and neutrons to produce incidence values large enough to be analyzed statistically. In this part of the experiment, RBE values of neutron irradiation somewhat in excess of 10 are found for the FA and AC, which is in agreement with the values for Sprague-Dawley rats at comparable doses. Experiments with considerably larger numbers of animals would be required to determine the RBE of neutrons at smaller doses.

In ACI rats treated with DES, a large number of early mammary AC is found. With neutron doses as low as 0.01 Gy (1 rad), this incidence is further substantially enhanced. The RBE of neutrons at 0.01 Gy is in excess of 100, and this is even larger than the corresponding value for Sprague-Dawley rats at this neutron dose.

A similar experiment designed with three rat strains (Sprague-Dawley, Wistar WAG/Rij, and Brown Norway) is currently under way at the Toegepast Natuurwetenschappelijk Onderzoek in The Netherlands. Interim results (*22, 23*) of this investigation indicate RBE values from 8 to 25 for neutrons of 0.5 MeV energy at somewhat higher doses than in our study; they also point at considerable differences in susceptibility between the three strains. Quantitative comparisons with the results of the present experiment will have to await completion of the experiment.

The high RBE for mammary tumor carcinogenesis in rats are in line with earlier findings of high neutron RBE in other biological systems. They are also consistent with predictions based on microdosimetric data and support the proposal that the quality factor of 10 presently used for neutrons in radiation protection may need to be reconsidered (*10*).

The observed nonlinear dose–effect relationship for neutrons has an even greater potential impact on radiation protection. At doses below 0.01 Gy of sparsely ionizing radiations, a mammalian cell is traversed by a substantial number of electrons. At comparable doses, the number of cells traversed by any neutron recoil is small. Accordingly, one should expect dose dependence diagrams with positive curvature for sparsely ionizing radiations and linear dose–effect relationships for neutrons; in the dose range where there is a quadratic dependence on X-ray dose and a linear dependence on neutron dose, the neutron RBE has to be inversely proportional to the square root of the neutron dose. In the present experiment, as with the earlier findings on Sprague-Dawley rats, the dose–effect relationships are not of the expected shape; they are not recognizably different from a linear relationship for X-rays and have negative curvature for neutrons. Nevertheless, one obtains the familiar dependence of the RBE of neutrons on the square root of the neutron dose. It appears, therefore, that the characteristic difference between the densely ionizing neutron radiation and the sparsely ionizing X-rays is preserved but that a multicellular reaction or a tissue factor causes a similar distortion for both dose–effect relationships. It must be concluded, that the dose–effect relationships for radiation tumorigenesis are not as yet fully understood, whereas the RBE–dose dependence reflects known biophysical principles.

It is evident that data obtained in animal experiments cannot provide numerical risk estimates for humans. However, the high values of RBE and the negative curvature of the dose–effect relationship at small neutron doses are of sufficient concern to necessitate further radiation carcinogenesis studies with low doses of neutrons.

Inhibition by Tumor-Promoting Phorbol Esters of Procollagen Synthesis in Promotable JB6 Mouse Epidermal Cells[1]

L. David Dion,[2] Jenifer Bear,[2] John Bateman,[3,4] Luigi M. De Luca,[5] *and* Nancy H. Colburn[2,6,7]

ABSTRACT—The JB6 mouse epidermal cell line has been developed to study promotion of neoplastic transformation in vitro. Treatment of JB6 cells with 12-*O*-tetradecanoylphorbol 13-acetate (TPA) or other tumor promoters resulted in the irreversible acquisition by JB6 cells of tumorigenicity in nude mice and anchorage-independent growth in soft agar. As previously reported, one of the biochemical responses that occurs during TPA treatment is a greater than 75% reduction in a mannose-labeled glycoprotein with an apparent molecular weight of 180,000. This TPA-sensitive glycoprotein has now been identified on the basis of collagenase and pepsin sensitivity as procollagen pro-α1(I) chain. [^{3}H]proline labeling also demonstrated a parallel decrease in the 150,000 procollagen pro-α2(I) component. Two nonphorbol promoters, mezerein and epidermal growth factor, were also active in decreasing procollagen synthesis. Promotion-sensitive and promotion-resistant clonal derivatives of JB6 showed similar basal levels of collagen synthesis as well as similar degrees of TPA-dependent procollagen loss indicating that the collagen decrease may be necessary but is not sufficient to produce the promotion response. Comparison of chemically transformed mouse epidermal cell lines with paired nontransformants suggests that reduced procollagen synthesis is a stably acquired phenotypic change and may therefore be involved in maintenance of the transformed phenotype as well as in its induction.—JNCI 1982; 69:1147–1154.

Tumor-promoting phorbol esters evoke a wide range of biochemical and cellular responses [reviewed in (*1, 2*)]. Many of these responses are clearly membrane-associated events, such as enhanced 2-deoxyglucose uptake (*3*), phospholipase A_2 stimulation (*4*), ganglioside changes (*5*), glycopeptide changes (*6*), and the loss of the extracellular matrix components fibronectin (*7*) and procollagen (*8*). Because of the pleiotropic nature of the phorbol ester response, it has been difficult to distinguish those elements of the TPA response that contribute directly to the acquisition of the tumor cell phenotype from those elements that are merely coincidental.

We have developed the JB6 mouse epidermal cell line (*9–12*) as a model for studying the mechanism of late-stage promotion of transformation. The JB6 cell line is anchorage-dependent and nontumorigenic in nude mice but, unlike a variety of normal cells, irreversibly acquires anchorage independence and tumorigenicity after exposure in monolayer or in soft agar to tumor-promoting phorbol esters or other promoters (*9–12*). As in many other systems, the anchorage-independent phenotype correlates well with tumorigenicity (*12*). Studies employing the promotable JB6 cell model therefore offer the potential to elucidate the biochemical events directly involved in phorbol ester induction of the neoplastic phenotype.

Retinoids have been demonstrated to be potent inhibitors of in vivo tumor promotion by phorbol esters (*13*). These compounds also block phorbol ester promotion of transformation in vitro as shown by Colburn et al. (*14*) and Bertram et al. (*15*). The retinoids thus appear to be a useful tool to probe the biochemical events that accompany exposure to phorbol esters since at least one biochemical step critical to the promotion pathway should be blocked or antagonized by the retinoids.

Retinoid enhancement of a 180,000-M_r glycoprotein has been reported by several laboratories using various cell culture models (*16–18*). Strickland et al. (*19*) have identified a retinoid-induced glycoprotein in embryonal carcinoma cells as procollagen. These reports along with the report of Delclos and Blumberg (*8*) of a TPA-dependent loss of procollagen from CEF suggested that procollagen might offer a well-defined biochemical entity with which to study retinoid antagonism of TPA-induced promotion.

We have recently reported that TPA reduces and RA enhances the synthesis of a 180,000-M_r glycoprotein by JB6 cells (*20*). We report here the identification of the gp180 from JB6 cells as procollagen. The TPA-dependent procollagen loss occurs rapidly and persists with continued TPA treatment. Reduced procollagen synthesis appears to be a stable, acquired characteristic of malignantly transformed mouse epidermal cells.

MATERIALS AND METHODS

The derivation of the JB6 cell line from mouse primary epidermal cell cultures has been described elsewhere (*12*), as has the derivation by nonselective cloning of promotable and nonpromotable JB6 clonal cell lines (*11*). Nontrans-

formed mouse epidermal cell lines were obtained from BALB/c (JB1 and JB6) (*12*) or from Sencar (D1 and 3M12a) (*10*) primary epidermal cultures. Transformed mouse epidermal cells were obtained from JB6 cells (RT101, R24, R681, T^{3}6271, and T^{3}6274) after TPA exposure in agar (*10, 21*) or after exposure to 7,12-dimethylbenz[*a*]anthracene (D11a and DT2) or *N*-methyl-*N*-nitro-*N*-nitrosoguanidine (JB8 and 3M12b) (*10, 12*). JB6 cells were passaged after trypsinization with a 0.06% trypsin solution, and cultures were always maintained below confluence. Minimum essential medium with Earle's salts (GIBCO, Grand Island, N.Y.) was supplemented with 10% fetal bovine serum (Flow Laboratories, Inc., Rockville, Md.) and antibiotics.

Phorbol esters were purchased from Chemical Carcinogenesis, Eden Prairie, Minn. Stock solutions at 0.1 mg/ml in spectral grade DMSO were stored at −20°C in a desiccated container. At the time of use, the stock was diluted 10^4-fold with medium to give a final concentration of 10 ng TPA/ml (1.6×10^{-8} *M*).

RA was from Hoffmann-La Roche Inc., Nutley, N.J. Stocks were maintained as dry crystals in small screw-cap vials stored in desiccators at −20°C. We prepared small stock solutions by dissolving 3 mg RA/ml DMSO. Stock solutions were not used longer than a week, and all operations were conducted under light from General Electric gold fluorescent lamps.

Metabolic labeling.—L-[5-^{3}H]proline (catalog No. NET 573) was purchased from New England Nuclear Corp., Boston, Mass. D-[2-^{3}H]mannose (catalog No. TRK 364) was purchased from Amersham, Corp., Arlington Heights, Ill. Cultures were incubated for 2 hours after radionuclides were added to the serum containing medium at 10 μCi/ml.

When [^{3}H]mannose was used, the medium was aspirated and replaced with low-glucose medium (50 mg/liter). Use of low-glucose medium did not change the pattern of glycoproteins obtained from SDS gels but did give a tenfold increase of incorporation into acid-precipitable material.

The cells were washed twice with phosphate-buffered saline and, when 35-mm dishes were used, dissolved directly into 300 μl of SDS sample buffer, transferred to 1.5 ml Eppendorf tubes, boiled for 3–5 minutes, sonicated, and immediately frozen. The SDS sample buffer consisted of 2.0% SDS, 0.1 *M* dithiothreitol, 0.08 *M* Tris, 10% glycerol, 0.002 *M* phenylmethyl sulfonyl fluoride, and 0.0012% bromophenol blue (pH 6.8).

Gel electrophoresis.—Polyacrylamide gels were prepared by the method of Laemmli (*22*) with the use of a Bio-Rad model 200 gel-casting apparatus. Separatory gels were 7.5% and stacking gels were 3.5%. Gels were loaded with equal trichloroacetic acid-precipitable counts per track to permit detection of changes in relative amounts of synthesis independently of changes in precursor uptake. Typically, 10,000–20,000 cpm was applied on each track for [^{3}H]mannose and 100,000 cpm for [^{3}H]proline, representing extracts from 200,000 to 300,000 cells. Electrophoresis was done for 4.5 hours at 25 mA/gel. Gels were fixed overnight in 7% acetic acid and 5% methanol, saturated with Enhance (New England Nuclear Corp.) for 2 hours, and washed with water for 2 additional hours. The gels were dried on a Bio-Rad gel dryer and autoradiographed on Kodak X-Omat XR-5 film. ^{14}C-labeled marker proteins were purchased from Amersham Corp. Scanning densitometry of the autoradiographs was done with the use of an EC scanning densitometer. When the relative collagen content was determined in this manner, the integrated areas under the 180,000- and 150,000-M_r peaks were added together and divided by the integrated value for the entire autoradiograph.

Collagenase digestion.—The collagen content of the cells was determined by a modification of the method of Peterkofsky and Diegelmann (*23*). Subconfluent monolayers of cells were treated with DMSO, TPA, or RA for 24 hours followed by a 6-hour labeling period with the use of 1 μCi L-[^{14}C]proline/ml. L-[^{14}C]proline was purchased from New England Nuclear Corp. (catalog No. NEC-285) (250 mCi/mmol). The acid-precipitable material was exhaustively digested with purified bacterial collagenase. The solubilized radioactivity represents collagen protein.

Pepsin digestion.—Pepsin-resistant α-chains of collagen were determined by treatment of [^{3}H]proline-labeled cell lysates with 100 μg pepsin/ml in 0.5 *M* acetic acid for 1 hour at room temperature.

RESULTS

Preferential Incorporation of [^{3}H]proline Into TPA-Sensitive 180,000- and 150,000-M_r Glycoproteins

When JB6 cells were treated with TPA (10 ng/ml) for 24 hours and then labeled with [^{3}H]mannose for an additional 8 hours, the synthesis of [^{3}H]mannose-labeled 180,000- and 150,000-M_r cell-associated glycoproteins was inhibited (*20*). When [^{3}H]leucine or [^{35}S]methionine was used as a precursor, TPA-sensitive components at 180,000 and 150,000 were only minimally labeled (data not shown). [^{3}H]proline (fig. 1), however, was preferentially incorporated into a 180,000 and a 150,000 protein [pro-α1(I) and pro-α2(I), respectively]. These two proteins displayed a marked TPA-dependent reduction, and the concentration dependency (fig. 1) of the response of the [^{3}H]proline-labeled 180,000 protein was the same as that of the [^{3}H]mannose-labeled gp180 (*20*). The effect in both cases was fully expressed at 1 ng TPA/ml medium and minimally observable at 0.1 ng TPA/ml. Figure 1 also shows a reduction in a [^{3}H]proline-labeled 220,000 band after TPA exposure. This 220,000 band has been identified as fibronectin by immunoprecipitation (data not shown). As described before (*20*), fibronectin appears to be affected by TPA and RA in a manner parallel to that observed for the 180,000 band, although to a lesser degree.

Identification of gp180 as Procollagen

The preferential labeling of the gp180 with [^{3}H]proline together with the previous report by Delclos and Blumberg (*8*) that TPA markedly reduced procollagen synthesis in CEF cultures suggested the identity of JB6 gp180. Figure 2 presents the results of a digestion of [^{3}H]mannose-labeled JB6 glycoproteins by purified bacterial collagenase. Most of the [^{3}H]mannose incorporated into 180,000- and 150,000-M_r material was collagenase-sensitive, and gp180 and gp150 were the only proteins that were digested under these conditions. The appearance of a [^{3}H]mannose-labeled 35,000-

M_r glycoprotein in collagenase-treated samples (fig. 2) is consistent with the enzymatic release of the COOH terminal peptide (*21*).

Collagen in helical form is resistant to pepsin, whereas most other proteins are not. After pepsin digestion of nonhelical N— and C— terminal regions, collagen is converted to α-chains (*24*). The partial purification of procollagen in the JB6 cells before pepsin (fig. 2) reflects the high solubility of procollagen in 0.5 *M* acetic acid relative to the solubility of other proteins. Pepsin digestion of [^{3}H]proline-labeled JB6 cell extracts demonstrates the formation of two chains in the molecular weight range of 100,000 corresponding to α1 and α2 chains (*24*). This finding therefore confirms the identity of the 180,000 and 150,000 proteins as collagen in JB6 cells.

Quantitation of Collagen Synthesis Responses

JB6 cells were labeled for 6 hours with [^{14}C]proline after 24-48 hours of exposure to TPA. We harvested the cells by scraping them, and we analyzed them for collagen content by the method of Peterkofsky and Dieglemann (*23*), which involves an enzymatic digestion with purified bacterial collagenase and determination of collagenase-sensitive cpm as a percent of total. In response to TPA, JB6 cells showed a 75% inhibition of collagen synthesis at both 24 and 48 hours (table 1). RA enhanced procollagen synthesis and partially antagonized the TPA-dependent decrease at 48 hours. At 24 hours, however, the RA had little effect on procollagen synthesis either alone or in combination with TPA. When the effect of TPA on collagen secretion was examined (not shown), TPA treatment was found to produce a 50–75% decrease. This effect on collagen secretion thus paralleled that on collagen synthesis.

Induction by Complete and Second-Stage Tumor Promoters of a Procollagen Loss by JB6 Cells

Analogues of phorbol esters were found to vary in their effectiveness at inhibiting procollagen synthesis in a manner that correlated with their activity in promotion of transformation (*25*) (table 2). TPA, as expected, was the most active phorbol ester used in this assay. Phorbol 12,13-didecanoate and mezerein, a nonphorbol diterpene, were nearly as active as was TPA.

TABLE 1.—*Collagenase digestion of [^{14}C]proline-labeled proteins showing TPA inhibition and RA enhancement of collagen from JB6 cells*[a]

Duration of treatment, hr	Percent collagen protein			
	DMSO, 0.02%	RA, 10^{-6} *M*	TPA, 10 ng/ml	RA + TPA
24	1.87±0.31	1.70±0.31	0.33±0.15	0.57±0.08
48	2.04±0.16	2.71±0.09	0.43±0.06	1.34±0.12

[a] Values were corrected for the fivefold enhancement of proline in collagen proteins and are expressed as ± one-half the range for duplicate culture dishes. Thus 10% collagenase-soluble radioactivity is expressed as 2% collagen protein. Cells were plated at 20,000/cm^2 and grown for 1 day before initial treatment. Treatment was continued for the duration indicated, followed by a 6-hr labeling period with [^{14}C]proline. Addition of 50 μg ascorbic acid/ml to the medium did not significantly affect precursor incorporation into collagen of JB6 cells.

TABLE 2.—*Induction by complete and second-stage tumor promoters of procollagen loss by JB6 cells*

Promoters[a]	Concentration, ng/ml[b]				
	0.1	1	10	50	100
TPA	−	+	+		+
Mezerein	−	±	+		+
Phorbol didecanoate	−	±	+		+
Phorbol dibenzoete	−	−	±		+
Phorbol dibutyrate	−	−	±		+
4-*O*-Methyl-TPA	−	−	−		+
Phorbol diacetate	−	−	−		−
Phorbol triacetate	−	−			−
EGF		−	+	+	
A23187		−	−	−	−

[a] Saccharin and sodium cyclamate were inactive at 1–500 mg/ml.

[b] Autoradiographs were scored for reduction of the 180,000-M_r band. + indicates ≈50% or greater reduction in optical density; − indicates no observable reduction in optical density; ± indicates <50% reduction in optical density.

Slaga et al. (*26, 27*) have recently demonstrated that tumor promotion is a multistage process and that tumor promoters can be categorized as being complete, early-stage, or late-stage promoters. Within this scheme, TPA is considered to be a complete promoter, since it is capable of promoting transformation of initiated mouse skin. Mezerein is a second-stage promoter in that it is capable of completing promotion only if it follows a TPA exposure but not if used alone. In this context, the strong mezerein effect on collagen synthesis is interesting because this response is consistent with the observation that mezerein is active as a promoter of transformation in JB6 cells (*11, 25*).

Mezerein has been shown to be similar in activity to phorbol didecanoate at releasing arachidonic acid and prostaglandin E_2 from CEF (*4*). 4-*O*-Methyl-TPA, which has been shown to be a weak complete promoter in vivo (*27*) and a weak promoter in the JB6 promotion of anchorage independence assay (not shown), was minimally active in this procollagen decrease assay. Phorbol diacetate and phorbol triacetate were inactive in this assay, as they were in the promotion of anchorage independence assay.

We have tested two other nonphorbol tumor promoters for procollagen-inhibiting activity. The calcium ionophore A23187 has been shown to be a first-stage promoter in mouse skin (*27*). Consistent with the other data showing that JB6 cells are partially promoted, A23187 does not induce anchorage independence in JB6 cells (*25*). A23187 also was inactive as an inhibitor of procollagen synthesis. EGF was active at 10–50 ng/ml in decreasing procollagen synthesis and has been shown to irreversibly promote JB6 cells to anchorage independence (*11, 28*). It appears that agents which are known as second-stage or complete promoters had a pronounced inhibitory effect on procollagen synthesis in JB6 cells, whereas first-stage and nonpromoting analogues were inactive at producing this biochemical response.

TABLE 3.—*Collagenase digestion of [^{14}C]proline-labeled proteins that shows TPA reduction of collagen in promotable and nonpromotable JB6 cell clones*

Cell line (phenotype)	Collagen content as a percent of [^{14}C]proline-labeled protein[a]		Ratio TPA:DMSO
	DMSO	TPA	
JB6 (parent cell line)	1.87±0.31	0.4±0.43	0.21±0.02
Promotable	1.65±0.22	0.33±0.15	0.20±0.12
Cl 41 (promotable)	1.89±0.54	0.32±0.28	0.15±0.10
Cl 21 (promotable)	1.00±0.19	0.23±0.06	0.23±0.03
Cl 30 (nonpromotable)	1.22±0.13	0.42±0.07	0.34±0.03
Cl 25 (nonpromotable)	1.76±0.06	0.64±0.08	0.36±0.04

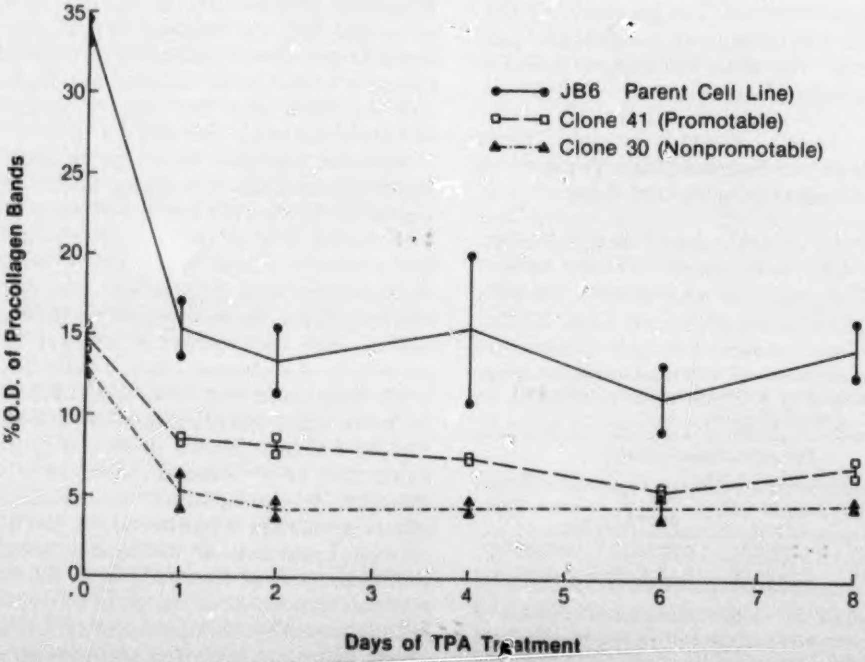
[a] Values were corrected for the fivefold enhancement of proline in collagen proteins and are expressed as ± one-half the range for duplicate culture dishes. Thus 10% collagenase-soluble counts are expressed as 2% collagen protein. TPA (10 ng/ml) or DMSO (0.02%) was added 24 hr after the cells had been plated. The cultures were treated for 24 hr followed by a 6-hr labeling period.

Demonstration by Both Promotable and Nonpromotable Clones of JB6 of TPA-Dependent Reduction of Collagen

The JB6 cell line has been used to generate cloned populations of cells that vary a hundredfold in their promotion responsiveness to TPA (*10, 11*). We have chosen two TPA promotion-sensitive cell lines (clones 41 and 21) and two TPA-resistant cell lines (clones 25 and 30) to determine whether the TPA-dependent reduction in collagen might correlate with promotion sensitivity. Table 3 demonstrates that when the collagenase digestion technique was used to determine the [^{14}C]proline-labeled collagen content, both promotable and nonpromotable cells demonstrated a similar (≈80%) collagen loss in response to TPA. Hence promotion resistance is not attributable to lack of procollagen response to TPA. Furthermore, the basal levels of collagen were similar, showing that lower (or higher) basal levels of collagen synthesis do not predispose the cells to promotability.

Rapid and Persistent TPA-Mediated Decrease of Procollagen Synthesis

Cultures of parental JB6 cells or clonal lines JB6 Cl 41 or JB6 Cl 30 were treated with TPA (1 ng/ml) for 1–8 days, and the cells were terminally labeled with [^{3}H]proline for 2 hours to determine whether the procollagen loss was a persistent effect of TPA treatment. We found (text-fig. 1) that the TPA caused a decrease in procollagen synthesis in all three cell lines as determined by densitometry of gel autoradiographs to 30–50% of control by 24 hours. Continuous exposure to TPA up to 8 days resulted in persistence of the reduced procollagen levels observed at 24 hours. Thus the JB6 cells do not become refractory to TPA for this phenotypic change but appear to undergo a persistent decrease in procollagen synthesis at least in the presence of TPA.



TEXT-FIGURE 1.—TPA-dependent reduction of procollagen is rapid and persistent. Cells were exposed to 1 ng TPA/ml as described in "Materials and Methods." Autoradiographs of SDS–polyacrylamide gels were prepared as described with the use of [^{3}H]proline-labeled proteins [(*20*); *see also* legend to fig. 1]. Scanning densitometer tracings of the autoradiographs were prepared and the integrated area under both the 180,000 and 150,000 regions as a percentage of the total integrated area was compared. Results are expressed as collagen optical density (O.D.) as a percent of total O.D. Values have not been corrected for the fivefold enhancement of proline in collagen protein. Hence 35% O.D. in procollagen is equivalent to ≈7% of total protein.

TABLE 4.—*Reduced procollagen synthesis in transformed mouse epidermal cell lines*[a]

Nontransformants		Paired transformants	
Cell line	[^{3}H]proline in collagen bands, %	Cell line	[^{3}H]proline in collagen bands, %
JB6	17.6±1.6	RT101	6.1±0.9
		R24	7.7±0.5
		R681	8.6±0.0
		T^{3}6271	15.0±0.75
		T^{3}6274	12.8±0.6
D1	16.3±1.8	D11a	11.0±1.4
		DT2	6.9±0.3
JB1	13.3±0.4	JB8	5.7±0.1
3M12a	22.5±0.6	3M12b	14.3±0.0

[a] Cells were plated at 10,000/cm^2; 24 hr after plating, the cultures were labeled with [^{3}H]proline for 2 hr. The labeled proteins were separated by SDS-PAGE. Autoradiographs were analyzed by scanning densitometry and results are expressed as percent of total optical density ± one-half the range for duplicate samples. Cell lines have been scored as transformed because they were demonstrated to be anchorage-independent and/or tumorigenic (*10, 12, 21*). Nontransformed lines were negative by both assays.

Retention by Transformed Mouse Epidermal Cells of Low Procollagen Phenotype

To further investigate the persistence of the TPA-produced procollagen decrease, we compared TPA-promoted, transformed cells with their nontransformed precursor (JB6) or with nontransformants of a different origin and their transformed derivatives (D1, JB1, 3M12a and D11a, DT2, JB8, 3M12b). As shown in table 4 when we labeled with [^{3}H]proline and compared for SDS-PAGE profiles, we found that the transformed cells synthesized less procollagen than did their paired nontransformed counterparts. This change was not dependent on the transforming agent since D11a (transformed) and DT2 (transformed) were transformed by 7,12-dimethylbenz[*a*]anthracene (*10*), whereas (*10*), the RT101, R24, and R681 were obtained after promotion to the transformed state by TPA exposure of JB6 Cl 41 cells (*21*). The magnitude of the change appeared to be similar to that found after TPA exposure of promotable cells shown in text-figure 1 with the use of the same methodology. This method may underestimate the magnitude of the TPA or transformation-sensitive decrease due to the presence of some noncollagen [^{3}H]proline-labeled material in the 180,000 and 150,000 bands. Due to its specificity, the collagenase digestion method used in tables 1 and 3 probably gives a more accurate measure of the decrease.

DISCUSSION

Our studies of glycoprotein changes induced by phorbol esters during promotion of transformation in JB6 cells were initially stimulated by previous reports that TPA inhibited the expression of two glycoproteins, fibronectin and procollagen (*7, 8*). The well-documented reports that retinoids generally enhanced glycoprotein synthesis and that retinoids antagonize TPA-induced preneoplastic progression further suggested that the two molecules may act antagonistically on glycoprotein synthesis. [For review, *see* (*1, 14*).] We have found that TPA and RA produce major and opposite effects on the synthesis in promotable JB6 cells of 180,000- and 150,000-M_r glycoproteins (*20*), which have been identified here as type I procollagen.

The identification of the TPA-sensitive gp180 and gp150 as procollagen is supported by four lines of evidence. The [^{3}H]mannose-labeled gp180 and gp150 glycoproteins were sensitive to hydrolysis by purified bacterial collagenase. Digestion with collagenase generated a 35,000 glycoprotein consistent with its being the carboxy terminal end of the procollagen peptides. The TPA- and RA-responsive 180,000 and 150,000 proteins are preferentially labeled with [^{3}H]-proline. That procollagen determined by collagenase digestion of [^{14}C]proline-labeled proteins shows the same decrease in response to TPA and increase in response to RA as observed for the 180,000 and 150,000 gel electrophoresis bands provides further confirming evidence for the procollagen identity of these two bands.

The presence of two molecular weight components and the failure of either to be precipitated by anti-type IV collagen antibody (Sobel M: Personal communication) have lead to the characterization of JB6 procollagen as type I procollagen. The presence of type I instead of type IV collagen in cultures of cloned cells that are well characterized as being of epidermal origin (*10*) may reflect an altered differentiation associated with growth as a cell line or may be part of the preneoplastic phenotype of the JB6 cells.

Another suggested identity for the TPA-sensitive gp180 was EGF receptor which has been reported to have a molecular weight around 165,000–180,000 (*29*). Antibody to EGF receptor did not isolate a glycoprotein from JB6 cells which could be seen in the 180,000 region of SDS gels (data not shown).

The TPA effect on procollagen synthesis is striking in both the extent to which and speed with which TPA acts. The procollagen [both the 180,000 pro-α1(I) and the 150,000 pro-α2(I) bands] content is depressed by more than 50% within 24 hours. The magnitude of collagen reduction was similar to that obtained with TPA-exposed CEF cultures (*8*), but maximum reduction was attained at a slower rate in CEF. Continued exposure to TPA over 8 days led to persistently reduced procollagen. Preliminary evidence suggests that more than 72 hours of TPA treatment are required to irreversibly reduce procollagen (Dion LD: Unpublished data). The reduced procollagen persists into the tumorigenic state.

We have screened several more promotable clones of JB6 for a loss of the mannose-labeled gp180 after TPA exposure (data not shown). All promotable cell lines tested have shown similar losses of gp180 in response to TPA. A promotable cell that does not give a reduced procollagen response would be needed to exclude this biochemical effect from the set of those effects that are necessary for promotion. Hence the procollagen decrease may be a required event. This response to promoters is, however, not sufficient to set in motion all subsequent events that bring about promotion of transformation in JB6 cells since it occurs in nonpromotable variants. It may be an event that is necessary for promotion and one that is involved in the antipromoting action of retinoids.

That reduced collagen occurs repeatedly in transformed mouse epidermal cells suggests that it may be involved not only in induction of the transformed phenotype but also in its maintenance. Reduced collagen synthesis in cells transformed by DNA viruses (*30*), RNA viruses (*8, 31–33*), and chemical carcinogen (*32*) has been a frequent observation. Recently, Bateman and Peterkofsky (*33*) reported that a shift to nonpermissive temperature of cells transformed by a temperature-sensitive retrovirus resulted in reversal of both collagen reduction and growth in soft agar. This observation also suggests the possible role of reduced collagen in maintenance of the transformed phenotype. Alternatively, both collagen reduction and neoplastic transformation could have a common cause without a causal relationship to each other.

TPA treatment of JB6 cells clearly reduced the synthesis and therefore the secretion of procollagen. Other secreted molecules may also be affected in a parallel manner. The secreted proteins, including collagens, fibronectin, chondronectin, laminin, and glycosaminoglycans, may all share some degree of coordinate regulation as part of the phenotypic state of differentiation. TPA by altering the spectrum of secreted molecules may thus be altering both a cell's program of gene expression and its extracellular microenvironment. The influence of the extracellular matrix on promotion of transformation is possibly of considerable importance but is a subject that has received little investigation.

Our current approach is to identify the biochemical level at which TPA and RA affect procollagen synthesis. Preliminary results suggest that TPA may be specifically inhibiting RNA transcription for procollagen (Sobel M, Dion LD: Unpublished data).

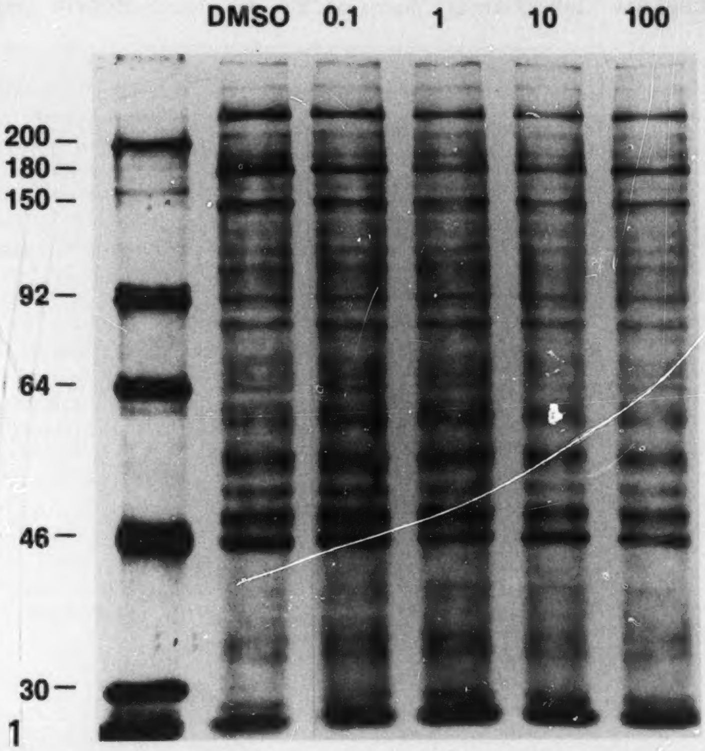

Figure 1.—[^{3}H]proline preferentially labels the 180,000- and 150,000-M_r TPA-inhibited proteins of JB6 cells. JB6 cells were treated with the indicated concentrations of TPA or 0.01% DMSO for 24 hr followed by a 2-hr labeling period with 10 μCi/ml of [^{3}H]proline. Total cellular proteins were separated by SDS-PAGE for autoradiography as described previously (*20*). *Left lane* contains ^{14}C-labeled molecular weight markers purchased from Amersham Corp.

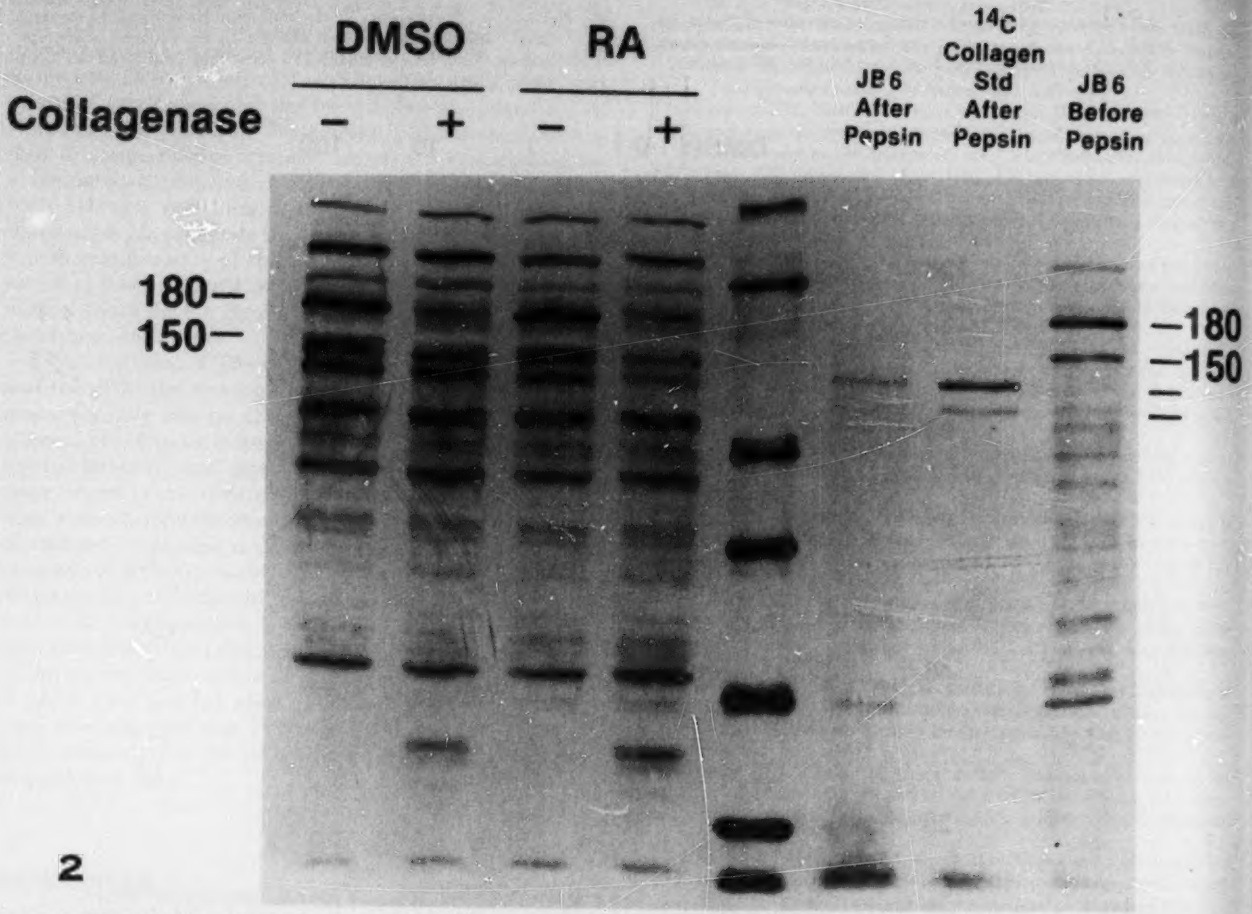

2

FIGURE 2.—The 180,000- and 150,000-M_r glycoproteins are collagenase-sensitive and yield pepsin-resistant glycoproteins characteristic of collagen. Collagenase-sensitive glycoproteins were determined by treatment of JB6 cells with DMSO (0.01%) or RA (10^{-6} *M*) for 24 hr followed by a 6-hr labeling period with [^{3}H]mannose (20 μCi/ml). Cells were harvested by being scraped into Tris-buffered saline (pH 7.4) and sonicated. The sample was split into two 100-μl aliquots, one of which received 10 μl of a Tris buffer containing purified collagenase (100-200 μg/ml) plus calcium chloride. The other aliquot received 10 μl of buffer without collagenase. The digestion proceeded at 37°C for 90 min and was stopped by introduction of an equal volume of a twofold concentration of SDS sample buffer. For the determination of pepsin-resistant proteins, [^{3}H]proline-labeled JB6 cells were harvested in 0.5 *M* acetic acid. Replicate aliquots received one-tenth volume of 0.5 *M* acetic acid ± pepsin to give a final pepsin concentration of 100 μg/ml. Incubation proceeded for 1 hr at room temperature. The acetic acid was removed by lyophilization. The lyophilyzed powder was solubilized in SDS-sample buffer. The positions of the characteristic pepsin-resistant products of collagen digestion are indicated by *horizontal marks*. These pepsin-resistant proteins have been identified as α1 and α2 collagen (*24*). Std=standard.

Effect of Carcinogen Release Rate on the Incidence of Preneoplastic and Neoplastic Lesions of the Respiratory Tract Epithelium in Rats [1,2,3]

ABSTRACT—Inbred F344 rat tracheal transplants were exposed to 7,12-dimethylbenz[*a*]anthracene (DMBA) delivered at different release rates from intraluminal pellets made of various matrices to study the effect of carcinogen dose rate on the induction of lesions in the epithelium. These matrices were beeswax, beeswax–stearyl alcohol, and beeswax–cholesterol. In addition, DMBA adsorbed onto carbon particles was dispersed in beeswax–stearyl alcohol. The fastest release was obtained from beeswax pellets from which 99% of the carcinogen (198 μg) was released in 4 weeks, and the slowest release was from DMBA adsorbed on carbon at a ratio of 1:9 from which only 56% (113 μg) was released in 16 weeks. Morphometry of histologic sections showed marked differences in the percentage of luminal surface covered by dysplastic–neoplastic epithelium (i.e., 7.5% in the tracheas exposed to the fastest releasing pellets and 46.3% in the tracheas exposed to the slowest releasing pellets). An inverse linear correlation was found between the cumulative amount of DMBA released from the different pellet matrices at 2 weeks and the incidence of dysplastic plus neoplastic lesions of tracheal epithelium at 16 weeks. The results indicate that lower doses of carcinogen delivered slowly are more effective in producing dysplastic plus neoplastic lesions than higher doses delivered rapidly.—JNCI 1982; 69:1155–1161.

During the past several years, considerable effort has been put forth to develop animal models of respiratory carcinogenesis in which carcinogen dose and the tumorigenic response could be carefully quantitated (*1*). In this respect, the tracheal transplant model developed in our laboratory has many advantages. In this model a known target, the heterotopically transplanted trachea, is exposed to carcinogen released from an intraluminal rod-shaped pellet from which a known amount of carcinogen can be delivered (*2, 3*). Several studies have been done with the use of this system, including dose-response studies with several polycyclic hydrocarbons and heavy metals on the induction of preneoplastic and neoplastic lesions, and two-step carcinogenesis (*4–10*). Since the establishment of this model (*2*), improved carcinogen delivery systems have been developed that permit slower release of both soluble and insoluble materials. In other in vivo experimental protocols, lipid matrices were often used to slow the release of polycyclic hydrocarbons to the tissue [e.g., (*11–16*)]. Recently, several systems for controlled release of carcinogens to the tracheal transplant have been reported by Pal et al. (*17*) and Klein-Szanto et al. (*18*). Beeswax, stearyl alcohol, cholesterol, or stearyl alcohol plus carbon was used as a vehicle, and more moderate, controlled release of carcinogens and of a tumor promoter was achieved. This report quantitates the effects of delivering the carcinogen DMBA at different dose rates directly on the epithelium of the tracheal transplant. Several matrices, allowing different release rates of DMBA, were used, and a morphometric evaluation of the epithelial changes was performed to measure the effects of dose rate on the induction of preneoplastic and neoplastic lesions.

MATERIALS AND METHODS

Materials.—White (U.S.P. grade) beeswax was obtained from Fisher Scientific Co. (Pittsburgh, Pa.). Before use, the molten beeswax was filtered under vacuum through a steam-heated funnel with a fritted glass disk of medium porosity. DMBA was obtained from Eastman Organic Chemicals (Rochester, N.Y.) and was purified by recrystallization from ethanol as described previously (*17*). Carbon particles (nut shell charcoal; Barnebey-Cheney Co., Columbus, Ohio; catalog #JF) were sequentially passed through sieve #200 and sieve #325, and the particles retained on sieve #325 were used. Cholesterol (primary standard grade, 99.5% by differential scanning colorimetry) was obtained from Eastman Organic Chemicals, and stearyl alcohol was obtained from Sigma Chemical Co. (St. Louis, Mo.).

Preparation of the pellets.—Beeswax, beeswax–cholesterol (1:1 and 1:9), and beeswax–stearyl alcohol (1:1 and 1:9) pellets containing DMBA were prepared with a pellet maker as described previously (*17*) with some modifications. Weighed amounts of DMBA and the matrix medium were heated in a glass scintillation vial placed in a cavity in an aluminum block heated on a thermostatically controlled hot plate. A clear homogeneous melt of beeswax and beeswax-

stearyl alcohol was obtained at 80°C; for cholesterol pellets it was necessary to heat to 150°C. An appropriate aliquot of the melt was transferred to the recess in the bottom half of the preheated pellet maker. The top half of the pellet maker was placed on the bottom half, and the melt rose to fill the cylindrical cavities in the top half. The mold was then rapidly cooled by being placed on a cylindrical copper block (3×3 inches in diameter) cooled on ice. When the melt solidified, the two halves were separated and the pellets were removed with a push pin.

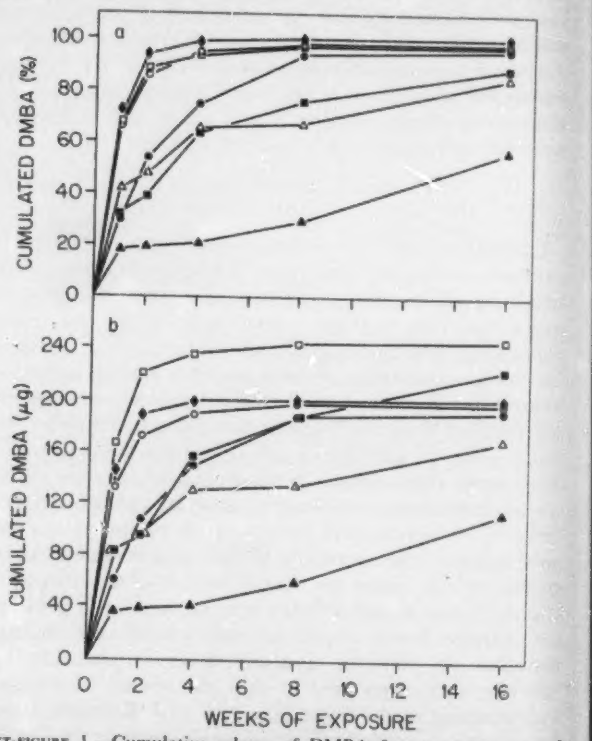
Pellets containing carbon could not be prepared in the pellet maker because these particles have a tendency to settle and agglomerate. Therefore, we made these pellets of carbon particles coated by heating and stirring with DMBA in an acetone solution as reported earlier for BP (*17*), except that we heated the final mixture of carbon and DMBA to 160°C for 1 minute. The final product was cooled in a desiccator. Then weighed beeswax–stearyl alcohol (1:9) was melted in a hot mortar and mixed thoroughly with the DMBA-loaded carbon particles by use of mortar and pestle. The complete mixture was allowed to cool until it congealed. It was then scraped out of the mortar and packed in the cell of a Greenerd Arbor Press (Fisher Scientific Co.) fitted with a disk with a hole (1.5 mm in diameter) in the middle. The cell was warmed to a suitable temperature (below the melting point of the mix), and the mixture was extruded rapidly. The extruded material was cut into equal lengths by use of a channeled Teflon block with a design similar to that of a carpenter's miter box. This procedure assures a uniform charcoal particle dispersion in the matrix as determined by spectrophotometric assays of random samples. This is an improvement on the previously reported method in which some difficulty in obtaining stable distribution was reported (*17*).

In this study, seven types of carcinogen-containing pellets were prepared: beeswax; 1:1 and 1:9 stearyl alcohol pellets in which beeswax and stearyl alcohol were mixed at weight ratios of 1:1 and 1:9; and 1:4 and 1:9 carbon pellets in which DMBA was adsorbed to carbon at weight ratios of 1:4 and 1:9 in a 1:9 beeswax–stearyl alcohol matrix. All these pellets contained 200 μg DMBA. Pellets in which beeswax and cholesterol were mixed at ratios of 1:1 and 1:9 contained 250 μg DMBA. On the basis of preliminary studies, we used 250 μg DMBA in the cholesterol-containing pellets to obtain the release of higher amounts of DMBA than the amounts obtained from rapid-releasing beeswax pellets (1:1 cholesterol pellets) and intermediate released amounts (1:9 cholesterol pellets). Four types of blank pellets were prepared: beeswax, beeswax–stearyl alcohol (1:9), beeswax–cholesterol (1:9), and beeswax–stearyl alcohol (1:9) containing 1,800 μg carbon (the amount used in 1:9 DMBA-carbon-coated particles).

Assay of the pellets.—We determined the uniformity of the pellets by assaying DMBA in pellets selected at random. The average weight of beeswax pellets was 24.48±0.62 mg (SD). Pellets containing DMBA were individually weighed, and those that did not fall within ±2% of the mean pellet weight were rejected. We determined the DMBA content of the pellets by extracting them for 2 hours with benzene in a Soxhlet extractor with a double-thickness cellulose thimble (Whatman, Inc., Clifton, N.J.). DMBA was assayed spectrophotometrically with $\epsilon_{301}=79{,}000$. The recovery of DMBA and the UV absorption spectra indicated negligible degradation of DMBA during the pellet-making process. This small variation in the pellet weight values as well as the careful and uniform preparation of the carcinogen matrix mixtures assured the homogeneity of the pellets.

Animals and tissues.—F344 female rats 10 weeks old, bred and maintained in our specific-pathogen-free barrier facility, were used. Tracheas attached to polyethylene tubing were transplanted into subcutaneous pockets on the backs of isogeneic recipients as previously described (*4*). Two tracheas were transplanted per animal. Twenty-eight days after transplantation, pellets were inserted into the tracheal lumina through an incision made at the end of the transplants. The incision was then closed with tantalum hemostatic clips (E. Weck Co., Research Triangle Park, N.C.). The skin wound was closed with metal clips.

A total of 156 tracheal transplants were prepared for this study. Twenty tracheas were used for each experimental group, and four grafts were removed at 1, 2, 4, 8, and 16 weeks after pellet insertion. The pellets removed from the



TEXT-FIGURE 1.—Cumulative release of DMBA from various types of pellets in the tracheal lumen during carcinogen exposure. a) *Points* represent mean percentages of DMBA released. b) *Points* represent mean amount of DMBA released. ◆, beeswax pellets containing 200 μg DMBA; □, 1:1 beeswax–cholesterol pellets containing 250 μg DMBA; ○, 1:1 beeswax–stearyl alcohol pellets containing 200 μg DMBA; ●, 1:9 beeswax–stearyl alcohol pellets containing 200 μg DMBA; ■, 1:9 beeswax-cholesterol pellets containing 250 μg DMBA; △, 1:4 carbon pellets containing 200 μg DMBA; ▲, 1:9 carbon pellets containing 200 μg DMBA. All the standard errors of each value were <1.5% (3 μg) for the 200-μg DMBA pellets and 4% (10 μg) for the 250-μg DMBA pellets.

tracheas at these times were assayed for remaining DMBA. For each control group, four tracheal transplants were removed at 16 weeks. After excision, the transplants were fixed in Bouin's fluid. For histologic assessment, each trachea was cross-sectioned into 8–10 pieces and embedded into one block of paraffin. At least four sections 150 μm apart were made from each paraffin block and stained with hematoxylin and eosin. The histopathology of these sections was assessed.

Histopathologic assessment.—The percentage of the tracheal luminal surface covered by different types of epithelium was calculated in all carcinogen-exposed animals with the use of cross sections of each trachea, as previously described (*19*). The following epithelial types were determined as defined in previous publications (*20, 21*): *a*) normal mucociliary epithelium, *b*) columnar hyperplastic epithelium, *c*) atrophic or cuboidal epithelium, *d*) squamous metaplasia with no or mild atypia, *e*) squamous metaplasia with moderate atypia, *f*) squamous metaplasia with severe atypia or carcinoma in situ, and *g*) invasive carcinoma. Each section was directly projected with a Zeiss projecting microscope attached to the screen of a Ladd graphic digitizer interphased with a Monroe 1860 calculator, and the extent of the luminal surface covered by each epithelial type was measured. This procedure is shown in figure 1. Lesions smaller than 100 μm could not be resolved by this method and were not included in this study. This analytic system permitted a precise planimetric determination of each type of epithelium. Percentages of the tracheal surface occupied by each type of epithelium were calculated for each trachea. The mean percentage from four tracheas was calculated to estimate the pathologic status of each group. Since the percentage of luminal surface covered by different lesions does not give an estimate of the number of lesions involved, the number of focal epithelial lesions including lesions less than 100 μm in diameter were counted. The total numbers of these lesions per trachea were averaged to give another estimate of the pathologic status of each group.

RESULTS

Delivery of DMBA In Vivo

The matrices composed of either beeswax, 1:1 beeswax–cholesterol, or 1:1 beeswax–stearyl alcohol exhibited a very fast release of DMBA (i.e., ≈90% of the DMBA was released in 2 wk and almost 100% of the DMBA was released in 4 wk) (text-fig. 1,a). Although these three matrices showed a similar release rate, the beeswax pellets presented a slightly faster release rate (text-fig. 1,a). In addition, since the beeswax–cholesterol pellets contained 250 μg DMBA and all the other pellets had only 200 μg DMBA, the cumulated DMBA released from the former pellets was slightly higher (text-fig. 1,b). When the beeswax-to-stearyl alcohol ratio was increased to 1:9, release of 90% DMBA required 8 weeks. With 1:9 cholesterol or 1:4 carbon pellets, 80–90% release of DMBA was achieved at 16 weeks. Finally, with 1:9 carbon pellets, only 56% of the DMBA was released at 16 weeks.

Histologic Observations

Control Pellets

None of the compounds used to make the pellet matrices (blank pellets) produced marked changes of the tracheal mucosa. Beeswax blanks induced no lesions, whereas 1:9 beeswax–cholesterol pellets caused occasional atrophy and/or hyperplasia of the epithelium. Pellets made of 1:9 beeswax–stearyl alcohol and this matrix with 1,800 μg of carbon

TEXT-FIGURE 2.—Percentages of the epithelial surface exhibiting specific types of nondysplastic epithelium in tracheas at different times after implantation of the following: a) beeswax pellets containing 200 μg DMBA, b) 1:1 beeswax–cholesterol pellets containing 250 μg DMBA, c) 1:1 beeswax–stearyl alcohol pellets containing 200 μg DMBA, d) 1:9 beeswax–stearyl alcohol pellets containing 200 μg DMBA, e) 1:4 carbon pellets containing 200 μg DMBA, f) 1:9 beeswax–cholesterol pellets containing 250 μg DMBA, and g) 1:9 carbon pellets containing 200 μg DMBA. ◆, normal columnar ciliated epithelium; □, hyperplastic epithelium; △, atrophic epithelium; ○, regular squamous metaplastic epithelium or squamous metaplastic epithelium with mild atypia. Standard errors of each value were ≤18.0% of the mean.

caused a somewhat stronger reaction, resulting in a few small foci of flattened or atrophic epithelium (not shown).

DMBA Pellets

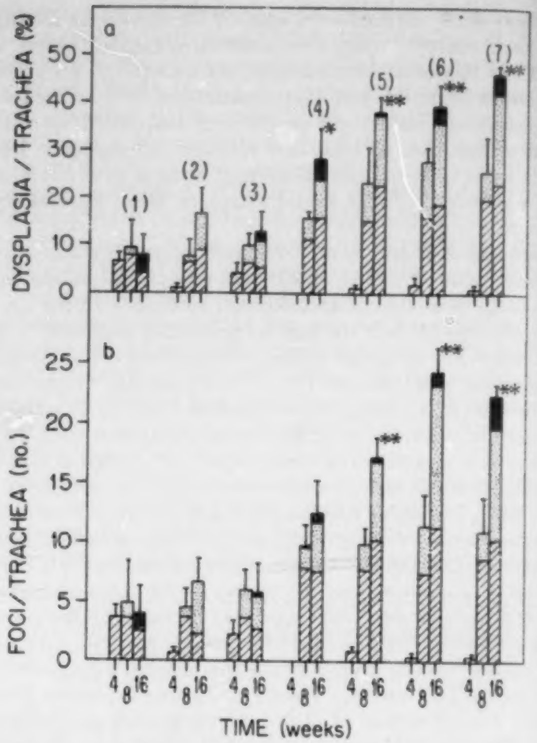
Nondysplastic lesions appeared very early after DMBA exposure. The types of lesions and their extent at different time points depended on the release rate of DMBA (text-fig. 2).

Early epithelial atrophy was seen in all groups and occupied a large percentage of the luminal surface at 1 week. The faster the release rate of DMBA, the larger the extent of luminal surface covered by atrophic epithelium at this time point (text-fig. 2,a–f). After the 1st week the percentage of atrophic epithelium covering the luminal surface decreased abruptly, and in most cases the atrophic epithelium was absent at 2 or 4 weeks. After 4 weeks the percentage of atrophic epithelium increased gradually, reaching in most cases a second, although lower, peak at 16 weeks. The extent of atrophic epithelium found in the trachea at this time was directly proportional to the DMBA dose rate. With fast DMBA release (e.g., beeswax, 1:1 beeswax–cholesterol), 40–60% of the luminal surface was occupied by atrophic epithelium. With slow DMBA release (e.g., 1:9 beeswax–cholesterol and 1:9 carbon pellets), atrophic epithelium covered approximately 10% of the luminal surface. The other pellets with moderate release rates showed intermediate values.

For determination of an eventual relationship between the initial toxic events induced by the early release of DMBA and the later appearance of involutional changes in the epithelium (atrophic epithelium), the percentage of luminal surface covered by atrophic epithelium at 16 weeks was plotted against the cumulative amount of DMBA released to the trachea at 1 and 2 weeks (plots not shown). Although no correlation was found at 1 week, a linear correlation (r=0.797, P<0.05) was noted between the relative percentages of the luminal surface covered by atrophic epithelium at 16 weeks and cumulative dosage of DMBA at 2 weeks.

Regular squamous metaplasia, which was practically absent at 1 week in all groups except the low-dose-rate groups (text-fig. 2,f and g), increased markedly between 2 and 4 weeks. This increase coincided with a reduction in the percentage of luminal surface occupied by atrophic epithelium. After this peak the extent of regular squamous metaplasia decreased gradually, and at 16 weeks the percentage of luminal surface occupied by this type of epithelium was 20–60%, being more prominent in the low-dose-rate group.

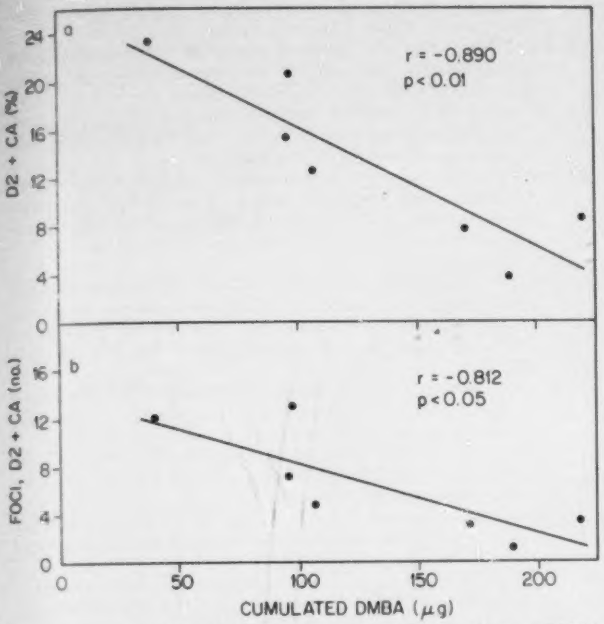
After 4 weeks of exposure most tracheal transplants began to develop dysplastic lesions (text-fig. 3). Although at 4 weeks the grade of atypia was moderate, some of the rapid-releasing pellets (i.e., beeswax and 1:1 beeswax–stearyl alcohol pellets) induced more extensive dysplastic lesions. At 8 weeks of exposure the total percentage of luminal surface occupied by all types of dysplastic lesions increased markedly in all groups, and severe dysplasia was also evident. Between 8 and 16 weeks the percentage of luminal surface occupied by dysplastic lesions continued to increase. This increase coincided with a reduction in the percentage of luminal surface covered by regular squamous metaplasia. At 16 weeks tracheas in the slow-release group (i.e., exposed to DMBA released from 1:9 stearyl alcohol, 1:4 and 1:9 carbon, 1:9 cholesterol pellets) showed three to six times higher percentages of luminal dysplasias than those in the fast-release group (beeswax, 1:1 cholesterol, 1:1 stearyl alcohol). All DMBA-exposed groups except the 1:1 cholesterol group showed invasive carcinomas.



TEXT-FIGURE 3.—Incidence of specific types of dysplastic epithelia in tracheal transplants at different time points after implantation of (1) beeswax pellets containing 200 μg DMBA, (2) 1:1 beeswax–cholesterol pellets containing 250 μg DMBA, (3) 1:1 beeswax–stearyl alcohol pellets containing 200 μg DMBA, (4) 1:9 beeswax–stearyl alcohol pellets containing 200 μg DMBA, (5) 1:4 carbon pellets containing 200 μg DMBA, (6) 1:9 beeswax–cholesterol pellets containing 250 μg DMBA, and (7) 1:9 carbon pellets containing 200 μg DMBA. a) Percentage of tracheal luminal surface occupied by dysplasia per each trachea + SEM. b) Number of dysplastic foci per each trachea + SEM. ▨, metaplasia with moderate atypia; ▩, metaplasia with severe atypia or carcinoma in situ; ■, invasive carcinoma. *, significant at P<0.05, compared with beeswax pellets containing 200 μg DMBA by Student's t-test. **, significant at P<0.01, compared with beeswax pellets containing 200 μg DMBA by Student's t-test.

The alterations in the epithelium of the tracheal mucosa were also quantitated in terms of numbers of foci of different types of dysplastic lesions per trachea (text-fig. 3,b). The dysplastic plus neoplastic foci were counted. In general, these data are similar to those found above (text-fig. 3,a). Tracheas in the slower release groups (i.e., 1:9 stearyl alcohol, the carbon-containing, and 1:9 cholesterol pellets) showed two to five times more dysplastic plus neoplastic foci than were seen with DMBA released from beeswax pellets.

The percentage of lumen covered by metaplasia with severe atypia plus carcinoma at the late time point was related to the cumulative amount of DMBA released to the



TEXT-FIGURE 4.—a) Correlation between cumulative amount of DMBA released at 2 wk of exposure and percentage of severe atypical metaplasia and carcinoma in situ (D2) plus invasive carcinoma (CA) at 16 wk. b) Correlation between cumulative amount of DMBA released at 2-wk exposure and number of foci of severe atypical metaplasia and carcinoma in situ (D2) plus invasive carcinoma (CA) at 16 wk.

tracheas at early time points. An inverse linear correlation ($P<0.01$) was noted between the relative percentage of these dysplastic and neoplastic epithelia at 16 weeks and the cumulative dosage of DMBA at 2 weeks (text-fig. 4,a). A similar but less significant negative correlation ($P<0.05$) was also observed between the number of dysplastic and neoplastic foci per trachea at 16 weeks and cumulative dosage of DMBA at 2 weeks (text-fig. 4,b).

DISCUSSION

In this study, we demonstrate that higher incidences of dysplastic plus neoplastic lesions are induced in the tracheal mucosa when the rate of release of DMBA to the trachea is lowered. These higher incidences were seen even though the total dose of carcinogen delivered at 16 weeks was also markedly reduced. The different rates of release were obtained by addition of various substances into the beeswax pellet matrix used to deliver carcinogen to tracheal transplants.

In the present experiments, carcinogen exposure was modified by incorporation of varying amounts of cholesterol, stearyl alcohol, and carbon particles into the beeswax matrix. Cholesterol has been previously used as a matrix for controlled release of steroids (*22*). Adding these substances to the beeswax was very effective in altering the release of DMBA when one considers that in 2 weeks 94% of the total DMBA was released from beeswax pellets and 39% was released from the 1:9 beeswax–cholesterol pellets, whereas only 19% was released when the DMBA was first adsorbed to carbon, and these were mixed into a 1:9 beeswax–stearyl alcohol matrix. Several attempts to decrease the release rate of carcinogen at different sites of the respiratory tract have been previously reported (*11–16, 23–27*). Shors et al. (*28*) and Saffiotti et al. (*29*), using BP within a silicon rubber matrix implanted intraluminally in the bronchi of hamsters, suggested that sustained slow exposure was more effective than previous instillation methods in which large doses were delivered in short exposures.

Carcinogen release from cylindrically shaped pellets such as those used by Shors et al. (*28*) and by us follows Fick's first law of diffusion (*30*). The release is controlled by diffusion rate and surface area and follows an exponential function. The detailed mechanism of release of BP from beeswax has been discussed by Pal et al. (*17*). It has been shown that at high concentration, most of the BP is present in the pellet in crystalline form. The crystals of BP gradually dissolve in the beeswax and diffuse into the surrounding medium. As for DMBA, it is conceivable that its release follows a similar mechanism. Since aromatic hydrocarbons are less soluble in cholesterol and/or stearyl alcohol than in beeswax, we selected these substances to obtain a slower release of carcinogen. In addition, DMBA absorbed on carbon particles is released with difficulty to the surrounding matrix. In the initial release phase, cylindrical pellets show an abrupt short-lived rapid-release rate which is called a "burst effect" (*31*). This rapid release probably has a very toxic effect on the surrounding tissues. By introducing cholesterol and stearyl alcohol and by changing the ratio of the pellet matrix components, we attained significant decreases in the release rate. Consequently, this produced a decrease in the initial burst effect, thus reducing the acute toxic effects and enhancing the chronic action of the carcinogen.

Histologic features of tracheal epithelium exposed to varying doses of DMBA with beeswax pellets have been reported earlier (*4, 20, 21*). In these earlier studies, extensive atrophy persisted a long time after the relatively brusque exposure to carcinogen. In our experiment, atrophic epithelium was the predominant type covering all tracheas 1 week after DMBA exposure, irrespective of the release rate. However, lower percentages of atrophic epithelium were noted in tracheas from some of the slow-release groups, compared with tracheas exposed to DMBA released from beeswax pellets. The percentages of atrophic epithelium that reappeared at later stages of exposure had significant positive correlation with higher amounts of DMBA released at early time points. These phenomena might suggest that such atrophic epithelium is a consequence of toxic damage to the epithelial cells as reported previously (*21*), and decreased toxicity is achieved with slow-release exposure.

Regular metaplasia was observed in all experimental groups, and no marked differences were observed between fast- and slow-release groups in the relative percentage of the lumina occupied by regular metaplasia. The percentage of the luminal surface covered by regular metaplasia at early time points was not a good indicator of the degree of dysplasia or neoplasia that appeared in later stages. These observations are coincident with the fact that early regular metaplasia disappeared after cessation of carcinogen exposure (*20*).

In the later stages of exposure, the slow-release pellets induced a higher percentage of dysplastic and neoplastic epithelia, though the total released dose of DMBA was smaller. In other respiratory carcinogenesis models, similar dose relationships have been reported. In hamsters, intratracheal BP-ferric oxide instillations, when administered repeatedly in fractioned small doses, were more effective in inducing respiratory tract tumors than was a large, single dose (*32, 33*). In rats, nitrosoheptamethyleneimine given orally in multiple small doses was more effective than a large equivalent single administration (*34*). Although it is difficult, if not impossible, to evaluate the amount of carcinogen delivered to the respiratory tract epithelium in these models, the observations imply that fractionation of the carcinogen dose is more effective in inducing neoplasia than the same total dose given in a single administration.

The rat tracheal transplant system, which allows a precise carcinogen exposure of a localized portion of the respiratory tract epithelium and at the same time allows a quantitative estimation of the amount of carcinogen released from the carcinogen delivery devices, is the model of choice to study the dose-rate relation of carcinogens. Our data show that the dose rate is an important factor in carcinogenesis, since an inverse correlation between initial cumulated amount of DMBA and final amount of dysplastic epithelium was observed. By the further development of sustained carcinogen-release technology, which is closer to naturally occurring carcinogenesis, more precise analyses of preneoplastic stages of respiratory epithelium should be achieved.

FIGURE 1.—Schematic presentation of morphometric method. Carcinogen-exposed tracheal transplants were cut in 8 or 10 rings and processed for routine histologic observation. Hematoxylin and eosin sections were directly projected on the screen of a graphic digitizer interphased with a calculator. Planimetric measurements were performed on these sections. In these two examples, the following epithelial types were detected: N, normal mucociliary epithelium; A, atrophic epithelium; M, regular squamous metaplasia; D_1, squamous metaplasia with moderate atypia; CA, invasive carcinoma. The extent of each epithelial type was determined and expressed in microns. *Numbers in parentheses* are percentages of luminal circumference occupied by each epithelial type. These determinations were performed in all tracheal rings, and average values obtained from all rings were used as a representative figure for each tracheal transplant.

Exclusive Binding of Immunoglobulin to Fcγ Receptors on Macrophages in 3-Methylcholanthrene-Induced Murine Tumors[1,2,3]

John M. Lindsay,[4] Linda Manning,[4] *and* Gary W. Wood[4]

ABSTRACT—Immunogenic, chemically induced, murine tumors generally are infiltrated with large numbers of Fcγ receptor (FcγR)-positive cells, most of which are mononuclear phagocytes. This study demonstrates in inbred C3H/HeN mice that such immunogenic tumors contain large amounts of cell-bound immunoglobulin (Ig) and that, within the sensitivity limits of indirect immunofluorescence, the tumor-associated Ig is bound exclusively to host-derived FcγR-positive cells. Depletion of FcγR-positive cells from tumor cell suspensions removed all Ig-bearing cells. Specific competitive elution of the endogenous Ig with heterologous nonimmune IgG established that the endogenous Ig was bound through the FcγR. Tumor-associated FcγR-positive, Ig-bearing cells could be detected with soluble antigen–antibody complexes, and mononuclear phagocytes to which the exogenous complexes were bound expressed FcγR at a level significantly above normal. The role of this macrophage-associated Ig in determining the level of interaction between host cells and the tumor remains to be determined.—JNCI 1982; 69:1163–1174.

Experimental chemically induced tumors evoke an immune response in syngeneic hosts. Those tumors also are infiltrated by high numbers of host cells, predominantly macrophages, monocytes, and K-cells (*1–4*). Although it is controversial (*5*), the response appears to be dependent on tumor immunogenicity (*6, 7*) and intact T-lymphocyte-dependent function [(*8*); Gollahon K, Wood G: Unpublished observation]. Even tumors that are infiltrated by very high numbers of macrophages grow progressively to kill the host, although there is some evidence that infiltrating macrophages have an inhibitory effect on tumor metastasis (*3, 6*).

Although there is considerable evidence for a cellular antitumor immune response, less attention has been given to humoral immune responses to tumors. Nevertheless, antibodies to antigens on chemically induced tumors are detected in autochthonous tumor-bearing animals (*9, 10*). Natural antibodies to tumor-associated antigens also have been detected (*11, 12*). The influence of antibodies on tumor behavior is unknown, but the potential is considerable for interaction between the cellular and humoral aspects of the host response to tumors. Cytotoxic cellular antitumor responses are blocked by antibody (antigen–antibody complexes) (*13, 14*). Antibody may either mediate or, if in its complexed form, block antibody-dependent cellular cytotoxicity (*15, 16*).

A few studies of both human and experimental tumors have indicated that tumor-associated Ig may be bound to host cells within tumors (*17–19*). It is not clear whether this bound Ig represents antitumor antibody because antigen–antibody complexes unrelated to the tumor will bind to tumor-associated cells (*18, 20*). The suggestion has been made that some of the antibody could be anti-idiotype (*21*). Finally, it is not clear how much of the tumor-associated Ig is bound to host cells relative to the amount bound to tumor cells. Many of the discrepancies may relate to differences in tumors studied; i.e., cells free in the peritoneum may not have the same properties as solid tumor cells.

The present study was designed to use an extensively studied chemically induced tumor system, murine MCA-induced sarcoma, to investigate the form of interaction between Ig and host cells within primary and passaged solid tumors.

MATERIALS AND METHODS

Tumors.—Tumors were induced in male inbred C3H/HeN mice (M.A. Bioproducts, Walkersville, Md.) with MCA and appeared in 3–5 months. Tumors were removed and tissue was immediately frozen in liquid nitrogen and stored in sealed vials at −70°C.

Two of the tumors, designated MCA-80-36 and MCA-80-42, were passaged to normal C3H/HeN male mice and have been maintained by subcutaneous implantation. These 2 tumors subsequently were also established in tissue culture. To obtain tumors from which single cell suspensions could be produced, we gave normal male C3H/HeN mice injections of 10^6 washed tumor cells from tissue culture. Tumors appeared in 10 days to 2 weeks and generally were removed at about 3 weeks. Single cell suspensions of tumor were prepared by collagenase (type I, 1 mg/ml; Sigma Chemical Co., St. Louis, Mo.) and DNase (0.025 mg/ml) digestion.

Normal tissue.—C3H/HeN male mice were killed and spleen and liver tissues were removed, immediately frozen in liquid nitrogen, and stored at −70°C.

Glucan (beta-1,3-polyglucose)-stimulated liver tissue.—Activation of the mononuclear phagocyte system with glucan was performed as described previously (*22*). Male C3H/HeN mice were given a single iv injection of either 15 or 30 mg glucan/kg body weight (from Dr. Y. Yamamura, Department of Pathology, Loyola University, Chicago, Ill.), or they

were given injections of an equivalent volume of physiologic saline as a control. After 24 hours, the livers and spleens were removed from mice in each group, frozen in liquid nitrogen, and stored at −70°C.

Antisera.—Rabbit antisera to murine IgG$_1$, IgG$_{2a}$, IgG$_{2b}$, IgG$_3$, IgA, and IgM were purchased from Litton Bionetics, Kensington, Md.

Specific rabbit anti-mouse macrophage serum was prepared as described previously (*23*). Rabbits were immunized with peritoneal exudate cells from C3H/HeN mice, and the immune serum was absorbed exhaustively with murine kidney homogenate and murine thymus homogenate. The antiserum was used routinely at a dilution of 1:40, and at that concentration it demonstrated no reactivity with C3H/-HeN thymocytes in cytotoxicity and immunofluorescence assays, produced positive fluorescence with 75% of C3H/-HeN peritoneal exudate cells, and failed to react with mouse serum by Ouchterlony gel-diffusion analysis.

Monoclonal antibodies to murine Ia^k antigens were obtained in cell culture from a hybridoma cell line (10-2.16), which was received from the Salk Institute Cell Distribution Center, La Jolla, Calif. The antibodies were of the IgG$_{2b}$ class.

Anti-BSA was produced in rabbits by footpad injection of BSA in Freund's adjuvant. The pooled antiserum was diluted and found to give a positive line of precipitation at a dilution of 1:16 in an Ouchterlony gel-diffusion test against 1 mg BSA/ml in Dulbecco's phosphate-buffered saline. The antiserum contained no rheumatoid factor activity as determined by a human IgG-coated latex agglutination test.

A 1.8-*M* ammonium sulfate fraction of rabbit anti-BSA was reduced with 0.1 *M* 2-mercaptoethanol and alkylated with 0.2 *M* iodoacetamide as described previously (*24*). The protein concentration of the reduced and alkylated antiserum was determined by the Lowry method (*25*). The reduced and alkylated anti-BSA produced a detectable precipitation line with 1 mg BSA/ml at a dilution of 1:16. Another portion of the fractioned antiserum was enzymatically cleaved with pepsin by means of standard methods. The $F(ab')_2$ fragments of anti-BSA produced detectable precipitation in gel diffusion at a dilution of 1:2.

Preparation of soluble immune complexes.—Soluble immune complexes were prepared in threefold antigen excess (by weight). A 1:40 dilution of whole rabbit anti-BSA was mixed with an equal volume of 250 µg BSA/ml, incubated 18 hours at 37°C, and centrifuged for removal of precipitates. The supernatant containing soluble complexes was removed and used in indirect immunofluorescence assays on tumor tissue.

Indirect immunofluorescence.—Indirect immunofluorescence was performed as described previously (*23*). All antisera were used at optimal concentrations, predetermined empirically to be the highest dilution at which a strong, positive reaction was produced. The reaction was developed with fluorescein isothiocyanate-conjugated goat anti-rabbit Ig. The anti-rabbit Ig failed to cross-react with mouse IgG in gel-precipitation analysis. The fluorescein-to-protein ratio of the conjugate was 3.8, and the dilution at which it was routinely used was 1:40. All reagents were centrifuged for 60 minutes at 140,000×*g* prior to use for removal of Ig aggregates.

Rosette formation with antibody-coated SRBC.—The percentage of FcγR-positive cells in tumors was determined by EA rosette formation with SRBC coated with rabbit anti-SRBC as described previously (*2*).

To deplete rosette-positive cells from the tumor cell suspension, we devised the following procedure: 2×10^7 tumor cells were mixed with an appropriate amount of EA, and the cells were rosetted. After the rosetted cells were sedimented, the supernatant was removed, and 20 ml of goat anti-rabbit IgG diluted 1:50 was added to the cells, which were resuspended and incubated for 15 minutes at 37°C. This procedure resulted in passive agglutination of the SRBC. The cells then were sedimented. The highly agglutinated rosettes were gently resuspended and allowed to resediment at unit gravity. The supernatant containing tumor cells essentially free of rosetted cells was removed and sedimented, and excess SRBC were lysed with Tris–ammonium chloride.

RESULTS

Association of Ig With Macrophages

Of 29 primary MCA-induced tumors, 27 were infiltrated by significant numbers of mononuclear phagocytes as determined by morphology, EA rosette formation, and nonspecific esterase staining (*23*). Tumor-associated macrophages were identifiable in sections of tumors with the use of anti-mouse macrophage serum (fig. 1), the specificity of which has been documented previously (*23*). The tumors also were stained with antiserum to various murine Ig (IgG$_1$, IgG$_{2a}$, IgG$_{2b}$, IgG$_3$, IgA, and IgM) (fig. 2). All IgG classes were represented in the tumors; IgA and IgM were variably detected. Details of these observations have been reported previously (*19*).

Qualitatively, the distribution of Ig and macrophages was similar when sequential sections of tumor were stained (figs. 1, 2). When double-labeling experiments were performed with rhodamine-tagged anti-mouse IgG and fluorescence-tagged antimacrophage serum on selected tumors, the red- and green-staining patterns were coincident. The distribution of macrophages and cells positive for Ig also was quantitatively similar. The two tumors that contained no identifiable macrophages also contained very small amounts of Ig. Tumors containing few sparsely distributed macrophages had comparable numbers of cells bearing identifiable Ig, and tumors that were heavily infiltrated with macrophages contained very high levels of Ig-bearing cells.

Coincidence of staining for Ig with distribution of FcγR-positive cells allows the possibility of an artifactual explanation. Therefore, it was necessary to exclude nonspecific interaction of reagents with FcγR. Normal rabbit serum at a fivefold higher concentration than that of the specific reagents did not exhibit significant attachment to tumor sections. When we removed tumor-associated Ig from sections by washing them with 0.1 *M* (pH 2.5) glycine–HCl buffer, we observed no FcγR-dependent attachment of anti-Ig reagents.

Observations of tissue sections necessarily are qualitative, demonstrating only that some tumor-associated Ig is associated with the FcγR-positive tumor-associated macrophages. To determine if most or all Ig was macrophage associated, we removed passaged tumors containing 30–50% macrophages from animals, and we tested single cell suspensions for Ig-bearing cells. Two cell populations were tested: the original cell population and a cell population depleted of FcγR-positive cells by unit gravity sedimentation of EA-rosetted cells. The cells then were stained by indirect immunofluorescence with rabbit anti-mouse IgG_1 and IgG_{2a}. Representative data are included in table 1. The percentages of cells with surface-associated Ig were similar to the percentages of EA rosette-positive cells in the suspensions. Thus when FcγR-positive cells were depleted from the tumor suspensions, Ig-positive cells also were removed. These experiments also demonstrated that at least some of the Ig observed in tumor tissue sections was bound to cell membranes.

Association of Ig With FcγR

Essentially, all Ig detectable by indirect immunofluorescence was eluted from each of the tumors when the tumor sections were washed at 22°C for 10 minutes with acetate buffer (pH 5.0). Two types of controls were introduced for this experiment. Two antisera that are reactive with macrophage-associated antigens were used as negative controls: the heterologous rabbit anti-mouse macrophage serum and a monoclonal alloantiserum reactive with Ia^k antigens. When tumor sections were reacted with either antiserum and then washed at 22°C for 30 minutes at pH 5.0, the amount of antibody bound to the tumor-associated macrophages was undiminished (fig. 3), whereas washing the tissue with glycine–HCl buffer (pH 2.5) totally removed the bound antibodies. Whereas in all tumors tested an approximately equal proportion of tumor-associated cells were Ig-positive, FcγR-positive, and reactive with the antimacrophage serum, a lower percentage of the cells was outlined by the anti-Ia^k serum; i.e., a subpopulation of the tumor-associated FcγR-positive cells was Ia antigen-positive. The positive control was provided when tumor sections were exposed to soluble antigen–antibody complexes (BSA and anti-BSA), washed at pH 5.0, and then stained for residual rabbit Ig. The pH-5.0 buffer treatment of sections covered with exogenous complexes resulted in complete removal of the added complexes. Tissue sections pretreated with pH-5.0 or pH-2.5 buffer bound high levels of exogenous complexes, demonstrating that receptors were unaffected.

TABLE 1.—*Association between Ig and cells isolated from progressing MCA-induced tumors*

Tumor[a]	Percent of total cells positive				
	FcγR[b]	Macrophage[c]	IgG_1[d]	IgG_{2a}[d]	IgM[d]
MCA-80-36 original[e]	37	39	32	35	12
MCA-80-36 depleted[e]	<5	<5	<1	<1	<1
MCA-80-42 original	47	43	34	38	20
MCA-80-42 depleted	6	5	<5	<5	<5

[a] Tumors were produced by sc injection of tumor cells from tissue cultures.

[b] Percentage of tumor cell suspension comprised by FcγR-positive cells was determined by EA rosette formation.

[c] Percentage of tumor cell suspension comprised by macrophages was determined by indirect immunofluorescence with antimacrophage serum.

[d] Percentage of tumor cell suspension comprised by cells with membrane-bound Ig determined by indirect immunofluorescence.

[e] The original cell suspension was derived by collagenase–DNase digestion of minced tumor. FcγR-positive cells were depleted from EA-rosetted tumor cell suspensions by agglutination and unit gradient sedimentation.

The second piece of experimental evidence demonstrating that the macrophage-associated Ig was bound to FcγR was obtained through competitive removal of endogenous Ig in the presence of a high concentration of heterologous IgG. Tumor sections were incubated in the presence of 10 mg normal human Ig/ml at 22°C for 60 minutes and then stained for residual murine Ig. This procedure reduced murine Ig to below detectable levels in each of the tumors tested (fig. 4), but tumors then were coated with significant amounts of human Ig. Tumor sections incubated in the presence of equivalent concentrations of albumin as a control were unaffected; i.e., significant amounts of Ig still were detected bound to the macrophages (fig. 5).

Attachment of Soluble Antigen–Antibody Complexes to Tumor-Associated Cells

Previous studies of FcγR-positive cells in tumor tissue used particulate antibody-coated erythrocytes, a method that does not outline individual cells (*1–4*). In the present study, soluble antigen–antibody complexes attached to cells in tissue sections and exhibited a distribution similar to that of macrophage antigen and Ig-positive cells (fig. 6).

All of the above results, including anti-Ig positivity, could be explained if the tumor-associated Ig contained rheumatoid factor. This possibility was excluded because complexes formed with BSA and mildly reduced and alkylated anti-BSA, which bind strongly to rheumatoid factor but not FcγR, failed to attach to tumor tissue, even though the presence of complexes was documented by sucrose density gradient sedimentation and gel-diffusion analysis. Further evidence for the lack of anti-Ig activity in tumor-associated Ig was obtained by elution of Ig from tissue at pH 2.5 and by demonstration that soluble complexes still attached to the tumor.

The fact that soluble antigen–antibody complexes exhibited facile binding to most tumor-associated macrophages in each of the tumors studied suggested that those cells might have altered, e.g., increased, FcγR expression. To test that possibility, we performed parallel experiments wherein exogenous complexes were added to the tumor, liver, and spleen. As in previous experiments, consistent attachment occurred to tumor-associated cells, but complexes failed to attach to cells in normal liver or spleen, suggesting that neither the Kupffer cells nor the splenic FcγR-positive cells expressed FcγR with sufficient density or affinity to bind the soluble complexes. Cells in livers and spleens from tumor-bearing animals were intermediate. Complexes attached weakly to Kupffer cells and splenic FcγR-positive cells from some animals but not others.

To test the possibility that, at the level of sensitivity of the soluble complex assay, there was discrimination between normal resting tissue macrophages and stimulated tumor-associated macrophages with heightened FcγR activity, we exposed normal mice to a reticuloendothelial system stimulant and then tested them for FcγR expression. Three groups of normal male C3H/HeN mice were given injections iv of 0, 15, and 30 mg/glucan kg body weight; glucan is a known stimulator of the mononuclear phagocyte system (*22*). Twenty-four hours later the animals were tested for FcγR expression. No attachment to liver sections from control mice (saline injected) was observed (fig. 7), but complexes attached to most, if not all, macrophages in livers from animals given injections of 30 mg glucan/kg (fig. 8). Animals given injections of 15 mg glucan/kg exhibited some attachment of complexes to liver sections, but this attachment was sparse and of low intensity. This experiment was repeated on several occasions with comparable results.

DISCUSSION

A great deal of confusion exists with respect to the association between host Ig and tumor cells (*9*). This is understandable because most of the early studies were performed without knowledge that very high numbers of host-derived cells could be present within tumors. Moreover, these studies were performed with methodology, such as ^{125}I-antiglobulin labeling, which is incapable of discriminating cell types, and methodology, which was not properly controlled for FcγR reactivity.

The variety of potential roles that antibody can play in an immune response to tumors requires that those problems be solved and the antibody–cell interaction be evaluated. In addition to direct, complement-dependent cytotoxicity on cells, antibody may be involved in mediating or blocking antibody-dependent cellular cytotoxicity (*15, 16*), it may function as a "blocking factor" (*13, 14*), or it could be involved in anti-idiotype regulation (*21*). The present study was designed to answer the following questions. With the use of the extensively studied MCA-induced murine sarcoma system, a prototype for immunogenic, rarely metastasizing tumors, how does Ig interact with tumor cells and/or tumor-associated host cells? Is Ig predominantly associated with one or the other? If Ig is associated with host cells, is it bound to cell antigens or is it bound to FcγR? If it is bound to FcγR, do those receptors have greater than normal avidity for Ig?

The results established several points: 1) In these particular tumors, at the sensitivity level of indirect immunofluorescence, Ig is bound exclusively to FcγR-positive cells. Numerous studies have established that, with the exception of a few granulocytes, the FcγR-positive cells are entirely accounted for as macrophages or monocytes (*1–4*). Therefore, most Ig was macrophage associated. Recently, several studies have indicated the presence of functionally defined "natural killer" and "natural cytotoxic" cells within tumors. Since we have not defined cells in any functional way, it is not clear what relationship there is to those types of cells. 2) Ig was both on the membrane of cells and in cell cytoplasm. This may be interpreted to mean that Ig first interacted with cell membranes and was then endocytosed. 3) Ig was FcγR associated. Many pieces of indirect evidence support this conclusion, but proof is provided by the fact that Ig could be specifically eluted with heterologous normal IgG. This is classic proof of receptor–ligand interaction. 4) The tumor-associated Ig exhibited no anti-Ig activity, but this did not formally prove absence of anti-idiotype. 5) The tumor-associated FcγR exhibited a significantly increased binding of Ig in the form of complexes in comparison with FcγR on normal resting macrophages. Uncomplexed Ig still exhibited minimal binding to the macrophages' FcγR. This finding is consistent with the observation that a variety of stimuli can result in increased expression of FcγR on monocytes and macrophages (*26*).

The results failed to establish several points, two of which are of extreme importance: 1) It is unclear whether the macrophage-associated Ig represented antibody to tumor antigens or was simply FcγR-associated normal Ig or unrelated complexes. 2) It is unclear whether the FcγR-associated Ig was in the form of cytophilic antibody, antigen-antibody complexes, or both. Nevertheless, we believe that the results we have presented in this study provide significant insight into the interaction between the immune system and developing tumors.

Independent Expression of Chemical Carcinogen-Induced Phenotypic Properties Frequently Associated With the Neoplastic State in a Cultured Guinea Pig Cell Line[1,2]

Charles H. Evans[3,4] *and* **Joseph A. DiPaolo**[3]

ABSTRACT—Relationships among carcinogen-induced morphologic transformation, anchorage independence, susceptibility to growth inhibition by the immunologic hormone lymphotoxin and to natural killer cell and natural lymphoid cell cytotoxicity, natural delayed-type (tuberculin) skin reactivity, and tumorigenicity were investigated with the use of a guinea pig cell culture model of carcinogenesis characterized by sequential, extended developmental stages. Twelve cultures of passage 90 nontumorigenic fibroblast-like line 118 cells derived from a 36-day-old strain 2/N guinea pig fetus were treated with 10 μg benzo[*a*]pyrene or 1 μg *N*-nitroso-*N*-methylnitroguanidine/ml medium for 3 days and maintained in exponential growth. One week later, all cultures exhibited morphologic alteration, and by 8 weeks two-thirds exhibited morphologic transformation. After 4 months, morphologically altered or transformed cells expressed progressive colony growth in semisolid 0.35% agar medium. Susceptibility to lymphotoxin colony inhibitory activity developed subsequent to morphologic transformation but independently of growth in semisolid medium. Susceptibility to natural lymphoid cell destruction was also independent of growth in semisolid medium. All four phenotypic properties were expressed only after carcinogen treatment and 12 months later remained unaccompanied by either natural delayed-type skin reactivity or by the ability of the cells to grow as tumors in syngeneic guinea pigs or *nu/nu* nude mice. Thus while morphologic transformation, colony formation in semisolid medium, and susceptibility to lymphotoxin and to natural lymphoid cell cytotoxicity were frequently associated with neoplasia, they could be expressed independently of one another; individually or collectively in a specific developmental sequence, they were insufficient for expression of either natural delayed-type skin reactivity or tumorigenicity.—JNCI 1982; 69:1175–1182.

Chemical carcinogen and irradiation carcinogenesis in strain 2/N guinea pig fetal fibroblast-like cells in culture develops with a latent period from 4 to 24 or more months between carcinogen treatment and neoplastic transformation (the ability of cells to grow as a tumor) (*1, 2*). This long latent period of carcinogenesis is characterized by discrete, extended, and sequential preneoplastic stages of morphologic alteration, a persistent deviation from the normal growth pattern, and morphologic transformation (a lack of orientation with random crisscrossing and piling up of cells) (*1*). Morphologic transformation, moreover, often develops months before the transformed cells are able to produce tumors. The expressions of carcinogen-induced phenotypic alterations in Syrian golden hamster (*3*) and in mouse (*4, 5*) cells also can develop sequentially, although their expressions frequently are more telescoped into a shorter latent period than those in guinea pig (*1, 2*), human (*6–8*), or rat (*9, 10*) cells. The presence of extended stages during the process of transformation in guinea pig cells derived from syngeneic animals with well-characterized tumor immunology (*11, 12*) facilitates study of the relationships among carcinogen-induced somatic cell alterations in terms of their temporal and sequential expression, interdependence, contribution to neoplastic transformation, and interaction with natural immunobiologic mechanisms possessing the potential to control carcinogenesis (*2, 13, 14*).

Morphologically transformed guinea pig cells with the ability to form progressively growing tumors express a variety of other phenotypic properties, including growth in semisolid agar medium (*1, 2*), susceptibility to the growth inhibitory activity of the immunologic hormone lymphotoxin (*2, 13, 15*), increased susceptibility to natural (spontaneous) lymphoid cell destruction (*11, 14*), and intradermal delayed-type (tuberculin-like) skin reactivity in nonimmune guinea pigs (*12, 15*). These somatic cell alterations appearing after carcinogen treatment of early-passage fetal guinea pig cells frequently develop temporally in close association with expression of tumorigenicity (*1, 2, 13*). This investigation further defines the relationships among these different somatic cell phenotypic properties after chemical carcinogen treatment of a more homogeneous cell population than is present in freshly isolated cells derived from whole fetuses. The temporal acquisition of these phenotypic properties during chemical carcinogen-induced transformation was, therefore, studied with the use of pseudodiploid, morphologically nontransformed and nontumorigenic cells of a strain 2/N guinea pig fibroblast-like permanent cell line, designated 118, that retains its nontumorigenicity and associated nontransformed properties after continuous cultivation for more than 1 year (*1, 16*). Originally, line 118 cells were the acetone-treated control for sister cultures transformed by a chemical carcinogen to the neoplastic state. Characteristics of those tumorigenic cells were an extended minimal latent period of 18 months between carcinogen insult and their ability to form colonies in agar and produce tumors in vivo (*1*). Because sequential preneoplastic stages of morphologic alteration and transformation were expressed during the development of carcinogenesis in those

cells, we decided to study the temporal expression of a variety of carcinogen-induced phenotypic properties in the more homogeneous line 118 cells derived from the same fetus.

MATERIALS AND METHODS

Derivation and carcinogen treatment of guinea pig line 118 cells.—The fibroblast-like, morphologically nontransformed and nontumorigenic guinea pig continuous cell line 118 was originally derived from a 36-day strain 2/N fetus (*1*). Cells stored in a liquid-nitrogen refrigerator were reintroduced in culture at the 88th 1:10 passage and subcultured in RPMI-1640 medium–10% FBS as previously described (*17*). Twelve 100-mm tissue culture dishes (Falcon Plastics, Oxnard, Calif.) were seeded with 1×10^5 cells at the 90th subculture; 24 hours later, six dishes (BP1–6) were treated with 10 μg BP/ml medium and 6 dishes (MNNG1–6) were treated with 1 μg MNNG/ml medium (*1*). After 3 days, the dishes were refed with medium without carcinogen. Subsequently, cells were detached when confluent with 0.1% trypsin and serially subcultured 1:3 to maintain continuous exponential growth. Development of morphologically altered cells and of morphologic transformation was monitored by examination of Giemsa-stained mass cultures and colonies from sparsely seeded cells (*1*).

Growth of cells in semisolid agar media.—The ability of carcinogen-treated line 118 cells to form progressively growing macroscopic colonies of greater than 50–100 cells in 0.35% agar medium (*1*) was evaluated at monthly intervals. We seeded 10^2, 10^3, 10^4, and 10^5 cells in 4 ml 0.35% agar–RPMI-1640–10% FBS over a 4-ml 0.7% basal agar medium layer in 60-mm tissue culture dishes. Ten or more dishes, collectively containing a minimum of 10^6 seeded cells, were examined microscopically for progressively growing colonies at 7, 14, and 21 days. Macroscopic colonies growing in the agar in dishes seeded with the lowest cell concentration producing colonies were individually isolated at 15 or 22 days by aspiration into a Pasteur pipette and dispersed by repeated pipetting; then the cells were subcultured as described for the parent cultures.

Lymphotoxin susceptibility.—Using a colony inhibition assay with a reproducibility of ±5% (*13*), we analyzed the sensitivity of the carcinogen-treated cells to the growth inhibitory activity of lymphotoxin at monthly intervals. Interferon-free lymphotoxin was obtained from 10^7 mineral oil-induced strain 2/N guinea pig peritoneal leukocytes incubated for 24 hours with 1 mg phytohemagglutinin in 10 ml RPMI-1640 medium–10% FBS. The resulting cell-free lymphokine medium with lymphotoxin activity was frozen and stored at −35°C. The units of lymphotoxin in the lymphokine medium were determined as previously described (*14*). The colony inhibitory activity of the lymphotoxin was assessed with the use of BP-transformed 104C1 syngeneic guinea pig tumorigenic cells (*1*) as a positive control. In the assays for lymphotoxin susceptibility of carcinogen-treated line 118 cell cultures, 100 cells in RPMI-1640 medium–10% FBS were mixed with dilutions of the lymphotoxin and 4 ml of the cell mixture was added to a 60-mm tissue culture dish. We determined colony formation by counting the number of colonies greater than 0.2 mm in diameter present after 7 days' growth. Colony formation was expressed at each lymphotoxin concentration as a percentage of the colonies formed in dishes without lymphotoxin. Inhibition was present when there was a 10% or greater reduction in the number of colonies of cells incubated with lymphotoxin. Frozen aliquots of the same lymphotoxin preparation stored at −35°C were used throughout the investigation.

Susceptibility to natural killer cell- and natural lymphoid cell-mediated destruction.—Whole spleen leukocytes and spleen leukocytes nonadherent to glass and nylon wool were prepared and added to 10^4 $[^3H]$dThd and ^{51}Cr-labeled target cells, respectively, at effector-to-target cell ratios from 1:1 through 200:1; the specific $[^3H]$dThd release and specific ^{51}Cr release were measured at 72 hours for natural lymphoid and 4 hours for natural killer cell cytotoxicity, respectively, with a reproducibility of ±5%, as described elsewhere (*2, 14*).

Natural skin reactivity.—Natural skin reactivity is the ability of cells to produce a persistent or increasing induration in the skin of nonimmune, healthy syngeneic guinea pigs, as evidenced by a zero or positive slope during the 4 days following injection of the cells (*12*). Natural skin reactivity in nonimmunized guinea pigs was measured as is tuberculin delayed-type hypersensitivity skin reactivity in specifically immune animals. The degree of skin induration after intradermal injection of 5×10^6 cells into syngeneic nonimmune 4- to 6-month-old male guinea pigs was measured daily. As previously described (*12*), each animal in groups of 6 received four different cell inocula at separate sites; at one site BP tumorigenic 104C1 cells (*1*) were injected as the positive control. Cultures were initially evaluated 4 months after carcinogen treatment and subsequently once every 2 months if colony formation in agar medium or susceptibility to lymphotoxin had occurred.

Tumorigenicity assessment.—Commencing 4 months after carcinogen treatment, cultures were evaluated once every 2 months for natural skin reactivity and for their ability to grow as progressively enlarging tumors in syngeneic newborn (<24 hr old) male guinea pigs and in 8- to 10-week-old male *nu/nu* NIH Swiss mice as described elsewhere (*17*). Cells were detached from monolayer cultures with the use of 0.1% trypsin, centrifuged at 200×*g*, and resuspended in medium without serum. Guinea pigs and nude mice received sc injections of 10^7 and 5×10^7 cells, respectively, in 0.5 ml medium by means of a 21-gauge needle. Groups of 3 animals were used for each culture evaluated for tumorigenicity. Nude mice were observed for 6 months and guinea pigs for 2 years before being considered as negative for tumor growth. Injections of 104C1 cells with a threshold subcutaneous tumorigenicity of 10^3 cells in guinea pigs and 5×10^5 cells in nude mice served as the positive controls (*17*).

RESULTS

After 1 week, all line 118 BP and MNNG-treated cells displayed morphologic alterations (fig. 1C); by 2 months, morphologic transformation (fig. 1D), i.e., a loss of cell orientation, developed in 67% (8/12) of the cell cultures (table 1). Morphologic transformation persisted with sub-

[a] 0=absent; +=present.

[b] HM4 cells were derived from a 49-day strain 2/N guinea pig fetus treated in utero with MNNG 48 hr before introduction of cells in culture (*1*). BP and MNNG cultures were derived from a morphologically transformed and nontumorigenic strain 2/N guinea pig continuous cell line treated for 3 days with BP or MNNG 18 mo after establishment in culture from a 36-day fetus. Subline BP4 was derived from a colony in semisolid medium at 4 mo. Sublines MNNG3 and MNNG4 were derived from colonies in semisolid medium at 6 and 4 mo, respectively. Untreated (control) line 118 cells at the time of BP and MNNG treatment of sister cultures (passage 90) and 12 mo later remained morphologically unaltered (fig. 1A, 1B), did not form colonies in semisolid medium, did not exhibit susceptibility to lymphotoxin, and did not produce natural skin reactivity or tumors in nude mice or syngeneic guinea pigs.

[c] A=altered; T=transformed.

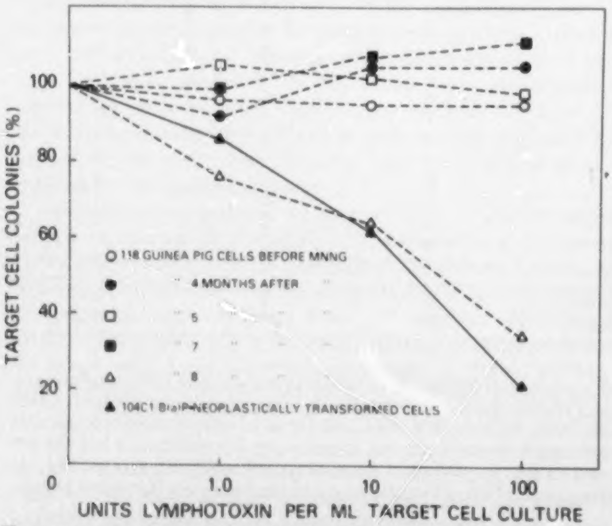
[d] Colony formation in 0.35% semisolid medium of BP4 at 4 mo, MNNG3 at 6 mo, and MNNG4 at 4 mo was 1×10^{-5}, 5×10^{-2}, and 5×10^{-4}, respectively; for sublines derived from colonies in semisolid medium, the frequencies when returned to semisolid medium were $1\text{-}9\times10^{-1}$. Frequency for HM4 was 2.5×10^{-1}. Untreated parent line 118 cells never formed colonies in semisolid medium.

[e] Susceptibility was defined as ≥10% colony inhibition (*see* "Materials and Methods").

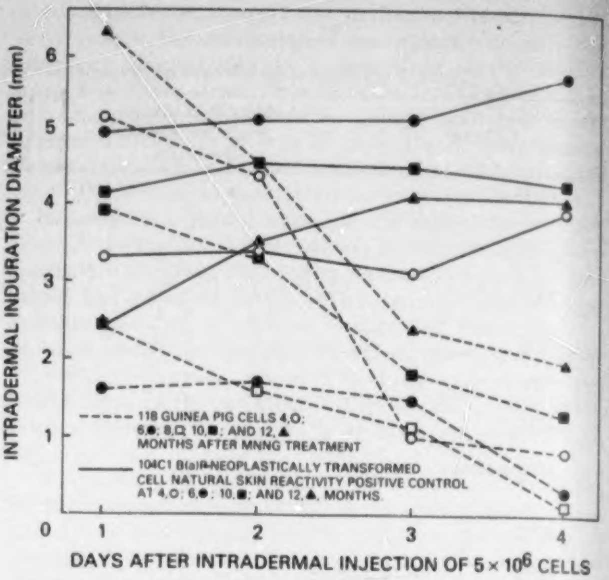
culturing, and neither altered nor transformed morphology was observed with untreated cells during 12 months of subculturing (figs. 1A, 1B). Morphologic alteration and morphologic transformation were dissociated from each other and the other studied phenotypic alterations. For example, either morphologic alteration (BP4) or morphologic transformation (MNNG4) was accompanied by or unaccompanied by (the remaining 11 cultures) colony formation in semisolid medium 4 months after carcinogen treatment (table 1). Twelve months after carcinogen treatment, morphologic alteration was accompanied by colony formation in semisolid medium (BP4), and morphologic transformation was accompanied by lymphotoxin susceptibility (MMNG2) or by lymphotoxin susceptibility and colony formation in semisolid medium (MNNG3 and MNNG4), further demonstrating the dissociability of morphologic changes from these other carcinogen-induced phenotypic alterations.

Colony formation in semisolid medium assessed at monthly intervals was first observed with a frequency of $>10^{-6}$ at 4 months in both morphologically altered (BP4) and transformed (MNNG4) cell populations. In some instances, the ability to form colonies in semisolid medium was expressed without the subsequent development of (BP4 cells) or prior to (MNNG3 and MNNG4 cells) the cells exhibiting susceptibility to lymphotoxin (table 1; text-fig. 1). Lymphotoxin susceptibility also incurred in morphologically transformed cells without subsequent development of the ability of the cells to form colonies in semisolid medium (MNNG2 in table 1).

The analysis of sublines, each derived from a colony growing in semisolid medium, verified that development of the ability of cells to proliferate in semisolid medium can precede expression of lymphotoxin susceptibility by an extended time. For example, MNNG4 formed colonies in semisolid medium at 4 months. One subline retained the ability to form colonies in semisolid medium, but the cells did not develop susceptibility to the growth inhibitory activity of lymphotoxin until 8 months after carcinogen treatment (table 1). Similarly, 4 sublines derived from 4 different MNNG3 colonies in semisolid medium at 6 months also developed sensitivity to lymphotoxin at the same time as the parent MNNG3 cultured, 8 months after carcinogen treatment.

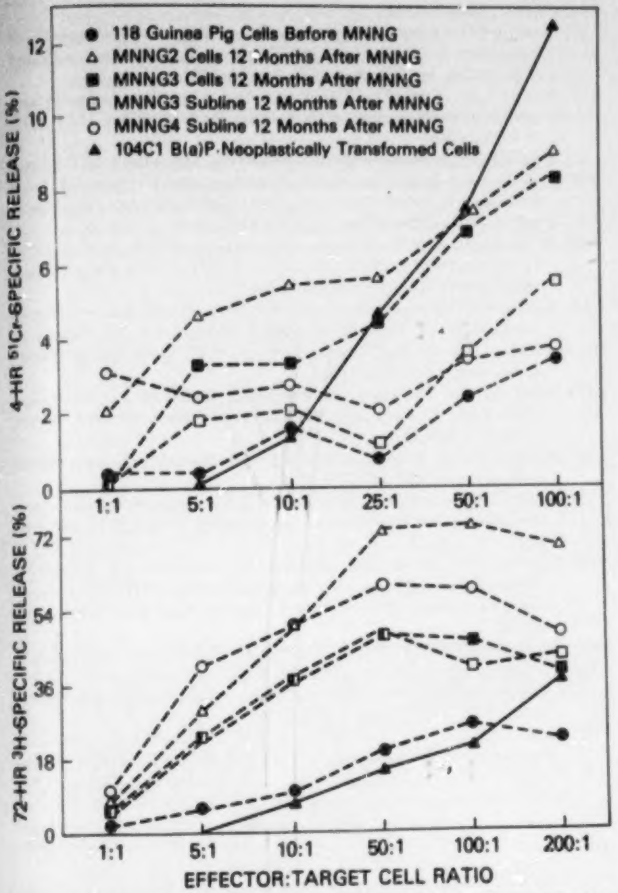


TEXT-FIGURE 1.—Susceptibility of continually subcultured MNNG-treated cells, culture MNNG3, to the growth inhibitory activity of lymphotoxin. Aliquots of lymphotoxin were incubated with 100 target cells in 4 ml medium/60-mm dish. The number of colonies >0.2 mm in diameter present after 7 days' incubation was counted, and the ratio of the number of colonies formed in the presence of lymphotoxin was compared to the number in medium alone expressed as percentage. B(a)P=BP. *Solid line,* 104C1 cells; *dashed lines,* 118 cell series.



TEXT-FIGURE 2.—Natural skin test reactivity of tumorigenic and continually subcultured MNNG-treated cells, culture MNNG3, in healthy, nonimmunized 14- to 16-wk-old syngeneic male guinea pigs. Values are mean diameters of induration (in mm) for groups of 6 animals. B(a)P=BP.

All 12 carcinogen-treated cell populations were nontumorigenic at 4 months following treatment. Three of these (MNNG2, MNNG3, and MNNG4) as well as sublines derived from colonies of BP4, MNNG3, and MNNG4 cells in semisolid medium were subsequently evaluated once every 2 months for natural delayed-type skin reactivity and tumorigenicity. Neither property was observed as late as 12 months after carcinogen treatment (table 1; text-fig. 2). At that time each line had acquired an increased susceptibility to natural killer cell-mediated cytotoxicity and/or natural lymphoid cell-mediated cytotoxicity (text-fig. 3). Susceptibility to natural lymphoid cell cytotoxicity was independent of expression of proliferation in semisolid medium; e.g., line MNNG2 that remained anchorage-dependent was the most susceptible to natural cytotoxicity. In the traditional 4-hour natural killer cell assay, moreover, several anchorage-independent sublines (MNNG3 and MNNG4) expressed the same susceptibility as the parent nontransformed 118 cells. The expression of carcinogen-induced morphologic alteration or transformation, anchorage-independent growth, and the susceptibility to growth inhibition by lymphotoxin, natural killer cells, or lymphoid cells in line 118 cell populations,



TEXT-FIGURE 3.—Susceptibility of line 118 cells to destruction mediated by syngeneic guinea pig spleen natural killer cells (4-hr ^{51}Cr release) and natural lymphoid cells (72-hr ^{3}H release). B(a)P=BP.

therefore, can develop independently of one another, of natural skin reactivity, and of the ability to grow progressively as tumors in newborn syngeneic guinea pigs or homozygous *nu/nu* nude mice.

DISCUSSION

The following are characteristics of tumorigenic fetal guinea pig fibroblast-like cells descended from carcinogen-treated, early-passage cell cultures (*1, 2, 12*): Morphologic transformation as a measure of diminished density-dependent inhibition of growth, colony formation in semisolid medium as a measure of anchorage-independent growth, and lymphotoxin, natural killer cell, and lymphoid cell susceptibility and natural delayed-type skin reactivity as measures of possible natural immunobiologic cytotoxicity. None of these phenotypic properties develops during culture of cells treated with noncarcinogenic chemicals. Whereas carcinogen-treated cultures of early-passage cells, including cells derived from the same fetus from which line 118 cells were derived, often develop morphologic transformation months before expression of tumorigenicity, the other properties frequently develop in closer temporal relationship with one another and with tumorigenicity (*1, 2, 12, 13*). Similar sequential–temporal (*3, 6–8*) yet dissociable relationships among morphologic transformation (*18*), anchorage independence (*19*), and tumorigenicity have been described for Syrian golden hamster and human cells.

The present investigation demonstrates that, as was observed in freshly isolated diploid cells, chemical carcinogen-induced changes in cells of a long-term continuous guinea pig fibroblast-like cell line develop with an extended and variable latent period between carcinogen treatment and expression of the various phenotypic somatic cell properties. Morphologic transformation, colony formation in a semisolid medium, and susceptibility to the growth inhibitory activity of lymphotoxin and to natural killer cell and lymphoid cell cytotoxicity, moreover, can develop independently of one another. In addition, during 12 months of continuous cultivation, the expression of these properties can be unaccompanied by the development of natural delayed-type skin reactivity or by any demonstrable ability of the cells to grow as a tumor in either newborn syngeneic guinea pigs or immunodeficient homozygous *nu/nu* nude mice with the use of identical conditions previously establishing the nontumorigenic or tumorigenic nature of strain 2/N fibroblasts including line 118 cells in this model of carcinogenesis (*17*). Morphologic transformation and susceptibility to lymphotoxin and to natural killer cell cytotoxicity, furthermore, have also been observed to occur independently of one another and before colony growth in semisolid medium, natural skin reactivity, or tumorigenicity in early-passage MNNG-treated or UV radiation-treated strain 2/N guinea pig fetal cells after treatment with a tumor-promoting compound, 12-*O*-tetradecanoylphorbol-13-acetate (*2*). Thus the independent expression of phenotypic properties during carcinogenesis may be more common than was previously recognized.

In other investigations in which colony formation in semisolid medium has been observed in the absence of tumorigenicity, it has been suggested that the lack of tumorigenicity might reflect residual immunologic rejection activity of the immunodeficient nude mice (*20, 21*) or immunosuppressed syngeneic mice (*22*). In the present investigation, large inocula of 1×10^7 cells for syngeneic guinea pigs and of 5×10^7 cells for nude mice were administered to reduce this possibility. These inoculum sizes greatly exceed those required to demonstrate tumorigenicity in all previously tested guinea pig cells. For example, the observed threshold tumorigenic inoculum of strain 2/N guinea pig fibroblast-like cell lines chemically transformed by carcinogens including BP, 3-methylcholanthrene, MNNG, and aflatoxin B_1 ranges from 10^3 to between 10^4 and 10^5 cells (*17*). This inoculum is one hundredfold or less cells than those inoculated in the current investigation. The MNNG-transformed HM4C1 cells, moreover, are immunogenic (*23*) and 10^3 cells produce tumors in fully immunocompetent, syngeneic guinea pigs (*14, 23*). An additional observation supporting the nontumorigenicity of the carcinogen-treated 118 cells is that all previously tested chemical carcinogen-transformed guinea pig cells in vitro having tumor-producing potential express a natural intradermal delayed-type skin reactivity in nonimmune syngeneic guinea pigs that does not occur with nontumorigenic cells, regardless of their phenotypic properties (*12*). Although carcinogen-treated line 118 cells have acquired many phenotypic alterations associated with tumor-producing cells, the lack of natural delayed-type skin reactivity in every instance is further evidence of their nontumorigenic nature.

Therefore, while independence from density-dependent inhibition of growth, presence of anchorage-independent growth, and susceptibility to the growth inhibitory activity of lymphotoxin and to natural killer cell and natural lymphoid cell cytotoxicity ordinarily are phenotypic properties possessed by tumorigenic guinea pig cells, they can be independent and possibly secondary carcinogen-induced alterations. Furthermore, they may be expressed in a random sequence and are not in themselves responsible for expression of conventionally assessed tumorigenicity. This situation is reminiscent of chemical carcinogen-induced transplantation rejection neoantigens in which the degree of immunogenicity of the tumor cells can increase in proportion to the carcinogen concentration but without neoantigen induction being a prerequisite for neoplasia since carcinogen-induced nonantigenic tumors do occur (*24–27*). Moreover, carcinogen-induced, tumor-specific neoantigen expression can be a preneoplastic event (*28, 29*). Transformation of guinea pig (*16*) and Syrian hamster (*30*) cells by chemical carcinogens can also occur in the absence of detectable chromosome abnormalities, suggesting that some of the many varied marker chromosomes and karyotypic patterns often observed in transformed cells are independent of or secondary alterations accompanying neoplastic transformation. Analysis of chemical carcinogen-treated Chinese hamster primary cell lines (*31*) and spontaneously transformed Syrian golden hamster cells (*18*) also demonstrates that morphologic transformation, karyotypic variation, and growth in semisolid agar medium can develop independently of one another. A similar dissociation of multiple phenotypic properties from each other has been observed in temperature-sensitive mutants of chemically transformed C3H/10T½ mouse cells (*32*) in which type I versus type II and III foci (*4, 5*) may be analogous to morphologic alteration and to morphologic transformation, respectively, in guinea pig cells. The present investigation is the first demonstration that carcinogen-induced phenotypic somatic cell alterations, which may be focal points for natural immunobiologic control of cell growth, can develop in a temporally dissociated manner, independently of one another, and in the absence of neoplastic transformation.

The development of persistent phenotypic alterations during the preneoplastic stages of carcinogenesis warrants further investigation. Why cells expressing such properties remain nontumorigenic is worthy of additional study in the several species where observations of this nature have now been described. Although nonessential for expression of tumorigenicity, such somatic cell alterations may provide selective advantages to the preneoplastic cell as well as be the basis for development of methods to enable the host to control or prevent the development of cancer.

Ceruloplasmin, Copper Ions, and Angiogenesis[1, 2]

Katari S. Raju,[3] Giulio Alessandri,[3] Marina Ziche,[3] *and* Pietro M. Gullino[3, 4]

ABSTRACT—The ability to induce new formation of capillaries in the cornea was tested for ceruloplasmin, the copper carrier of serum, for fragments of the ceruloplasmin molecule with and without copper, for heparin, and for glycyl-L-histidyl-L-lysine, bound or not bound to copper ions. Male or female 2- to 3-kg New Zealand White rabbits were used. These experiments were prompted by the previous observation of copper accumulation in the cornea during angiogenesis and by the inability of copper-deficient rabbits to mount an angiogenic response. The results showed that the three different molecules were all able to induce angiogenesis provided that they were bound to copper. Fragments of the ceruloplasmin molecule also induced angiogenesis but only when copper was bound to the peptides. The data are interpreted to indicate that copper ions are involved in the sequence of events leading to angiogenesis and that the carrier molecules may be of quite a different nature.—JNCI 1982; 69:1183–1188.

The ability of transplanted tissues to elicit vascularization from the host has long been recognized as an essential factor for the survival of a transplant or for the growth of a tumor. However, the conditions that control the formation of a capillary network during growth of primary or metastatic tumors are poorly defined. In previous work undertaken in our laboratory, E-type PG, PGE_1 in particular, were found to be highly angiogenic in the rabbit cornea test at doses insufficient to induce an inflammatory reaction. Moreover, an accumulation of copper ions was detected within the cornea during the angiogenic response induced by PGE_1 (*1*).

Serum ceruloplasmin, the copper-carrier protein, has often been found to be increased in humans and in experimental animals bearing a variety of tumors (*2–4*), and under the same conditions, an elevated production of PG has also been frequently observed (*5–7*). The reciprocal relationship between PG production by the tumors and serum ceruloplasmin levels was particularly striking in the VX_2 carcinoma of the rabbit. Plasma PGE metabolites and ceruloplasmin rose about twentyfold and sixfold, respectively, 3–4 weeks after VX_2 transplantation. Indomethacin, an inhibitor of PG synthesis, substantially reduced the ceruloplasmin levels in serum either when the administration was started at the time of tumor transplantation or later during tumor growth when hyperprostaglandinemia was established (*8*).

The objective of this study was to ascertain whether ceruloplasmin is angiogenic in the corneal assay or whether the transfer of copper is the event controlling angiogenesis.

MATERIALS AND METHODS

Reagents.—Human ceruloplasmin (type III), porcine heparin (intestine), and trypsin (type XI, diphenyl carbamyl chloride-treated) were purchased from Sigma Chemical Co., St. Louis, Mo. Sephadex G-50 and Ultragel AcA 202 gel filtration columns were purchased from Pharmacia, Piscataway, N.J., and LKB Instruments, Inc., Rockville, Md. respectively. DEAE–cellulose (DE.52) was purchased from Whatman, Inc., Clifton, N.J. Reagents for copper determination were purchased from the G. Fredrick Smith Chemical Co., Columbus, Ohio. The tripeptide GHL was purchased from Pierce Chemical Co., Rockford, Ill. All other chemicals were of analytical grade.

Angiogenesis assay.—The angiogenic activities of the samples were evaluated by the rabbit cornea assay as previously reported (*9, 10*). A pocket, about 2×3 mm, was surgically prepared in the cornea of a 2- to 3-kg male or female New Zealand White rabbit. The material to be tested was incorporated into a polymer pellet and introduced into the pocket. The pellet assured slow release of the angiogenic stimuli, an essential condition for angiogenesis to occur (*11*). The pellet consisted of an ethylenevinyl acetate copolymer (Elvax 40; DuPont Co., Wilmington, Del.) prepared from a casting solution of 10% Elvax 40 in methylene chloride. Under sterile conditions the test material was lyophilized and carefully mixed in the appropriately diluted solution of Elvax. Drops of 10–20 µl of the solution were deposited with a glass micropipette on a sterile surface and evaporated under vacuum to produce hard pellets of repolymerized Elvax. Before use the pellets were kept under vacuum at 4°C overnight. All tests were performed under "blind" conditions. On days 4–5 after implantation, capillary buds appeared on the limbal vessels facing the pellet. By the 7th day, a dense network of capillaries had invaded the cornea and was progressing toward the pellet (fig. 1). Since the cornea is avascular and transparent, the new formation of vessels is clearly visible and was followed daily in the unanesthetized rabbit with the use of a Zeiss slit lamp stereomicroscope. Histologic examinations were performed on each cornea at the end of the assay.

Preparation of ceruloplasmins with various copper contents.—The commercial preparation of human ceruloplasmin was purified further by DEAE–cellulose chromatography to obtain a fraction containing 6 copper atoms per molecule (native ceruloplasmin) (table 1; text-fig. 1A). Ceruloplasmin was dialyzed against 0.05 *M* sodium acetate (pH 7.2) and loaded on a DE.52 column (1.5×25 cm) equilibrated with the same

buffer. The chromatogram was developed by a constant volume gradient elution in which the higher salt concentration was 0.4 *M* NaCl in 0.05 *M* sodium acetate (pH 7.2).

A colorless ceruloplasmin with 3 copper atoms per molecule (Tris-ceruloplasmin) was prepared by the treatment of ceruloplasmin with Tris-HCl buffer (0.1 *M* ionic strength) at pH 8.0 for 48 hours. This treatment converts only a fraction of the native protein to the more acidic colorless component (*12*). Native and colorless ceruloplasmins were separated by DEAE-cellulose chromatography (text-fig. 1B).

Apo-ceruloplasmin containing 0.44 copper atoms per molecule or less was prepared by the DDC method of Morell and Scheinberg (*13*). Native ceruloplasmin, 200 mg, was taken in 25 ml of 1.2 *M* sodium acetate buffer (pH 5.2), and 125 mg of crystalline ascorbic acid was added, which instantly decolorized the blue solution. During the next 5 hours the solution was stirred and kept at 4°C, while 6.5 ml of 0.4% sodium DDC in water was added dropwise. The final mixture, golden brown and slightly cloudy, was centrifuged for 3 hours at 40,000 rpm at 4°C. The black precipitate was discarded. The slightly yellowish but clear supernatant solution was passed through a column of ion-exchange resins containing 1R-120 and 1RA-400. From this procedure, a flow-through fraction—a clear, colorless solution that contained the apo-protein—was obtained (*13*). The apo-protein still contained small amounts of the colorless component with about 2 copper atoms per molecule. These components were separated by DEAE-cellulose chromatography.

Isolation of copper-rich peptides (11K fragment).—Native ceruloplasmin (100 mg) was digested with trypsin in 5 ml of 0.2 *M* ammonium bicarbonate at an enzyme-to-protein ratio of 1:25 (wt/wt). The trypsin digestion lasted 18 hours at 37°C, and then the products were lyophilized, dissolved in 0.05 *M* ammonium acetate buffer (pH 7.0), and fractionated by gel filtration chromatography on a Sephadex G-50 column (1.5×50 cm) equilibrated with the same buffer. Peptides eluted from the column were detected by absorbance at 280 nm. The copper content of each fraction was estimated by a colorimetric method as described below. The copper-rich fractions were pooled, lyophilized, and further purified by gel filtration on an AcA 202 column (1.5×50 cm) equilibrated with 0.05 *M* ammonium acetate buffer (pH 7.0). The angiogenic activities of the copper-rich fractions eluted from this column were tested.

Apo-ceruloplasmin was subjected to tryptic digestion in the same manner as the native ceruloplasmin. The absorbance profile of the peptides was identical except that copper was not detected in any fraction.

Copper content estimation.—Copper content was determined by the method of Diehl and Smith (*14*) modified to analyze copper concentrations of 0.5–2.5 µg per sample. The sample was digested with 0.1 ml of concentrated H_2SO_4, cooled, and further ashed by the addition of H_2O_2, until the digest (~0.02 ml) was clear and colorless. After cooling, 0.2 ml of 10% hydroxylammonium chloride and 1.5 ml of 5 *M* sodium acetate (pH 7.0) were added and the sample was mixed thoroughly. The orange color of bisbathocuproine was formed by the addition of 0.2 ml of 0.01 *M* bathocuproinedisulfonic acid in water followed by vigorous mixing for about 2 minutes. Absorbance was measured at 479 nm against a cupric sulfate standard in the range of 0.5–2.5 µg per sample.

Protein estimation and molecular weight determination.—Protein was estimated by the method of Lowry et al. (*15*). Molecular weight for the copper-rich peptide was determined by gel filtration chromatography (*16*) on an AcA 202 column in 0.05 *M* ammonium acetate buffer (pH 7.0). RNase a (13,700), cytochrome c (11,500), insulin (6,000), and bacitracin (1,422) were used as molecular weight standards.

Amino acid composition.—The protein samples were hydrolyzed for 22 hours at 110°C in sealed, evacuated tubes containing 400 µl of 5.7 *N* HCl and 1 µl of 1% phenol. Amino acid analyses were done on a Beckman amino acid analyzer (model 121 M) according to the method of Spackman et al. (*17*). The mole percents obtained were corrected for decompositions during acid hydrolysis of threonine (7%), serine (10%), and tyrosine (2%).

Preparation of copper-carrying GHL and heparin.—GHL-copper complexes were obtained by the procedure of Pickart and Thaler (*18*). $CuSO_4$ (0.5 m*M*) and GHL tripeptide (0.5 m*M*) were dissolved together in phosphate-buffered saline at pH 7.4, allowed to stand overnight, and then chromatographed on a Sephadex G-10 column equilibrated in water. GHL-copper complexes elute before GHL and were detected by chromatographic profile and by copper content determination.

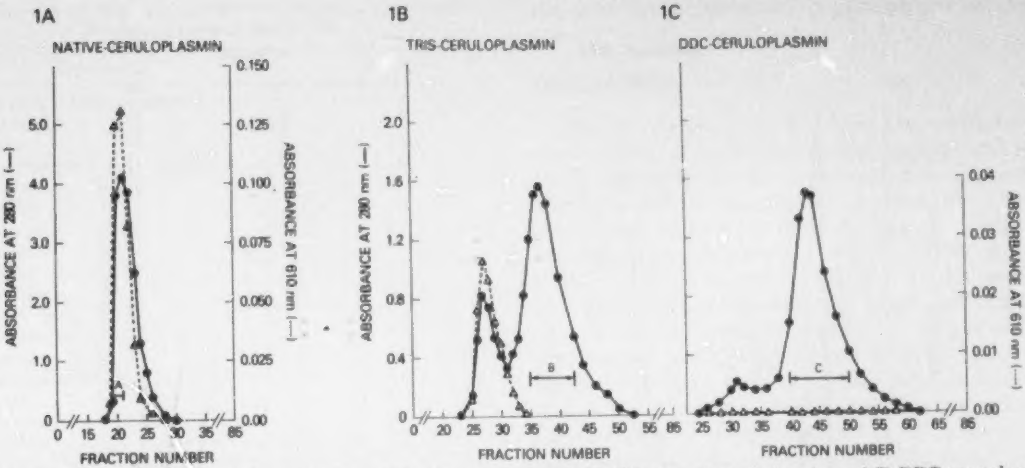
Copper was bound to heparin as described by Lages and Stivala (*19*). Heparin (25 mg) and $CuSO_4$ (5 mg) were dissolved in 3 ml of 0.1 *M* Tris-HCl (pH 7.5) buffer, allowed to stand overnight, and chromatographed on a Sephadex G-25 column equilibrated in water. Fractions containing copper-heparin complexes were detected by absorbance at 237 nm or by copper content determination (*14*).

RESULTS

Angiogenesis by Ceruloplasmin

The first group of experiments was designed to assess whether the angiogenic capacity of ceruloplasmin depended on the presence of copper in the molecule. From a commercial source of human ceruloplasmin, three fractions were prepared to contain 6.0, 2.3, and 0.44 copper atoms per molecule, respectively. Text-figure 1A shows the peak of native ceruloplasmin and the fraction (zone A) utilized to test both copper content and angiogenic activity. Text-figure 1B shows the pattern obtained after the native ceruloplasmin was treated with Tris buffer (pH 8). The fractions indicated by zone B were pooled and tested for copper content and angiogenesis. Text-figure 1C illustrates the pattern obtained after DDC treatment of native ceruloplasmin. The fractions indicated by zone C were pooled and tested.

Table 1 reports the copper content and the angiogenic capacity of these fractions. Each sample was lyophilized and incorporated into an Elvax pellet. Each pellet contained the same amount of protein and different amounts of copper. In the first experiment, 10 rabbits received native cerulo-



TEXT-FIGURE 1.—DEAE-cellulose column chromatography of A) native ceruloplasmin, B) Tris-treated ceruloplasmin, and C) DDC-treated ceruloplasmin. Ceruloplasmin, native or treated (20-30 mg), was dialyzed against 0.05 *M* sodium acetate buffer (pH 7.2) and loaded on a column equilibrated in the same buffer. The ceruloplasmins, native or treated, did bind to the column. The chromatogram was developed by a linear gradient elution in which the higher salt concentration was 0.4 *M* NaCl in 0.05 *M* sodium acetate (pH 7.2). Marked zones (2.35 ml/tube) were pooled, tested for copper content, lyophilized, and tested for angiogenic activity.

TABLE 1.—*Angiogenic response of ceruloplasmin with various copper contents*

Material tested	Copper/mg protein,[a] µg	Copper atoms/ molecule[b]	Protein/pellet, µg	Copper/pellet, µg	Samples showing positive angiogenic response/total samples
Native ceruloplasmin	2.45	6.0	200	0.5	19/25
Tris-treated ceruloplasmin	0.94	2.3	200	0.2	1/5
Apo-ceruloplasmin	0.18	0.44	200	0.08	0/10
Elvax 40	—	—	—	—	0/10

[a] Copper content was estimated as described in "Materials and Methods." Protein content was determined by the method of Lowry et al. (*15*).

[b] The number of copper atoms per molecule was calculated from the measurement of copper content and by the assumption of a molecular weight of the purified ceruloplasmin to be 132,000.

plasmin in the right cornea and Elvax alone in the opposite cornea. In the second experiment, 10 rabbits were implanted with native ceruloplasmin in one cornea and apo-ceruloplasmin in the contralateral cornea. In the third experiment, 5 rabbits received native ceruloplasmin in one cornea and Tris-ceruloplasmin in the opposite cornea. In table 1 the angiogenic responses to native ceruloplasmin observed with three separate experiments have been added. Table 1 shows that removal of copper from the molecule coincides with the disappearance of the angiogenic capacity.

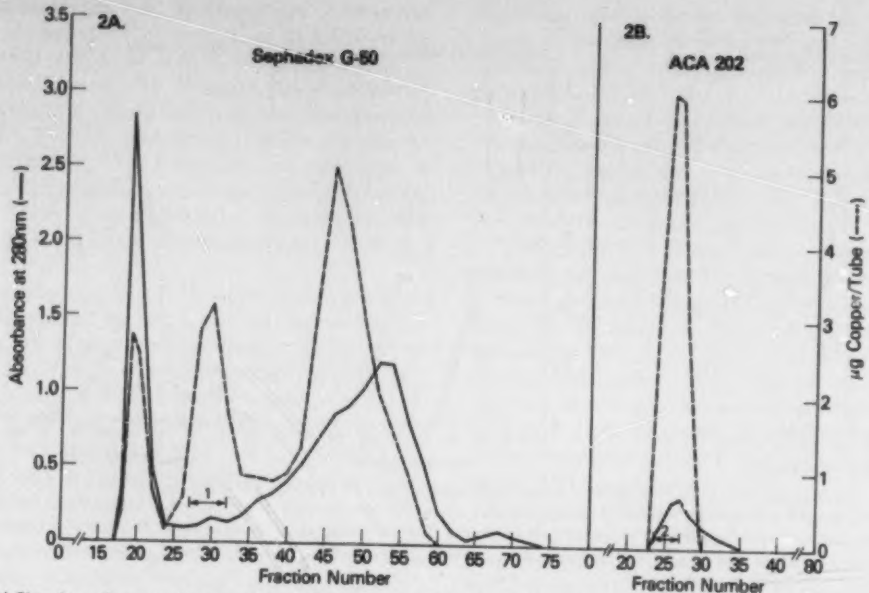
Angiogenesis by Ceruloplasmin Fractions

In a second group of experiments, we evaluated whether induction of angiogenesis required the whole ceruloplasmin molecule or a smaller "angiogenesis-active site" and, if so, whether the site or sites coincided with molecular fragments rich in copper.

Tryptic digests were prepared from native ceruloplasmin (text-fig. 1A, zone A) and from native ceruloplasmin deprived of copper by DDC treatment (text-fig. 1C, zone C). The digests were fractionated with Sephadex G-50. From the native ceruloplasmin digest, the fractions corresponding to zone 1 of text-figure 2A were the richest in copper. They were pooled, and further concentrations of copper-bearing peptides were obtained in the AcA 202 column. The peptide absorbance pattern of 280 nm comprised a single broad peak with a shoulder; the copper content pattern, however, showed a single sharp peak (text-fig. 2B). The fractions of zone 2 of text-figure 2B, the richest in copper, were pooled, lyophilized, and incorporated into Elvax pellets in the appropriate amounts for testing. The same procedure was followed for the DDC-treated ceruloplasmin.

An aliquot of zone 2 fractions (text-fig. 2B) was taken for the determination of the molecular weight by gel filtration chromatography; a value of 11,000 was estimated (11K fraction).

Angiogenic activity was tested by the implantation in the same rabbit of a pellet containing the 11K fraction from native ceruloplasmin in one cornea and a pellet with the 11K fraction from apo-ceruloplasmin in the contralateral cornea. Each pellet contained 100 µg of protein. For the fraction containing copper, 12 of 15 implants gave positive responses. In contrast, for the fraction devoid of copper, only 3 of 15 implants gave positive responses. The experiment was repeated with each pellet containing 50 µg of protein, and the results were comparable to those of the experiment with the pellet that carried 100 µg protein. Comparison of



TEXT-FIGURE 2.—A) Gel filtration of tryptic digest products of native ceruloplasmin on a Sephadex G-50 superfine column (1.5×50 cm) equilibrated with 0.05 *M* ammonium acetate buffer (pH 7.0). Flow rate was 10 ml/hr. Fractions (1.5 ml/tube) were collected and monitored by absorption at 280 nm for protein and by reaction with bathocuproinedisulfonic acid for copper determination. Marked zone 1 was pooled and further purified; *see* 2B. B) Gel filtration of zone 1 of 2A on an AcA 202 column (1.5×50 cm) equilibrated with 0.05 *M* ammonium acetate buffer (pH 7.2). Flow rate was 8 ml/hr. Fractions (1.5 ml/tube) were collected and monitored for peptide absorbance and copper determination as described in 2A.

TABLE 2.—*Angiogenic responses to ceruloplasmin fractions*

Material tested	Copper atoms/ molecule[a]	Protein/ pellet, µg	Copper/ pellet,[b] µg	Samples showing positive angiogenic response/total samples
Native ceruloplasmin fraction (11K)	3	100	1.6	12/15
	3	50	0.8	8/10
	3	50	0.8	4/6
	3	30	0.5	9/10
Apo-ceruloplasmin fraction (11K)	0	100	0	3/15
	0	50	0	3/10
Sephadex G-50 fractions 60–65[c]	0	100	0	1/16

[a] The number of copper atoms per molecule was calculated from the copper content of the sample and by the assumption of the molecular weight of the native ceruloplasmin fraction to be 11,000.

[b] The amount of copper released by each pellet was estimated to be ≈1.0 ng/hr. The value was calculated by the preparation of 10 equal pellets and the measurements of the copper content in 5 at the time the remaining 5 were implanted in the corneas. After 7 days, the implanted pellets were removed and the copper content was determined. A reduction of 160±12 ng was found.

[c] The results of two experiments have been added; the contralateral cornea was implanted with 11K fraction of native ceruloplasmin, 50 µg per pellet in the first experiment and 30 µg per pellet in the second experiment.

the 11K fraction from native ceruloplasmin at 50 and 30 µg protein in each pellet with fractions 60–65 of the Sephadex G-50 columns (text-fig. 2A) that were totally deprived of copper again showed that removal of copper from the molecule sharply reduced the angiogenic response. Moreover, the 11K fraction was actively angiogenic at relatively low doses (table 2).

The amino acid composition of the 11K fraction (table 3) was compared with the amino acid sequence of 50,000-M_r and 19,000-M_r fragments of ceruloplasmin, as reported by Dwulet and Putnam (*20*). The high content of acidic amino acids and isoleucine suggested that more than a single peptide constituted the 11K fraction. Indeed, electrophoresis in 7.5% acrylamide gel revealed the presence of three bands indicating that at least three peptides were present within the 11K fraction.

Angiogenesis by Copper Carriers

From the above observations we conjectured that if the angiogenic activity of ceruloplasmin and the 11K ceruloplasmin fraction depended on the presence of copper, other copper carriers could also be angiogenic.

Copper was bound to two quite different molecules—a tripeptide, GHL, and heparin, a sulfated polysaccharide. A dose of 150 µg of heparin in each Elvax pellet was implanted in one cornea and compared with the same dose of heparin bound to copper implanted in the contralateral cornea of the same rabbit. The "control" dose of 150 µg of heparin for each pellet was selected because it was not angiogenic and did not mobilize inflammatory cells during the 6–7 days of the experiment. In a second experiment, the angiogenic activities of smaller doses of heparin bound to copper were evaluated. Pellets with 60 µg heparin and copper were implanted in one cornea and pellets with 30 µg heparin and copper were implanted in the opposite cornea of the same rabbit. The data reported in table 4 indicate that copper

TABLE 4.—*Angiogenesis by copper carriers*

Carrier compound	Amount/pellet, μg		Positive angiogenic response/ total samples
	Carrier	Copper[a]	
Heparin	150	0	0/10
	150	2.5	8/10
	60	1.0	8/10
	30	0.5	1/10
GHL	200	0	0/10
	200	3.7	10/14[b]
$CuCl_2$		10.0	8/10
		5.0	2/6
		1.0	0/7
		0.5	0/8

[a] The amount of copper released by each pellet was estimated to be ≈2.0 ng/hr. The computation was done as explained in footnote *b*, table 2.

[b] Results from two experiments were added, the first with 7/10 positive implants and the second with 3/4 positive implants. In the second experiment 1.0 μg $CuCl_2$/pellet was implanted in the contralateral cornea.

attached to heparin transforms the molecule into an effective "angiogenic factor."

The same type of experiment was repeated for the tripeptide GHL. A dose of 200 μg of tripeptide was not sufficient to mobilize inflammatory cells and was not angiogenic. In 10 rabbits, 200 μg GHL bound to copper was implanted in one cornea and the same amount without copper was implanted in the contralateral cornea. The copper-carrying peptide was strongly angiogenic in 7 of 10 implants, whereas none of the 10 implants of the copper-free peptide was angiogenic (table 4).

The angiogenic capacity of copper chloride was also tested. Pellets that contained more than 10 μg of copper chloride elicited rapid migration of inflammatory cells. Pellets with 10 μg of copper chloride at each dose were angiogenic but often mobilized leukocytes. Doses of 5 μg or less were not inflammatory and were only slightly angiogenic. We found it difficult to induce angiogenesis with copper chloride without mobilizing inflammatory cells. We reached the same conclusion when we used copper sulfate (data not shown).

DISCUSSION

The experiments reported here were stimulated by two observations: *a*) In rabbits, during angiogenesis induced by PGE_1, copper ions were concentrated in the cornea immediately before the capillaries invaded the tissue, and *b*) rabbits kept on a copper-deficient diet were unable to mount an angiogenic response to neoplastic cells or to doses of PGE_1 that were strongly angiogenic in the intact host (*1*). Since ceruloplasmin is the natural copper carrier in blood (*21*), it seemed logical to evaluate the roles of ceruloplasmin and copper in the angiogenesis process. The experiments showed that *a*) ceruloplasmin was angiogenic in the rabbit cornea assay provided that copper ions remained bound to the molecule, *b*) small fragments of the ceruloplasmin molecule were still able to induce angiogenesis if they carried copper, *c*) heparin and GHL acquired angiogenic activities when bound to copper, and *d*) copper chloride as well as copper sulfate were angiogenic only at doses that usually induced an inflammatory reaction.

The compound to be tested was incorporated within an Elvax pellet to obtain slow release (*11*), and the initial dose was always chosen so that it would produce a transparent cornea at 48 hours after the pellet implant.

Inflammatory cells are powerful inducers of angiogenesis (*22, 23*); therefore, in experiments that utilize the corneal test, one has to make sure that the response obtained is not due to an inflammatory reaction. The formation of the corneal pocket always induces edema and the mobilization of a few leukocytes, despite sterile conditions. Within 48 hours, however, both the edema and leukocytes disappear and the cornea becomes transparent when observed with the slit lamp microscope. By day 4 or 5, the capillary buds penetrate the cornea and a vascular network is formed. If at this time any leukocytes are found on a histologic section, one cannot be sure whether they are the effectors of angiogenesis or have just escaped from the newly formed capillaries that are notoriously leaky at the time of canalization. To avoid these uncertainties, we always compared the molecules carrying copper with the analogues without copper in the same animal. Under these conditions the mobilization of some leukocytes is equal in both corneas at the time of implant, but at day 6 one cornea shows a positive response, whereas the other cornea of the same rabbit exhibits a negative angiogenesis response. This observation indicates that the few leukocytes mobilized by the initial surgery are not determinant effectors of the angiogenesis process.

The data presented are interpreted to indicate that copper ions are involved in the sequence of events that induces angiogenesis. The role of copper carriers, however, remains obscure. It seems clear that molecules of different nature can act as carriers; however, native ceruloplasmin and 11K fractions were angiogenic at a dose containing copper in amounts smaller than those bound by heparin and GHL. Moreover, copper in the form of chloride or sulfate salt induced angiogenesis only at elevated concentrations and in most cases with mobilization of inflammatory cells. Copper (*24*) and heparin (*25*) have also been shown to enhance the motility of the endothelium. In vitro observations on the chemokinetic and chemotactic effects of copper carriers on capillary endothelium will be reported in a forthcoming paper.

Isolation of Tumoricidal Macrophages From Lung Melanoma Metastases of Mice Treated Systemically With Liposomes Containing a Lipophilic Derivative of Muramyl Dipeptide[1,2,3,4]

M. E. Key,[5] J. E. Talmadge,[5] W. E. Fogler,[5] C. Bucana,[6] *and* I. J. Fidler[5]

ABSTRACT—The systemic administration of multilamellar liposomes—composed of phosphatidylcholine and phosphatidylserine (7:3 mol ratio), containing the immunomodulator, muramyl tripeptide phosphatidylethanolamine (MTP-PE)—into C57BL/6N mice bearing the syngeneic B16-BL6 melanoma was associated with the eradication of spontaneous lung and lymph node metastases. Immunofluorescence and electron microscopic analyses revealed that 24 hours after the tumor-bearing mice were given iv injections of liposomes, 15% of the alveolar macrophages and 5% of the metastasis-associated macrophages contained phagocytosed liposomes. However, only macrophages isolated from lungs or metastases of mice given injections of liposomes containing MTP-PE (treatment success), but not macrophages from mice treated with empty liposomes (treatment failure), were tumoricidal against the target cells in vitro. These data provide direct evidence that the regression of established metastases, after treatment of tumor-bearing mice with liposomes containing MTP-PE, was associated with tumoricidal macrophages residing within the metastases.—JNCI 1982; 69:1189–1198.

Normal noncytotoxic macrophages can be rendered tumoricidal in vitro or in vivo after interaction with various biological agents such as lymphokines (*1*, *2*), whole microorganisms, or their products (*3*, *4*). MDP, a microbial product initially isolated from *Mycobacterium* and subsequently synthesized, can activate macrophages to the tumoricidal state (*5*). Recent studies in our laboratory have shown that free MDP or MDP entrapped within liposomes activates macrophages to the tumoricidal state both in vitro (*6*) and in vivo (*7*). Furthermore, the repeated injection of liposome-entrapped MDP into tumor-bearing mice resulted in destruction of spontaneous lung and lymph node metastases (*8*). Subsequent studies have provided circumstantial evidence that macrophage activation and regression of metastases are related; e.g., we have shown that when macrophages activated in vitro with liposome-entrapped MDP were adoptively transferred into mice bearing metastases, the growth of the metastases was significantly inhibited. However, pretreatment of mice bearing metastases with macrophage toxins abrogated the therapeutic effectiveness of the treatment with liposome-entrapped MDP (*9*).

Although these data strongly suggested that activated macrophages were involved in the destruction of metastases in this tumor system, their precise role remained unclear. In this report, we provide direct evidence that tumoricidal macrophages are the effector cells responsible for the destruction of established metastases in mice treated systemically with liposome-entrapped MDP. We base this conclusion on morphological and functional analysis of macrophages isolated from pulmonary metastases of mice given iv injections of liposomes containing an MDP derivative, MTP-PE. Specifically, we show that in these mice macrophages containing phagocytosed liposomes infiltrate and localize within pulmonary metastases. Furthermore, once localized, macrophages that have engulfed liposomes containing MTP-PE (treatment success), but not macrophages that have engulfed liposomes containing a placebo (treatment failure), retain their tumoricidal activity against the metastatic tumor cells.

MATERIALS AND METHODS

Animals.—Specific-pathogen-free C57BL/6N mice were obtained from the NCI-Frederick Cancer Research Facility's Animal Production Area. Mice used in each experiment were matched by age (6–8 wk) and sex.

Tumor culture.—B16-BL6, a tumor variant obtained by in vitro selection for invasion (*10*), originated from the spontaneous malignant B16 melanoma, which is syngeneic to the C57BL/6N mouse. The B16-BL6 tumor cells were grown as monolayer cultures and were maintained in Eagle's minimum essential medium supplemented with 5% fetal bovine serum, vitamin solution, sodium pyruvate, L-glutamine, and other nonessential amino acids. The components of this medium were obtained from Flow Laboratories, Inc., Rockville, Md. The medium was endotoxin-free as determined by the *Limulus* amoebocyte lysate assay (Associates of Cape Cod, Woods Hole, Mass.). Cultures were incubated at 37°C in a humidified atmosphere containing 5% CO_2. All cell

cultures were free of mycoplasma, reovirus type 3, pneumonia virus of mice, K-virus, Theiler's encephalitis virus, lymphocytic choriomeningitis virus, ectromelia virus, and lactate dehydrogenase virus (assayed by M.A. Bioproducts, Walkersville, Md.).

Metastasis system.—The pulmonary tumor colonies (experimental metastases) used in this study were obtained from syngeneic mice that had been given 1×10^5 tumor cells iv into a lateral tail vein. Cells to be injected were harvested by trypsinization from cultures at mid-log phase, and single cell suspensions of >95% viability were resuspended in Ca^{2+}- and Mg^{2+}-free HBSS. Within 4 weeks of injection, all inoculated mice had macroscopic and/or microscopic pulmonary metastases.

Mice bearing established spontaneous pulmonary and lymph node metastases were used in therapy studies. To initiate spontaneous metastases, we gave an injection of 2.5×10^4 viable tumor cells, suspended in 0.05 ml HBSS, into one hind footpad of each mouse. When the local tumors had reached 10–12 mm in diameter, the tumor-bearing legs, including the popliteal lymph node, were amputated at midfemur. This experimental protocol results in metastases in the lungs and lymph nodes of approximately 90% of the mice (*10*).

Reagents.—Synthetic hydrophilic MDP and a lipophilic derivative, MTP-PE, were the generous gifts of Ciba-Geigy Ltd. (Basel, Switzerland). Neither the MDP nor MTP-PE contained endotoxins as detected by the *Limulus* amoebocyte lysate assay. Chromatographically pure egg PC and beef brain PS were purchased from Avanti Polar Lipids, Inc. (Birmingham, Ala.).

Preparation of liposomes.—Multilamellar lipid vesicles (liposomes) were prepared from a mixture of PC and PS (7:3 mol ratio) and were formed as previously described (*11*). Liposomes containing MTP-PE were prepared by the combining of 5 µg MTP-PE/1 µmol lipid, as described elsewhere (*12*). Fluorescent liposomes were prepared by incorporation of 0.1% of the fluorescent lipid NBD-PE into the liposomes, as described in (*12*). PC-PS liposomes were used because they are not toxic at the doses used in this study and because, when they are injected iv, they are arrested efficiently in the lungs (and in other organs of the reticuloendothelial system) (*13*).

In situ activation of metastasis-associated macrophages.—Mice bearing experimentally induced metastases ranging in size up to 4 mm in diameter (≈4 wk after injection of tumor cells) were given injections on 3 consecutive days of liposomes (2.5 µmol lipid), containing a total of 10 µg MTP-PE, or injections of liposomes containing HBSS and suspended in 10 µg MDP (placebo preparation). Fluorescent liposomes were used in the final injection. Mice were killed 24 hours after the last injection, and the lung metastases were recovered. Single cell suspensions prepared from these tissues by enzymatic dissociation were analyzed by means of fluorescence and electron microscopy.

Treatment of spontaneous metastases by iv injection of liposomes containing MTP-PE.—Three days after surgical removal of the primary footpad tumor, mice bearing spontaneous lung and lymph node metastases were given iv injections of liposomes (2.5 µmol phospholipid) suspended in 0.2 ml HBSS. The liposomes contained either MTP-PE (10 µg/mouse) or HBSS. Liposomes containing HBSS were then resuspended in HBSS containing free MDP (10 µg/mouse). An additional control group included mice that received iv injections of HBSS only. The animals were treated twice a week for 4 weeks and were monitored daily for 180 days. Dead or moribund animals were necropsied to ascertain the presence or absence of secondary tumors. Animals surviving at least 100 days after the last liposome treatment were considered to be disease-free (*14*).

Determination of macrophage content.—Experimentally induced pulmonary metastases, ranging in size up to 4 mm in diameter, were removed en bloc and dissected free of nontumorous tissue. Normal lung parenchyma or tumor fragments of approximately 1 mm^3 were digested with continuous stirring in trypsinization flasks at 37°C, as previously described (*15*). Three 30-minute digestion cycles produced 95–100% digestion of the tumor fragments and 65–85% digestion of the lung fragments to single cell suspensions. The digestion medium consisted of HBSS containing 0.14% collagenase type I and 0.10% deoxyribonuclease type I (Sigma Chemical Co., St. Louis, Mo.). The suspension of single cells was adjusted to contain $1–5\times10^6$ cells/ml serum-free medium. India ink (0.10 ml; 1:40 dilution) was added to the cells. This mixture was placed in a 5-ml polystyrene tube and incubated for 2 hours at 37°C. The cells were then washed twice with serum-free medium and adjusted to 5×10^5 cells/ml in medium containing 10% fetal bovine serum. Cytocentrifuge preparations of all cell suspensions were fixed, stained with Giemsa, and prepared for light microscopy. The percentage of macrophages present in the preparations was determined by identifying the cells morphologically and by observing the phagocytosis of carbon particles. A minimum of 200 cells/slide were examined to determine the percentage of macrophages.

To determine the macrophage content of the dissociated tissues when examined by fluorescence microscopy, we used the method of Korn et al. (*16*) for detecting Fc-receptor-positive cells. SRBC were sensitized with a subagglutinating dilution of murine anti-SRBC antisera. A sensitizing dilution was chosen that allowed most macrophages and monocytes, but not lymphocytes or granulocytes, to bind with the sensitized SRBC. Sensitized SRBC were incubated for 5 minutes on ice with the single cell suspensions from the tissue digests at a ratio of 30 SRBC:1 nucleated cell. After centrifugation the pellet was gently resuspended, and the cells were prepared for fluorescence microscopy. To test the validity of this technique, cytocentrifuge preparations of some of the cell suspensions were stained with Giemsa and examined by light microscopy.

Macrophage-mediated cytotoxicity assay.—Macrophages were isolated from the single cell suspensions by allowing them to adhere to plastic. Two methods of isolating macrophages were used: 1) Tumor or lung digests were seeded into MicroTest II wells (Falcon Plastics, Oxnard, Calif.) and allowed to adhere for 5 minutes. The wells were rinsed, and the process was repeated until the desired density of adhering cells was obtained, as determined by cell counts in an inverted microscope. 2) The adherent cells were removed from a plastic petri dish by means of a rubber policeman.

The recovered cells were counted and replated at the desired density into MicroTest wells. Because viability of the recovered cells was about 60%, plating was based on viable cell counts only. In both procedures, we estimated that macrophages composed about 80% of the cell population, as determined by their ability to form rosettes with sensitized SRBC. Most of the contaminating cells appeared to be tumor cells. We did not observe any differences in the ability to adhere to plastic among the macrophages obtained from the various treatment groups.

Macrophage-mediated cytotoxicity was assessed by a radioactive release assay, as described previously (*17*). Macrophage monolayers were washed with medium, and 5×10^3 [^{125}I]IdUrd-labeled B16-BL6 target cells were added to each well in 0.2 ml medium. Target cells alone were always plated as an additional control. The cultures were washed 24 hours after the addition of target cells and then were refed to remove nonplated cells. Adherent target cells were lysed with 0.1 ml of 0.2 *N* NaOH at 72 hours after plating. The lysate was absorbed on cotton swabs and monitored for radioactivity in a γ-counter. The percentage of specific cytotoxicity in the macrophage assays was computed by the following formula: [(cpm target cells with control macrophages − cpm targets cells with activated macrophages)/cpm target cells with control macrophages]×100. The statistical significance of differences between groups was determined by Student's two-tailed *t*-test.

Analysis with fluorescence microscopy.—Cell suspensions were examined on a hemacytometer with the use of a Zeiss fluorescence microscope (Carl Zeiss, Inc., New York, N.Y.). The number of cells containing fluorescent material was scored in each section of the hemacytometer, and by means of light microscopy the total cell count was estimated by counting all cells contained within a single section. In this way we were able to rapidly evaluate several thousand cells per tissue digest.

Analysis with electron microscopy.—The dissociated cells were centrifuged, and the cell pellet was fixed with 3% glutaraldehyde and 2% paraformaldehyde in 0.1 *M* cacodylate buffer at pH 7.4 for 1 hour. The cells were then rinsed in buffer, fixed for 20 minutes with 1% tannic acid in 2% glutaraldehyde, rinsed in buffer, and fixed for 1 hour with 1% buffered OsO_4. After a brief rinse in distilled water, the cells were stained with 1% aqueous uranyl acetate for 30 minutes and then rinsed again with distilled water. The samples were dehydrated in a graded series of ethanol and embedded in Spurr's low-viscosity medium. Thin sections were cut with a glass knife in a LKB Ultratome III, (LKB Instruments, Inc., Rockville, Md.), counter stained with Reynold's lead citrate, and examined in a Hitachi HU-12A electron microscope (Hitachi Scientific Instruments, Tokyo, Japan) at an accelerating voltage of 75 kV.

RESULTS

Treatment of spontaneous metastases by systemic administration of liposome-entrapped MTP-PE.—The repeated administration of liposomes (PC:PS, 7:3 mol ratio) containing MTP-PE was associated with the regression of established pulmonary and lymph node metastases. Nearly all mice treated with HBSS or with liposomes containing HBSS and suspended in free MDP had died by day 90 (table 1). In contrast, 70% of mice given iv injections of liposomes containing MTP-PE survived for more than 100 days after the last iv treatment. This period exceeds the time (40–50 days) necessary for as few as 10 surviving tumor cells to kill their host (*14*). These mice were killed on day 180 of the experiment and found to be disease-free.

Macrophage content of lung tissue and lung metastases.—The content of macrophages in lung parenchyma (nontumorous) and in pulmonary metastases from untreated or liposome-treated mice was determined from single cell preparations of the dissociated tissues. Tissues from both tumor-bearing and tumor-free mice were analyzed. Treatment with liposomes containing MTP-PE or liposomes containing HBSS and suspended in MDP was given once daily for 3 days prior to determination of macrophage content. As shown in table 2, the percentage of macrophages infiltrating into lung metastases of the B16-BL6 melanoma ranged from 11 to 13% and was independent of treatment with either type of

TABLE 1.—*Eradication of spontaneous metastases by the systemic administration of liposomes containing MTP-PE*

Treatment group[a]	Mice, %, surviving by day:[b]

[a] Viable B16-BL6 cells (25,000) were implanted in the footpads of syngeneic C57BL/6 mice (20 mice/group). Tumors (10–12 mm in diameter) were amputated 4 wk later. Liposome therapy commenced 3 days after surgery and consisted of iv injections of 2.5 μmol liposomes/mouse twice weekly for 4 wk. Liposomes either contained HBSS and were suspended in 10 μg MDP (liposome–HBSS) or contained 10 μg MTP-PE (liposome–MTP-PE).

[b] Differences in median life-span were highly significant ($P < 0.001$, chi-square test).

TABLE 2.—*Macrophage content of nontumorous lung tissues and lung melanoma metastases*

Treatment group[a]	Macrophages, %, in:[b,c]	
	Melanoma metastases	Nontumorous lung tissue

Liposome–HBSS	11	31
Liposome–MTP-PE	13	33

[a] Mice received iv injections of 1×10^5 B16-BL6 tumor cells 4 wk before assay. Control and tumor-bearing mice were treated daily for 3 consecutive days with 2.5 μmol liposomes containing HBSS and suspended in 10 μg MDP (liposome–HBSS) or with liposomes containing 10 μg MTP-PE (liposome–MTP-PE). Macrophages were harvested 24 hr after the third treatment.

[b] Macrophages in single cell suspensions of lung or tumor tissue were identified by phagocytosis of india ink.

[c] Pulmonary metastases or nontumorous lung tissue were harvested and pooled; 3 mice/group.

liposome preparation. The content of lung macrophages in mice bearing metastases increased slightly after treatment with liposomes (31 and 33% vs. 22%). This increase was less apparent in the lungs of liposome-treated, tumor-free mice (29 and 25% vs. 21%). We concluded that treatment of mice with either liposome preparation had little effect on the macrophage content of pulmonary metastases.

Characterization of macrophages containing liposomes.—After we ascertained that 11–13% of the cells in pulmonary metastases of the B16-BL6 melanoma were actually infiltrating macrophages, we determined whether cells of the macrophage type that had engulfed liposomes within the lung microvasculature (*18*) could infiltrate and localize within pulmonary metastases. Liposomes containing NBD-PE (fluorescent lipid) were injected iv into mice, and 24 hours later lungs and pulmonary tumor colonies were removed, dissociated, and prepared for macrophage analysis. To identify the macrophages, we used a technique based on the ability of these cells to form rosettes with sensitized SRBC (*16*). The validity of this procedure was first analyzed by light microscopy in cell preparations stained with Giemsa.

Under the conditions used, most of the macrophages from both tumor tissue and nontumorous lung tissue (92 and 69%, respectively) formed rosettes with sensitized SRBC, whereas only 5% of PMN and 2% of lymphocytes from lungs formed rosettes. Tumor-infiltrating PMN and lymphocytes, which comprised less than 5% of the total cell population, were not observed forming rosettes with sensitized SRBC. Examination of cell suspensions by fluorescence microscopy revealed that all cells exhibiting fluorescent liposomes also formed rosettes with sensitized SRBC. Thus liposome-containing cells recovered from either nontumorous lung tissue or pulmonary metastases were identified as Fc-receptor-positive cells with a macrophage-like morphology. A typical example of cells isolated from a progressing lung metastasis of the B16-BL6 melanoma is shown in figure 1. Fluorescence microscopy revealed that one of the cells exhibited numerous fluorescent bodies; light microscopy revealed that this same cell formed a rosette with sensitized SRBC, thus identifying it as a macrophage. PMN are another type of phagocytic cell that could infiltrate into tumors; however, we did not observe PMN containing liposomes in tissue samples prepared 24 hours after liposomes were administered systemically (fig. 2).

We verified by electron microscopy that the liposome-containing cells residing within metastases were in fact macrophages. Liposomes within cells were readily identified at the ultrastructural level by their characteristic multilamellar configuration (*19*). In some experiments ferritin encapsulated within liposomes was used as a marker for the identification of internalized liposomes. Macrophages seen in dissociated tumor preparations varied in their internal structure. Most macrophages contained membrane-bound aggregates of melanin, large vacuoles with remnants of melanin granules, or lysosomes associated with aggregates of melanin. These macrophages often had an eccentric nucleus and prominent cytoplasmic processes or vellum (fig. 3). A second type of macrophage had the normal complement of cytoplasmic organelles as well as prominent cytoplasmic processes (fig. 4) but no internalized melanin granules. Both types of macrophages, however, contained intracytoplasmic liposomes. The multilamellar structure of the internalized liposomes is clearly visible in figures 3 and 4. In the macrophage shown in figure 3, the liposomes appear to be contained within a single phagosome, whereas the macrophage shown in figure 4 contains liposomes within individual phagocytic vacuoles.

Quantitation of macrophages containing liposomes.—Twenty-four hours after mice were given injections of fluorescent liposomes, the animals' lungs and pulmonary tumor metastases were removed and analyzed for the presence of macrophages containing fluorescent material (table 3). Only macrophages obtained from mice that had been treated with fluorescent liposomes displayed fluorescent material, suggesting that the fluorescent staining was not caused by autofluorescent artifacts. Only minor differences in the percentage of macrophages containing liposomes were observed between mice that received iv injections of liposomes containing MTP-PE and mice that received iv injections of liposomes containing HBSS. This suggested that the uptake of liposomes by macrophages in situ is independent of the MTP-PE component. The percentage of liposome-containing cells within tumors was relatively low compared to the total cell population. However, when these numbers were

[a] Mice received iv injections of 1×10^5 B16-BL6 cells 4 wk before assay. Mice were treated daily for 3 consecutive days with 2.5 µmol liposomes containing HBSS and suspended in 10 µg MDP (liposome–HBSS) or liposomes containing 10 µg MTP-PE (liposome–MTP-PE).

[b] 1×10^4 B16-BL6 tumor cells prelabeled with [^{125}I]IdUrd were plated onto macrophage monolayers (*see* "Material and Methods"). Cultures were refed 24 hr after tumor cells were added and then incubated for an additional 48 hr. Data are expressed as mean cpm ± SD from triplicate cultures. Pulmonary metastases or nontumorous lung tissues were pooled and enzymatically dissociated to obtain single cell suspensions; 3 mice/group. *Numbers in parentheses* show percent cytotoxicity as compared to control macrophages ($P<0.01$, Student's *t*-test).

converted to reflect the percentage of fluorescent macrophages (as determined from table 2), we found that approximately 5% of the tumor-associated macrophages were labeled within a 24-hour period. This figure was somewhat higher for lung (alveolar) macrophages and ranged from 11.6 to 15.2% (table 3). Again, the tumor-bearing status or treatment of the host had relatively little effect on the uptake of liposomes by macrophages.

Activation of tumor-associated and alveolar macrophages.—We next wished to determine whether the systemic treatment of mice with liposomes containing MTP-PE would lead to activation of the metastasis-associated macrophages. Macrophages were isolated from the cell suspensions by allowing them to briefly (5 min) adhere to the plastic test wells. Because it was difficult to control accurately the precise number of adhering effector cells, we also used a second technique to isolate macrophages. In this technique, macrophages were first allowed to adhere to plastic petri dishes. The adherent cells were then recovered with a rubber policeman and replated at the desired concentration of viable cells per well. Despite the use of different isolation techniques, both methods yielded similar results. The data in table 4 demonstrate that only macrophages derived from animals given injections of liposomes containing MTP-PE were tumoricidal. Alveolar macrophages from both tumor-bearing and tumor-free mice mediated a similar degree of cytotoxicity (50–57%), which was somewhat greater than the cytotoxicity expressed by tumor-associated macrophages (32–40%). However, the lower levels of cytotoxicity mediated by tumor-associated macrophages may have been due to the lower percentage of macrophages containing liposomes (table 3). Macrophages obtained from either nontumorous lung tissue or lung metastases of mice that were not given iv injections or that received injections of liposomes containing HBSS were not tumoricidal in vitro (table 4).

DISCUSSION

In the present studies we investigated the mechanism by which systemic treatment of tumor-bearing mice with liposomes containing MDP or its derivatives leads to eradication of spontaneous lung and lymph node metastases. Because the iv injection of liposome-entrapped MDP can generate tumoricidal macrophages in vivo (*7*) and macrophages have been implicated in the regression of tumors in several systems (*20–22*), we wanted to determine whether liposome-activated macrophages were the effector cells responsible for the destruction of the metastases in the tumor system used in this study. Twenty-four hours after the iv injection of fluorescent liposomes into tumor-bearing mice, 5% of the macrophages isolated from lung metastases contained liposomes. Recent studies demonstrated that free liposomes do not extravasate through capillaries to reach organ parenchyma but, rather, are first engulfed by fixed and circulating phagocytic cells that later extravasate into organ parenchyma (*18*). Those data suggest that the metastasis-associated, liposome-positive macrophages probably originate from the circulating blood monocyte pool. Furthermore, our data would indicate that during a 24-hour period, the influx of macrophages into lung metastases is at least 5% of the total number of infiltrating macrophages. When one considers the rapidity with which macrophages enter the metastases and the relatively long duration of macrophage activation achieved by this treatment (*8*), it seems likely that well-timed multiple liposome treatments could activate a high proportion of metastasis-associated macrophages to the tumoricidal state.

The presence of tumor-associated macrophages containing liposomes was also confirmed by electron microscopic analysis. Two morphologically distinct types of macrophages were observed. In one type, large accumulations of melanin granules were observed, and the intracytoplasmic liposomes were contained within a single phagocytic vacuole. In the other type, the macrophage did not contain melanin granules, and the liposomes remained in individual phagosomes. Melanin deposits in macrophages suggest that these cells have been in contact with tumor material long enough to have phagocytosed some of the tumor cell products, whereas the absence of intracytoplasmic melanin deposits may characterize a newly arrived blood monocyte. Previous in vitro studies had shown that liposomes engulfed by macrophages eventually are concentrated into a common phagocytic vacuole before their fusion (*19*). Presumably, a similar sequence of events also occurs in vivo.

Multiple iv injections of liposomes containing MTP-PE, but not those containing HBSS, led to eradication of metastases in 70% of mice bearing spontaneous lung and lymph node metastases. Furthermore, metastasis-associated macrophages obtained from mice treated with liposomes containing MTP-PE (treatment success) but not from mice treated with liposomes containing HBSS (treatment failure) were able to express tumoricidal activity in vitro. These findings suggest that there is a direct correlation between the activation of macrophages by liposomes containing immunomodulators and the regression of disseminated tumor. However, the protocol for studying activation of metastasis-associated macrophages was not the same as that for studying regression of metastases (therapy). Macroscopic metastases that can be recovered and dissociated (>1 mm in diameter) are already too large to respond to therapy, whereas microscopic metastases, which will respond to treatment, are too small to allow studies of macrophage content. Therefore, this problem required that we study metastases of different sizes and under different conditions. Despite these differences there is no reason to assume that microscopic metastases are not also infiltrated with activated macrophages. Indeed, histologic studies have shown that pulmonary metastases of the B16-BL6 melanoma are infiltrated with macrophages at the earliest stages at which these lesions can be identified (Key et al.: Unpublished observations).

Further evidence that macrophages play a role in the regression of these metastases is provided by the observations that 1) only liposomes that localize in lungs are able to activate alveolar macrophages and eradicate pulmonary metastases (*9*, *13*), 2) agents toxic to macrophages abrogate the therapeutic effectiveness of this treatment (*9*), and 3) macrophages activated in vitro with MDP are effective in eliminating tumors when adoptively transferred into tumor-bearing hosts (*9*). In the present studies, we found that the iv injection of liposomes into mice bearing pulmonary metastases did not lead to an increase in the number of macrophages infiltrating the tumor nodules. Thus the effectiveness of systemic administration of liposomes containing MTP-PE in eradicating metastases could not be related simply to an increase in the number of macrophages infiltrating metastases. These findings agree with previous reports that the regression of tumors in several systems is influenced not only by the presence of macrophages but also by their cytotoxic potential (*20*, *22*). We consider it most significant that only macrophages from mice given injections of liposomes containing MTP-PE were cytotoxic to tumor cell targets in vitro. Thus the only difference we have been able to detect in the macrophage populations among the different treatment groups was a quantitative increase in the tumoricidal activity of macrophages infiltrating the metastases of the mice that responded to therapy.

In summary, we conclude that systemically administered liposomes (PC:PS, 7:3 mol ratio) containing MTP-PE are phagocytosed by macrophages that subsequently infiltrate lung metastases. These metastasis-associated macrophages can be shown to be tumoricidal in vitro. In contrast, metastasis-associated macrophages isolated from mice given injections of liposome preparations that have no therapeutic benefit are not tumoricidal against the target cells. These data provide direct evidence that the regression of metastases that occurs after multiple iv injections of liposomes containing macrophage activators (*8*, *23*) is mediated by tumoricidal macrophages.

Induction of Mammary Tumors in Virgin Female BALB/c Mice by Single Low Doses of 7,12-Dimethylbenz[*a*]anthracene[1,2,3]

Stephen P. Ethier[4] *and* **Robert L. Ullrich**[5,6]

ABSTRACT—The induction of mammary tumors in virgin female inbred BALB/c mice after administration of 7,12-dimethylbenz[a]anthracene (DMBA) over a wide range of doses was studied. Mice were exposed at 12 weeks of age to single or multiple doses of DMBA ranging from 0.0025 to 12.0 mg by gastric intubation and were checked regularly for mammary tumors. The experiment was terminated when the mice were 800 days of age. In the dose range of 0.0025–0.125 mg DMBA, the incidence of mammary tumors was dose-dependent. At higher doses, the mammary tumor incidence became less dose-dependent and was nearly independent of doses above the 0.25-mg level. Analysis of the data for the rate of appearance of mammary tumors with age of the animals and for the age at death of non-mammary tumor-bearing animals indicated that in the low dose range induction of mammary tumors was the predominant effect of DMBA exposure, whereas at moderate to high doses the toxic and carcinogenic effects of DMBA on other tissues significantly influenced the final incidence of mammary tumors. Greater than 90% of the tumors that resulted from administration of low doses of DMBA were adenocarcinomas. In contrast, adenocarcinomas and adenoacanthomas were found in approximately equal proportions following administration of high doses of DMBA. JNCI 1982; 69:1199–1203.

The mouse mammary tumor system has been used for many years for the study of factors that are involved in the development of neoplastic disease. This model system is an attractive one because of the numerous factors that can be studied which influence tumorigenesis in this system. Although it has long been known that chemicals such as 3-methylcholanthrene and DMBA are carcinogenic to mammary tissue (*1–4*), most experiments in which these agents were used have been designed to study the role of the MuMTV (*5*) or the influence of gonadotropic and mammotropic hormones on the pathogenesis of this disease (*6–10*). The few experiments that have been reported in which virgin female MuMTV$^-$ mice were exposed to carcinogenic chemicals alone have involved exposure regimens in which high doses of carcinogen were administered (*11–13*). For example, Butel et al. (*13*) reported that exposure of virgin female BALB/c mice to 2, 4, or 6 mg DMBA, delivered as weekly 1-mg exposures, resulted in mammary tumor frequencies of 25, 39, and 26%, respectively.

The purpose of these experiments was to extend the information concerning the induction of mammary tumors by DMBA, over a wide range of doses, and to thereby determine the dose range over which mammary tumor induction is dose-dependent. These experiments have also been designed to investigate the relative effectiveness of single versus multiple carcinogen exposures in the induction of mammary tumors in virgin female BALB/c mice.

MATERIALS AND METHODS

Animals.—The animals were germfree-derived, specific-pathogen-free virgin female BALB/cAnNBd mice, which were bred and maintained in the Biology Division barrier facility. The mice were housed 8 per cage and were fed Purina Laboratory Chow and water ad libitum.

Carcinogen exposure.—DMBA (Sigma Chemical Co., St. Louis, Mo.) was dissolved in stripped corn oil (Eastman Kodak Co., Rochester, N.Y.) and administered to unanesthetized mice by gastric intubation via a 20-gauge needle ending in a silver-soldered bulb. Control animals were given stripped corn oil only.

Experimental protocol.—DMBA or corn oil was administered to the mice when they were 12 weeks old. When multiple exposures were used, the mice were given their first dose when 12 weeks old and then weekly thereafter. The mice were checked regularly for mammary tumors and were killed either when mammary tumors attained a size of 10 mm or when the mice reached 800 days of age. The experiment was terminated at this time because in previous experiments in this laboratory no further increase in the incidence of mammary tumors in control animals was observed beyond this time (*14*). All mice were necropsied and mammary tumors were processed for histologic examination. The tissues were fixed in Zenker's fixative and embedded in paraffin from which 5-μm sections were prepared. Histologic sections were stained with hematoxylin and eosin.

Correction procedure.—A modification of the age-adjustment procedure was used to compensate for different distributions of ages at death among the various groups. This procedure adjusts the incidence values to those that presumably would have been observed if all the groups had the same distribution of age at death as had the control group. In this procedure we calculate an expected incidence by multiplying the age-specific death rates for the disease in question observed in the experimental group by the number of days at risk in the control population as follows: In the ith interval, $d_i(X)$=number of deaths due to the disease of interest in the group treated at dose X and $N_i(X)$=number of mouse days at risk at dose X.

ABBREVIATIONS USED: DMBA=7,12-dimethylbenz[*a*]anthracene; MuMTV =murine mammary tumor virus.

Our model is that $d_i(X)$ has a Poisson distribution with mean $\lambda_i(X)\ ng(X)$, where $\lambda_i(X)$ is the true death rate from the disease of interest in the ith interval at dose X. If the treated group has the same distribution of mouse days at risk as the control group, then the expected number of tumors in the treated group, summed over all intervals, is

$$E(X)=\Sigma_i\lambda_i\quad(X)n_i\text{ (control)}.$$

This expected number can be estimated by

$$\hat{E}(X)=\Sigma_i\frac{d_i(X)}{n_i(X)}n_i\text{ (control)},$$

where n_i (control) is the mouse days at risk in the ith interval in the control group; since we assume that $d_i(X)$ has a Poisson distribution, the estimated variance of $E(X)$ can be obtained by

$$\text{Est var }\hat{E}(X)=\Sigma_i\frac{n_i^2\text{ (control) }d_i(X)}{n_i^2(X)}.$$

We convert the values to percent incidence by dividing by the sample size of the control population. The assumptions and limitations of this procedure have been presented in previous publications (*14, 15*).

RESULTS

Induction of Mammary Tumors by Single or Multiple Doses of DMBA

The dose-response relationships for the induction of mammary tumors following administration of single doses of DMBA are shown in text-figure 1. As can be seen from the text-figure, the dose-response curve rose rapidly and the incidence of mammary tumors increased even at a dose level of 0.0025 mg of DMBA. Further, in the range of 0.0025–0.125 mg DMBA, the incidence of mammary tumors increased steadily with increasing dose. At doses greater than 0.125 mg DMBA, the dose-response curve became progressively more shallow and became nearly flat in the range of 0.25–1.25 mg DMBA.

To examine the effects of higher doses of DMBA on mammary tumor induction, we exposed several groups of mice to doses of DMBA ranging from 1.5 to 12.0 mg. In these groups the DMBA was administered in several weekly fractions to reduce the toxic effect of the treatment. The data obtained from these groups are given in table 1. Administration of 1.5, 3.0, or 6.0 mg DMBA resulted in mammary tumor frequencies not significantly different from those obtained following administration of a single dose of 0.25 mg DMBA. Thus these data agreed with the data obtained from the groups exposed to single doses of DMBA and indicated that the final incidence of mammary tumors was independent of dose at levels greater than 0.25 mg DMBA.

We examined the influence of fractionating the total dose of DMBA on mammary tumor incidence by exposing several groups of animals to low total doses of DMBA (for which single-dose data were available) in either 2 or 10 weekly fractions (table 1). Administration of 0.125 mg DMBA as multiple exposures did not significantly change the incidence of mammary tumors relative to that observed following exposure to DMBA as a single dose. Similar results were obtained when total doses of 0.025 or 0.25 mg were administered as 2 weekly fractions. Inasmuch as it has been demonstrated that sensitivity to mammary carcinogenesis after DMBA exposure in the rat declines with increasing age (*16, 17*), 1 group of animals was exposed when 22 weeks of age to 0.125 mg DMBA as a single dose. This protocol

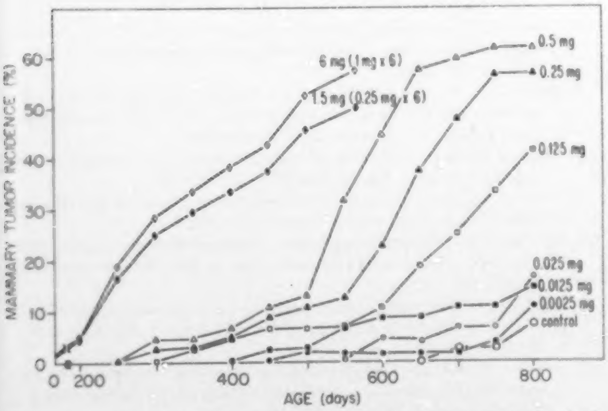
[a] *Numbers in parentheses* are the percent tumor incidence±SE.
[b] Animals were exposed to DMBA at 22 wk of age.

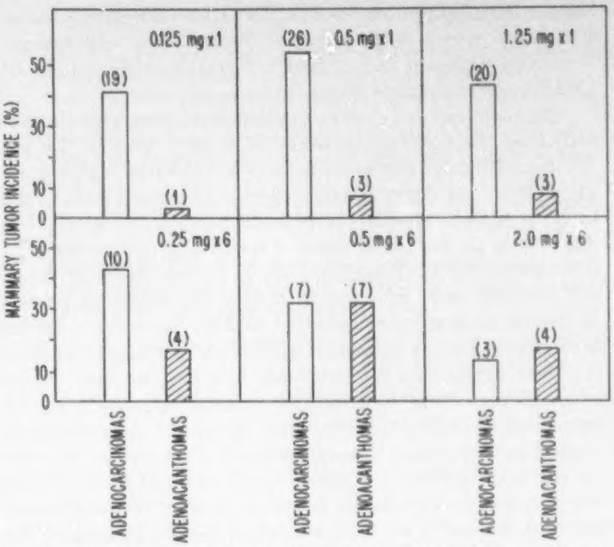
resulted in a tumor incidence not significantly different from that observed following a similar exposure of animals at 12 weeks of age (table 1). This finding is consistent with previous observations for mammary tumorigenesis in these mice following neutron irradiation over the age span of 12–25 weeks (*14*). These data indicate that the mammary tumor incidences which we observed were not influenced by the mode of carcinogen administration and that age-related changes in susceptibility did not significantly influence our results.

The data for the incidence of mammary tumors as a function of the age of the animals for the various exposure groups are shown graphically in text-figure 2. Mammary tumors first appeared in control animals at approximately 650 days of age. The mammary tumor incidence in control animals then increased with time until a tumor incidence of 7.1% was attained by 800 days of age. In other studies from this laboratory, no further increase in mammary tumor incidence has been observed in control mice that lived through 1,000 days of age (*14*). The incidence versus time curves for the groups exposed to single doses of DMBA indicated that a significant effect of exposure was to shorten the time of appearance of mammary tumors. The data shown in text-figure 2 indicate that the time of appearance of mammary tumors was shortened progressively as the dose of DMBA was increased. Administration of higher doses of DMBA given as multiple exposures served to shorten still further the time of appearance of mammary tumors without, however, increasing the final incidence. Thus while increasing the dose of DMBA above the 0.25-mg level was not effective in increasing the tumor frequency, higher doses of DMBA did result in earlier expression of mammary tumors. These higher doses affected the life-span of non-mammary tumor-bearing animals in a similar manner. Over the dose range of 0.0025–0.125 mg, DMBA had little influence on the survival times of those animals that did not develop mammary tumors, whereas at doses above 0.25 mg, the mean survival times of the non-mammary tumor-bearing animals were clearly reduced.

Deaths from other causes can potentially have a confounding influence on observed tumor incidences (*18*). Since at high doses DMBA influenced both the time of appearance of mammary tumors and the survival times of animals that did not develop mammary tumors, the present data suggested that deaths from other causes may have influenced the incidences of mammary tumors observed at these doses. To examine the influence of competing risks, we also evaluated the data by using a procedure that compensates for competing causes of death. The data analyzed in this fashion are shown in text-figure 1. There were essentially no differences in the observed or age-adjusted incidences in the dose range of 0–0.125 mg. At higher doses the age-adjusted incidences, rather than plateauing like the nonadjusted data, continued to increase to an incidence of greater than 90% at 0.5 mg DMBA.



Text-figure 2.—Incidence versus time curves for groups exposed to single and multiple doses of DMBA.



Text-figure 3.—Distribution of adenocarcinomas and adenoacanthomas in groups exposed to low and high doses of DMBA.

Histologic Classification of DMBA-Induced Mammary Tumors

The mammary tumors that we observed in this study were classified either as adenocarcinomas or adenoacanthomas, and the relative abundance of these tumor types is given in text-figure 3. As is shown in the text-figure, adenocarcinomas were by far the predominant tumor type in groups exposed to low to moderate doses of DMBA. The histologic appearance of the adenocarcinomas varied widely. Most tumors were highly variable in appearance and exhibited tightly spaced chords of epithelial cells as well as cysts and papillary structures. A few tumors had areas that appeared fairly well differentiated and exhibited many closely spaced acini; however, even these tumors exhibited significant variability. Thus most tumors would be classified as type B adenocarcinomas according to Dunn's classification. (*19*).

DISCUSSION

The principal aim of the experiments reported here was to examine the relationship between exposure of virgin female BALB/c mice to DMBA and mammary tumor frequency over a wide range of doses. These experiments were also designed to compare the relative effectiveness of DMBA given as single or multiple exposures.

The dose-response curve obtained from these experiments indicated that at doses between 0.0025 and 0.125 mg DMBA, the incidence of mammary tumors was highly dose-dependent. At doses greater than 0.125 mg DMBA, the incidence of mammary tumors became progressively less dependent on dose and became essentially independent of dose above the 0.25-mg level. Thus in the low dose range (<0.125 mg) the induction of mammary tumors appeared to be the predominant effect of DMBA exposure, whereas at higher doses the influence of DMBA was more complex. At doses above 0.25 mg, the toxic and carcinogenic effects of DMBA on other tissues became important, which in turn appeared to influence the final incidence of mammary tumors at these doses. The influence of these competing risks on the final incidence of mammary tumors at doses of 0.25 mg and greater was clearly demonstrated by our analysis of the data in which we used a method that compensated for competing causes of death. The data for the incidence of mammary tumors as a function of age given in text-figure 2 and the data from table 1 showing the survival times for those animals that did not develop mammary tumors also support this view. At doses of 0.25 mg and above, the incidence of mammary tumors rose steadily in animals 600–700 days of age. Since the survival times of non-mammary tumor-bearing animals were reduced by these doses, few animals survived to be at risk for the further development of mammary tumors beyond these times. Thus no further increase in tumor incidence was possible. At the 0.5-mg level, only 3 of 48 animals survived to 700 days of age, whereas at higher doses, no animals survived to this age. At 0.25 mg DMBA, the incidence was probably also affected by these same factors on the basis of the slight increase in incidence seen after the age adjustment and the reduction in the mean survival time of non-mammary tumor-bearing animals (only 8 of 48 animals survived beyond 700 days), although the effect was not as dramatic as at higher doses. Thus these data suggest that at doses above 0.125 mg DMBA, competing risks for other neoplasms as well as the toxic effects of DMBA significantly affect the final incidence of mammary tumors such that at these doses the observed incidence of mammary tumors depends largely on the number of animals that live long enough to develop these neoplasms. At doses below 0.125 mg DMBA, which did not appear to significantly decrease the life-span of the non-mammary tumor-bearing animals, the primary effect of DMBA was on the development of mammary tumors. Over this lower dose range, the incidence of mammary tumors was dose-dependent.

These findings are particularly relevant to studies in which modifying influences of DMBA-induced mammary tumorigenesis have been investigated. Smith et al. (*5*) found that exposure of MuMTV-S^+ C3H/StWi mice to 6.0 mg of DMBA resulted in mammary tumor frequencies not significantly different from those obtained following similar treatment of C3H/StWi mice that were free of MuMTV. Similarly, no interaction was observed in a study reported by Butel et al. (*13*) in which BALB/c mice were exposed to 6.0 mg DMBA in combination with 200 rad X-rays. These authors interpreted these findings to indicate that neither the mammary tumor virus nor X-rays interact with DMBA in the induction of mammary tumors in mice. Our data, however, suggest that 6.0 mg DMBA is more than sufficient to induce the maximum frequency of mammary tumors. Thus if these agents have the potential for interaction, it may not have been detectable given the protocols used in the above experiments. In this regard, it would be of considerable interest and importance to examine the potential for interaction after lower single doses of DMBA.

A final aspect of the data obtained from these experiments concerns the distribution of the histologic types of tumors observed in the DMBA-treated groups. In all dose groups where the DMBA was administered in a single exposure (≤1.25 mg), adenocarcinomas were by far the predominant tumor type and adenoacanthomas were rarely observed. Adenoacanthomas became more prevalent, however, in the groups exposed to higher doses. This finding is consistent with reports of other workers (*9, 10, 20, 21*) of a high proportion of adenoacanthomas in BALB/c mice after administration of relatively high doses of DMBA.

In summary, our experiments provided what is to our knowledge the first data concerning the induction of mammary tumors in virgin mice by DMBA over a wide range of doses. The data obtained from these experiments indicated that the predominant effect of low doses of DMBA is the induction of mammary tumors and that the expression of these tumors is relatively uncomplicated by other effects of DMBA. In contrast, the final incidence of mammary tumors following moderate to high doses of DMBA is strongly influenced by the toxic and carcinogenic effects of this chemical on other tissues.

Announcements

The Journal *will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.*

New NIH Biotechnology High Voltage Electron Microscope (HVEM) Resource Available to Biological and Medical Researchers

The Biotechnology Resources Program, Division of Research Resources, National Institutes of Health, is supporting part of the operation of the 1.2-million volt electron microscope at the New York State Department of Health installation at Albany. This installation, under the direction of Dr. Donald Parsons, is operated as a State facility in the Northeast Region, and is now available to users on a national basis. Users must be qualified scientists with appropriate biomedical projects, regardless of institutional affiliation or geographical location.

When applying, please state justification for appropriateness of the Albany installation. Interested scientists should submit a brief proposal of 1-4 pages, which includes the following information:

1) title, name, address, and phone number
2) curriculum vitae of the investigator
3) description of the proposed project demonstating how the HVEM study will be part of this project
4) statement of the biomedical value of the project
5) justification for the use of the HVEM (explanation of its appropriateness to the project proposed)
6) results already obtained by light or conventional electron microscopy at 100 kv, 200 kv, or lower voltages; selected micrographs should be enclosed
7) nature of the specimens, specific methods used in specimen preparation, and suitability for HVEM should be documented
8) a concise bibliography directly relevant to the proposed project should be given
9) microscope time must be estimated in your application; an initial visit for a pilot study will be allowed in relation to your plan for microscope time, with further visits subject to review by the Advisory Committee.

Potential users are encouraged to consult members of the Resource Group and the Advisory Committee for technical advice on specimen preparation; advance study is advisable before a visit. Instructions on HVEM technique, the various modes of operation, and the accessories of the HVEM are available from the Resource Group and should be obtained early. Periodic workshops on the theory and practice of HVEM and associated image processing will be arranged.

Please mail your outline to Dr. Donald F. Parsons, Director, HVEM Laboratory, Center for Laboratories and Research, New York State Department of Health, Empire State Plaza, Albany, New York 12201 (telephone: 518-474-7047/7049).

Harvard Medical School Continuing Education Program

The following course is being offered by the Department of Continuing Education, Harvard Medical School, and the Joint Program in Nuclear Medicine:

Clinical Nuclear Medicine: 1983—Seventh Annual Postgraduate Course; AMA Category I credit 24 hours; William D. Kaplan, M.D., Program Director; course date March 14-18, 1983.

The following course is being offered by the Department of Continuing Education, Harvard Medical School, and the Department of Radiology, Brigham and Women's Hospital:

Orthopedic Radiology; AMA Category I credit 26 hours; Barbara N. Weissman, M.D., Program Director; course date April 25-28, 1983.

For additional information contact Ms. Jo-Anne Latino, Coordinator, Continuing Education Department, Harvard Medical School, 25 Shattuck Street, Boston, Massachusetts 02115 (telephone: 617-732-6265).

The 1983 Oncology Update Symposium

This symposium, sponsored by Northridge Hospital Medical Center, will be held at the Biltmore Hotel, Los Angeles, California, on April 9, 1983. The meeting is designed to update the medical community on advancements in oncology and will feature leading oncology specialists speaking on the latest developments in cancer prevention, early cancer detection, cancer immunology, cancer surgery, and oncology nursing.

Registrants can receive eight hours of Category I credit toward the California Medical Association's Certificate in Continuing Medical Education, the American Medical Association's Physician Recognition Award. This course has been approved for eight hours by the California Board of Registered Nursing.

For reservations or further information contact Ms. Sandra Rozzen, Northridge Hospital Medical Center, 18300 Roscoe Boulevard, Northridge, California 91328 (telephone: 213-885-5311).

Sixty-Fifth Annual Meeting of the American Radium Society

Savannah, Georgia, will be the site of this meeting to be held on April 5-9, 1983 at the Hyatt Regency Hotel. For additional information contact Mrs. Sally Polek, Office of the Secretariat, American Radium Society, 925 Chestnut Street, Philadelphia, Pennsylvania 19107 (telephone: 215-574-3179).

Eighth Summer Program in Methods of Immunologic Research and Diagnosis

The eighth biennial program on current methods of immunologic research and diagnosis will be offered by The Earnest Witebsky Center for Immunology of the State University of New York at Buffalo, New York, in June 1983. The opportunity will be presented for a choice between a three-week program for tyros that comprises elementary and advanced technologies or a two-week program offering only the advanced procedures for persons more familiar with the basic immunologic techniques.

Both programs will consist primarily of combination of core and elective practical laboratory exercises to allow the participant to become acquainted with the techniques by personally carrying them out at the bench. These will be complemented by demonstrations, lectures, and discussions so that the entire program is designed to provide the participant with a survey of presently available methodology together with insight into the underlying immunologic principles. It is open to individuals at the post-doctoral level, supervisory senior technologists, and graduate students beyond the master's level.

Further information may be obtained from Dr. James F. Mohn, M.D., Director, The Ernest Witebsky Center for Immunology, State University of New York at Buffalo, 210 Sherman Hall, Buffalo, New York 14214 (telephone: 716-831-2848). Inquiries should be received by January 15, 1983.

Eighth International Congress of Cytology

This Congress, organized by the International Academy of Cytology, the Canadian Association of Pathologists, and the Canadian Society of Cytology and cosponsored by the Quebec Association of Pathologists and National and Regional Societies of Cytology, will be held on June 19–23, 1983 at the Queen Elizabeth Hotel in Montréal, Canada. The scientific program will comprise the most recent advances in all fields of diagnostic and investigative cytology as of 1983.

There will be invited and guest lectures, lectures by the recipients of the 1981, 1982, and 1983 Goldblatt Cytology Awards, panel discussions, symposia, a slide seminar, and proffered papers.

Please address inquires to Dr. Alexander Meisels, M.D., Secretary-General, Eighth International Congress of Cytology, 1050, Chemin Sainte-Foy, Québec, P.Q., Canada G1S 4L8 (telephone: 418-688-3640).

E.O.R.T.C. Symposium on Treatment of Advanced Gastrointestinal Cancer

Padua, Italy, will be the site of this symposium to be held on June 23–24, 1983. The aim of the symposium is to evaluate the current modalities available for the treatment of advanced tumors of the gastrointestinal tract. The meeting will focus on chemotherapy, radiotherapy, and surgery, either alone or in combination. The program will include invited presentations and free communications. Free communications will be selected on the basis of submitted abstracts.

Abstracts should be received no later than March 31, 1983; address abstracts to Pr. M. Lise, Director, Istituto di Patologia Chirurgica I^a, Universita degli Studi di Padova, 64 via Gattamelata, 35100 Padua, Italy. Seating is limited and preregistration is recommended. For further information and registration contact Ms. D. Eeckhoudt, Executive Secretary, EORTC Data Center, 1 rue Héger-Bordet, 1000 Brussels, Belgium (telephone: (2)539.30.20 - Telex: 22773).

Journal of the National
Cancer Institute

December 1982
Volume 69
Number 6

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department. Use of funds for printing this periodical has been approved by the Director of the Office of Management and Budget through August 30, 1985.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S Government Printing Office, Washington, D.C. 20402. Price per copy, $7.00. Subscription price for two volumes per year in the United States, $70.00; foreign, $87.50. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20816.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20816.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAPS facilities should indicate in a footnote how their additional data may be obtained.

Approximately one-half of all manuscripts submitted to the Journal are accepted for publication. Publication of manuscripts is contingent on transfer of copyright to the Journal. Forms for this purpose will be sent to authors when a manuscript has been approved for publication. All material published in the Journal is in the public domain; therefore, permission to reproduce any portions is not necessary. As a matter of courtesy, communication should be made to the author(s) concerned.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, noninbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols: *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Biochemical Nomenclature and Related Documents* (IUB, 1978) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1978) of the IUB for recommended names of enzymes and information on nomenclature of isozymes; *The Merck Index* (9th ed) for chemical compounds; "Standard Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40: 2083–2128) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221–245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends, and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs*. Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Medicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3–10/Ann Intern Med 1979;90:95–99/Br Med J 1979;1:532–535/ or Lancet 1979;1:428–430).

Letters to the Editor

Noncontraceptive Estrogen Use and the Occurrence of Ovarian Cancer[1,2]

SIR: Dr. Weiss and his colleagues[3] reported on an increased risk of endometrioid carcinoma of the ovary related to noncontraceptive estrogen use, even if the overall risk for all types of epithelial ovarian cancers was not significantly increased. For this reason and for other reasons (only a 56% interview rate among users and the lack of increased risk with increased dosage and duration of use), Weiss et al. concluded that "... the observed association between menopausal estrogen use and the occurrence of ovarian endometrioid tumor should be interpreted cautiously until the results of additional studies are available."

We had the opportunity to consider the histology-specific pattern of noncontraceptive estrogen use in a case–control study on ovarian cancer and have reported the general methods and results elsewhere.[4] Cases were 161 patients with epithelial ovarian cancers admitted between May 1979 and February 1980 to the first Obstetrics and Gynecology Clinic of the University of Milan; controls (561) were age-matched patients who had not undergone bilateral oophorectomy and who had been admitted for acute disorders other than malignant, hormonal, or gynecological disorders to six wards of four major university hospitals in Milan. None of the eligible patients and controls refused to be interviewed. All histologic specimens were reviewed by the same pathologist who was unaware of the epidemiologic data, and the interviewers did not know the histologic diagnosis. Only the 135 cases and 437 controls aged 40–69 were considered here (noncontraceptive estrogen use being concentrated in these age groups). The estimated relative risks for the use of estrogen-replacement therapy are given in table 1. Although exposure to noncontraceptive estrogens was not associated with an increased likelihood of developing ovarian cancer [relative risk (RR)=1.0], there was an excess risk of borderline significance [RR=2.3; 95% confidence interval (CI)=1.0–5.3] of endometrioid cancers and a nonsignificant one (RR=1.6; 95% CI=0.3–8.4) of clear cell cancers. (Since adjustment for age in decades by the Mantel-Haenszel procedure did not materially change any of the RR estimates, unadjusted ones are chosen for presentation.) Three patients with endometrioid tumors, but only 2 in the other categories, reported a long-term use (>5 yr), but no clear duration–risk relationship was evident.

A more detailed analysis of the histologic tumor type-specific epidemiologic and clinical characteristics of a part of our study population has been published elsewhere.[5] Ovarian cancer patients showed several characteristics that have been described as risk factors for endometrial cancer, but patients with endometrioid carcinomas seemed to have them to a greater extent, especially late menopause and nulliparity or low parity. It is also of interest that the RR estimate for estrogen use in endometrioid cancers (RR=2.3 is similar to that found in a case–control study of endometrial cancer conducted on the same Italian population.[6] Thus there seems to be a broad agreement between our data and the suggestions made by Weiss et al.,[3] although the following points are worth stressing:

1) Our findings, too, are based on limited numbers and, methodologically, represent a typical example of data dredging. Therefore, they should be taken more as a further suggestion than as a confirmation.

2) The possibility that estrogens may affect the histologic tumor type differentiation of preexisting ovarian neoplasms rather than actually inducing the tumor appears unlikely to be ruled out by a case–control study of this size.

Immune Alterations Related to Age, Sex, and Mammary Tumor Detection in Murine Mammary Tumor Virus-Infected Mice

SIR: In a recent paper, Specter and Friedman[1] reached the conclusions that in inbred RIII mice, known to be infected neonatally by murine mammary tumor virus (MuMTV), female mice, compared to male mice of the same ages and in spite of a constant increased spleen weight, had a significant depression of the antibody response of their splenocytes against sheep red blood cells (SRBC). This depression was deepened by the presence of a detectable adenocarcinoma. Furthermore, using blastogenic tests with lipopolysaccharide (LPS) or phytohemagglutinin (PHA), the authors reported that old tumor-bearing female mice alone showed a significant decrease of their response to PHA.

Using C3H/Bi mice, also known to be infected by MuMTV, our group has obtained almost identical results.[2] As compared to age-matched males, female mice display constant increased spleen cell numbers. The antibody response to SRBC is significantly decreased in aged (5–6 mo) female mice as compared to young (2–4 mo) female mice or male mice of the same ages. This decrease seems not to be due to a B-cell defect since antibody response to trinitrophenyl-substituted LPS, a T-independent antigen,[3] remains constant throughout the first 8 months of life of female mice. In addition, PHA blastogenic response of spleen cells does not decrease with age in female mice, but a significant depression is observed in old tumor-bearing mice as compared to tumor-free female mice of the same age.

One of the major discrepancies between the results observed in RIII mice[1] or C3H/Bi mice[2] resides in the antibody response against SRBC in old tumor-bearing mice. Whereas in RIII mice tumor presence is associated with a strong depression of the immune response, in C3H/Bi mice the presence of an adenocarcinoma is associated with an increase of the anti-SRBC antibody response in tumor-bearing female mice compared to tumor-free female mice of the same age. Although this unexpected event seems to be related to tumor emergence in C3H/Bi mice, we agree with Specter and Friedman's conclusions on the difficulty of attributing a specific immune phenomenon to tumor appearance, taking into account the complex relationships between sex, age, and immune responsiveness in these two MuMTV-positive mouse strains. The discrepancies observed at the antibody production level between tumor-bearing RIII and C3H/Bi mice could be attributed to many other parameters, such as genetic background, hormonal factors (since we used C3H/Bi breeders whereas Specter and Friedman used RIII virgin mice), or intrinsic viral properties because it has been recently reported[4] that MuMTV displayed different bioactivities in C3H and RIII mice.

Human Retroviruses and Adult T-Cell Leukemia–Lymphoma[3]

The last several years have seen exciting developments concerning the presence of retroviruses in humans and its association with certain types of T-cell leukemia–lymphoma. Retroviruses have long been identified in many species and have been shown to induce leukemias and lymphomas or have been closely implicated in the etiology of these diseases in a number of species. Transmission of leukemia with cell-free filtrates was reported for chickens in 1908 by Ellerman and Bang (*1*). Gross (*2*) later showed the induction of leukemia in inbred strains of mice with murine leukemia virus. Induction of leukemia was demonstrated in cats with FeLV by Jarrett et al. (*3*), and seroepidemiologic studies among outbred cat populations by Cotter et al. (*4*) showed that transmission of FeLV is responsible for most, if not all, naturally occurring leukemias in cats. Retroviruses are primary causes of naturally occurring leukemias in at least several other species, including cattle, turkeys, and gibbon apes [for reviews, *see* (*5, 6*)].

There are two general categories of retroviruses based on their life cycles. Endogenous viruses are contained in the germ line of a species, transmitted genetically, not usually expressed into RNA, protein, or extracellular virus, and do not seem to be pathogenic except in some inbred animals. The retroviruses associated with leukemias and lymphomas, in contrast, are transmitted by infection with exogenous virus. These retroviruses can also be subdivided into 2 general groups based on their biologic activity, a reflection, of course, of differences in their genome. One group is competent for virus replication, causes disease after a long latent period, and does not appear to directly transform cells. BLV and FeLV belong to this group. The other group is generally replication-defective and is comprised of viruses that have undergone recombination with host cell DNA sequences. These host cell sequences, called "*onc*" genes, allow these viruses to directly transform cells in vitro, and disease onset is rapid. Sarcoma viruses and Abelson murine leukemia virus belong to this group. Replication is possible only in the presence of competent "helper" viruses.

Identification and Characterization of a Human Retrovirus

Until recently, retroviruses had never been unequivocally demonstrated in humans, although data suggestive of their presence were frequently reported. For example, definitive evidence was obtained in human leukemias for virus-like reverse transcriptase (*7*), and extra, presumably acquired, DNA sequences were also reported in this disease (*8*). No convincing evidence or demonstration of a human retrovirus, however, was reported. It is now evident that the inability to show the existence of retroviruses was in part due to the uncertainty of where to look (tissue type, cell type, and type of diseases) and in a large part due to the inability to successfully culture the appropriate types of cells in vitro.

Our laboratory had long been interested in learning how to grow different types of hematopoietic cells. In particular, the growth of T-cells seemed of interest since many virally induced leukemias of animals are of T-cell origin (*9*). In 1976, we reported the discovery of a factor from short-term cultures of mitogen-stimulated peripheral blood human lymphocytes. This factor (TCGF) supported the long-term growth of human mature T-cells (*10, 11*). TCGF has been purified to near homogeneity and is a protein whose monomeric molecular weight is 12,000–13,000 (*12*).

With the use of purified or partially purified TCGF, mature T-cells from normal sources could be grown only after mitogen activation, indicating that TCGF is a second signal in T-cell growth (*12*) due to lack of TCGF receptors on unactivated T-cells. It was soon realized, however, that purified TCGF alone was sufficient to grow mature T-cells from the blood of patients with cutaneous T-cell lymphoma–leukemia and certain other T-cell cancers (*13*). Some of the biochemical markers of these cells, as well as the requirement for prior activation of normal T-cells for TCGF-supported growth, suggest that the T-cells grown with purified TCGF consist, at least in part, of the malignant T-cells of these patients. The lack of a requirement for prior activation of these cells appears to be due to their constitutive expression of receptors for TCGF (*14*).

Several such cell lines were studied from an adult black man (CR) with a particularly aggressive cutaneous T-cell lymphoma (mycosis fungoides) (*15*). Typical retrovirus particles were visible by electron microscopy (fig. 1), and particulate reverse transcriptase activity was detected in the media. This enzyme activity had all of the biochemical parameters of retrovirus reverse transcriptase, and both the

Editor's note: Periodically, the Journal publishes solicited guest editorials as a means of transmitting to investigators in cancer research the essence of current work in a special field of study. The Board of Editors welcomes suggestions for future editorials that succinctly summarize current work toward a clearly defined hypothesis regarding the causes or cure of cancer.

particles and the reverse transcriptase activity banded in equilibrium sucrose density gradients at the appropriate density (1.16 g/cm^3). The reverse transcriptase activity was not inhibited by antisera against the reverse transcriptases of several other retroviruses, including primate retroviruses. This virus was provisionally designated HTLV. The genomic RNA of HTLV was shown to be a polyadenylated 70S RNA, in common with other retroviruses. With the use of cDNA transcribed from the viral genomic RNA, it was shown that HTLV was not significantly related to any previously described animal retroviruses and that it was not endogenous to humans [i.e., not a ubiquitously germ line-transmitted human virus (*16*)]. Furthermore, HTLV was not transmitted via the germ line in patient CR but was acquired by postzygotic infection. This conclusion was based on the presence of HTLV provirus in the DNA of some of the T-cells from three independently derived T-cell lines from CR, including one from the laboratories of Dr. S. Broder and Dr. T. Waldmann (National Cancer Institute), and its absence from the DNA of a B-cell line from the same patient, as well as from DNA of other T-cells (*17*). All these lines were positively identified as having originated from patient CR by their HLA haplotype (*17*).

The major HTLV core protein was identified as p24, which was shown to be serologically distinct from the core proteins of all previously described viruses (*18*). A second core protein, p19, was also shown to be novel (*19*). The reverse transcriptase (also serologically distinct) is somewhat larger than that of type C retroviruses (95,000 daltons) and slightly prefers Mg^{2+} over Mn^{2+} as the divalent cation, a property shared by the reverse transcriptase of BLV (20). Consistent with this observation, the amino acid sequence of the p24 core protein has recently been determined by Oroszlan et al. (*21*) to be most closely homologous to that of the major core protein of BLV among all the analogous retroviral proteins tested. On the basis of this finding, HTLV appears to be distantly related specifically to BLV. However, the relationship is not sufficiently close to suggest current interspecies transmission. In fact, by conventional immunologic assays and nucleic acid hybridization assays, the proteins and nucleic acids of BLV and HTLV are not detectably related (*16, 18, 19*). In addition, natural antibodies to BLV in cows do not react with proteins of HTLV, and, conversely, human antibodies to HTLV do not react with BLV (*22, 23*).

A second isolate of HTLV was subsequently obtained from the cultured T-cells of another adult patient (MB) with a highly malignant variant of Sézary T-cell leukemia (*24*). This virus was shown by nucleic acid hybridization and protein serology to be very closely related or identical to HTLV. Moreover, viral proteins and proviral DNA were detected in *uncultured* tissue from the same patient, which virtually ruled out a laboratory contamination.

Presence of HTLV in Japanese ATL

Because of the initial association of HTLV with cutaneous T-cell lymphoma (patient CR) and Sézary T-cell leukemia (patient MB), a number of serum samples were screened from each type of patient. With the use of solid-phase immunocompetition and competition radioimmunoprecipitation assays, antibodies to p24 and p19 were detected in the sera of a few of these patients and shown to be absolutely specific for HTLV (*22, 23*). Antibody to HTLV p24 was also found in the normal spouse of one of the HTLV-infected T-cell lymphoma patients, although all other normal sera were negative. It has become apparent that most cases readily identifiable as positive for HTLV have strikingly common clinical features: adult onset, usually a rapid disease course, often hepatosplenomegaly, lymphadenopathy, large and usually pleomorphic lymphocytes with lobulated nuclei and mature T-cell surface phenotype markers (usually OKT4$^+$), often hypercalcemia, and skin manifestations in over half. In spite of the OKT4$^+$ phenotype, the T-cells from this type of disease often have a suppressor function [*see* CTC-16 in (*25*)]. A typical cell is shown in figure 2. Despite the similarity in most cases of HTLV-positive disease, however, HTLV has also been identified in a few instances in the typical, more benign Sézary syndrome (Popovic M, Sarin P, Robert-Guroff M, et al.: Manuscript in preparation). Moreover, since in most instances we have tested only for serum antibodies to HTLV and since we have identified HTLV antigen in cultured T-cells of a few antibody-negative persons, HTLV may be more prevalent in classical Sézary syndrome and mycosis fungoides than is now evident.

A T-cell cancer, representing a type of leukemia observed in adults and endemic to regions of southern Japan, was first recognized and described by Takatsuki and his colleagues (*26*). This disease, called ATL, has clinical symptoms very similar to those observed with HTLV-positive cases of cutaneous T-cell lymphoma and frequently has cutaneous manifestations (*27, 28*). Like the T-cells from cases in the United States, the T-cells from these patients are generally OKT4$^+$ and function as suppressor cells. These similarities prompted us to make a seroepidemiologic survey of patients with this disease from the endemic region of Japan. It was quickly evident that almost all of these ATL patients had specific antibodies to HTLV p19 and p24, while a few normal persons from this region were also antibody-positive (*29–31*). Consistent with these findings were the subsequent results obtained by investigators in several laboratories in Japan. These investigators have shown the presence by electron microscopy of retrovirus particles in cultured T-lymphocytes from a few ATL patients and have demonstrated serum antibodies directed against determinants on cells producing these particles in almost all Japanese ATL patients (as well as 26% of normal persons from the endemic area of Japan) (*32, 33*). The similarity in the distribution of this antibody and the antibody against HTLV suggested that the two agents are very similar or identical. This relationship has now been confirmed in our laboratory in collaboration with colleagues in Japan by characterizing the virus produced by two of the cell lines, MT-1 and MT-2, used in the studies by Hinuma et al. (*32*) and Miyoshi et al. (*33*). This virus has antigenic determinants identical to those of HTLV p24 and p19, and its mRNA and provirus hybridize virtually completely to cDNA from HTLV (*34*).

Cocultivation of the other cell line in (*33*), i.e., MT-2, with cord blood T-lymphocytes results in the induction of TCGF-independent T-cell lines (*35*). This result suggests that in the MT-2 cell line the virus may have acquired an oncogene, enabling it to directly transform human T-cells. We found that transmission of several of our strains of HTLV to cord blood T-cells usually results in several reproducible biologic effects, including a reduction in their requirement for TCGF, an apparent loss of the so-called "crisis period" which generally prevents these cells from growing indefinitely in vitro, the capacity to form large colonies in agar, and the ability to grow to high cell density (Popovic M, Sarin P, Robert-Guroff M, et al.: Manuscript in preparation). In at least some cases, TCGF independence is induced. Moreover, the virus apparently infects only mature T-cells and, despite repeated efforts, we have been unable to infect human B-cells, fibroblasts of human and animal origins, or human bone marrow cells.

Presence of HTLV in ATL in the Caribbean

In collaboration with Dr. W. Blattner and his colleagues (Environmental Epidemiology Branch, National Cancer Institute), Dr. D. Catovsky and Dr. D. Galton (Medical Research Council Leukemia Unit, Hammersmith Hospital, London), and Dr. M. Greaves (Imperial Cancer Research Fund Laboratories, London), our laboratory has found that the Caribbean basin is a second region in which HTLV is unusually prevalent. A relatively high incidence of a disease clinically similar to ATL was identified among blacks of Caribbean origin in Great Britain. All cases tested to date have antibody to HTLV (*36*) and, when available, the leukemia cells have released infectious HTLV. T-cell leukemia–lymphoma also seems to be of relatively high incidence in the Caribbean itself, and antibody to HTLV is found in those patients with the disease, as well as in some normal persons (*37*). Various types of T-cell leukemia–lymphoma in conjunction with HTLV have now been found in the southeastern United States, the Boston area, the Seattle area, Japan, the Caribbean, Venezuela, Brazil, Guyana, Ecuador, Israel, and Alaska (*38*). It seems likely that, as other populations are tested, HTLV will also be identified in other parts of the world.

How might HTLV induce ATL? One possibility is that insertion of a viral RNA transcriptional promotor switches on cellular genes whose inappropriate expression results in the leukemia phenotype. This phenomenon has been shown to occur in avian bursal lymphomas and has been termed "downstream promotion" (*39, 40*). It has been suggested that infection with HTLV may result in the downstream promotion of the gene for TCGF, causing its constitutive and inappropriate expression, and some but not all of the available evidence favors this model (*41*). Obviously, infection with HTLV is not in itself sufficient to induce ATL, since not only do many nonleukemic persons manifest persistent serum antibodies to HTLV (*23, 29–32, 37*), but also, in at least some cases, they harbor HTLV in some of their peripheral blood T-cells (Robert-Guroff M, Kalyanaraman VS, Blattner WA, et al.: Submitted for publication). Host-specific or environmental factors, age at first infection, repeated infections, route of infection, or even random chance, as for example, the appropriate integration site, may play a role in pathogenesis by HTLV. Estimates of HTLV infection and association with leukemia or lymphoma have been made by Suchi (personal communication) who believes that about 1 in 2,000 infected people develop disease. This incidence is similar to BLV induction of bovine leukemia. Perhaps HTLV is involved in other diseases, including some of a nonneoplastic nature.

Are all isolates identical? The three CR isolates, the MB isolate, and the MT-1 isolate are certainly very closely related (*24, 34*). In addition, five other isolates (from the Caribbean, the United States, Japan, and Israel) are very closely related by serology and molecular hybridization (Popovic M, Sarin P, Robert-Guroff M, et al.: Manuscript in preparation). One isolate, however, from the Mo cell line (*42*) (originating from a patient in the United States described as having a T-cell variant of hairy cell leukemia) appears to differ in the serologic behavior of its p24. Although this virus thus also belongs to the HTLV group, it may represent a second subtype (HTLV-II). It is possible that others of this type, or yet different types, will be identified in the future. Our provisional nomenclature refers to each strain of HTLV in the order of establishment as a separate strain by Roman numeral followed with letters for the patient or cell line [e.g., HTLV-I(CR)]. A detailed comparison of all the HTLV-I isolates and the possible example mentioned above of HTLV-II will be greatly facilitated by the molecular cloning of a portion of the HTLV genome which has recently been achieved (Wong-Staal F, Manzari V, Gallo RC: Manuscript in preparation).

How is HTLV transmitted? If a substantial portion of the population in the endemic area is indeed infected, as judged by serum antibodies to HTLV, there is probably no need for a nonhuman reservoir to maintain the presence of HTLV. It seems that HTLV is not readily infectious and may require prolonged intimate contact for transmission. This transmission might occur within families (e.g., mother's milk and sexual contact) or could result from, for example, blood transfusions or insect vector transmission. Although a large body of data has become available on HTLV, obviously a great deal of work remains. The identification of this virus, however, raises the possibility of eventually being better able to find, treat, and prevent ATL. Moreover, it may also stimulate thoughts about certain other human neoplasias and the possible role of this type of virus.

Changes in Human Adenovirus 5 Propagated in Burkitt's Lymphoma Cells[1]

Nicole Faucon,[2] Georges Ogier,[2] *and* Yvette Chardonnet[2,3]

ABSTRACT—The effect of host cells on human adenovirus 5 properties was studied with the use of Burkitt's lymphoma cell lines (Raji and Jijoye) that poorly replicate the virus. Only a small fraction of the cell population was producing adenovirus 5. The major virus components were synthesized; however, the purified virus particles differed from those produced in HeLa cells by lower density in CsCl gradient, lower content in DNA, limited changes in DNA restriction enzyme pattern, and polypeptide composition. After one passage in HeLa cells, modifications of polypeptides reversed.—JNCI 1982; 69:1215–1220.

In humans, lymphocytes harbor some viruses, particularly Ad that replicate poorly in these cells. In vivo and in vitro interactions between Ad and lymphocytes have not yet been extensively studied. We previously reported that cultures of human cord blood lymphocytes can produce very low amounts of virus (*1*) and that virus production is enhanced when these lymphocytes are transformed by EBV (*2*). Several established B-cell lines either having tumor origin or transformed in vitro by EBV also support Ad5 replication (*3–5*). However, only a small proportion of the cell population is involved in virus replication. The virus produced is modified in its structure. In this paper, we have studied the infection with human Ad5 of human cells derived from Burkitt's lymphoma and we describe the properties of the modified virus.

MATERIALS AND METHODS

Cells.—The lines Jijoye (EBV-positive) and Raji (EBV-negative) were derived from Burkitt's lymphoma. They were propagated in suspension in medium RPMI-1640 (GIBCO, Grand Island, N.Y.) containing 20% heat-inactivated fetal calf serum. HeLa cells were maintained in minimum essential medium containing 10% heat-inactivated fetal calf serum.

Virus.—Ad5 (Ad75 prototype; from Dr. G. C. Godman, Columbia University, New York, N.Y. was multiplied in HeLa cells and used between passages 16 and 35.

Infection of cell lines with Ad.—Cells were infected with Ad5 at a multiplicity of 50–100 PFU/cell. The viruses were studied either immediately after infection or after three serial passages of infected cells.

Labeling of Ad5 components.—Viral DNA was labeled by the addition of [^{3}H]thymidine (sp act, 35 Ci/mmol; CEA, Saclay, France) to infected cultures. Proteins were labeled by the addition of [^{35}S]methionine (sp act, 700–900 and 1,013 Ci/mmol; CEA and New England Nuclear Corp., respectively) to a medium containing 5% of the normal concentration of methionine and 10% dialyzed fetal calf serum.

Purification of the virus.—Pooled lysates from about 10^8 infected cells (Raji, Jijoye, and HeLa) were used as previously described (*6*). The lysates were frozen and thawed six times. Cellular debris were removed by low-speed centrifugation, the supernatant was treated twice by Freon, and centrifuged on a discontinuous CsCl gradient of densities 1.3–1.6 g/ml for 90 minutes at 45,000 rpm in an SW50-1 rotor. The band of partially purified virus was recovered from the interface and centrifuged on a continuous CsCl gradient (1.2–1.4 g/ml).

In some experiments, to avoid disrupting virus particles, we did the second centrifugation on a 5–20% preformed sucrose density gradient at equilibrium. In both centrifugation procedures, the band of purified virus was dialyzed against 10 m*M* Tris-HCl (pH 7.2) for 24 hours.

Assays of Ad.—Infectivity was titrated either on HeLa cells in plates of 96 wells with dilution step $10^{0.5}$ (three to five wells were used) or by a plaque assay on A 549 cells, a heteroploid non-HeLa cell line established from a human lung tumor by Dr. W. A. Nelson-Rees (University of California, Oakland, Calif.) and given to us by Dr. G. Winberg (Karolinska Institute, Stockholm, Sweden). The titers were expressed either in ID on HeLa cells or in PFU on A 549 cells. Several titrations of the same inoculum in duplicate on HeLa and A 549 cells have established that 1 ID equals 10 PFU. For neutralization tests, the virus was diluted to contain 100–500 PFU/assay.

Hemagglutination was done with a unit volume of 50 µl and a 0.5% suspension of rat (Sprague-Dawley) red blood cells with the addition of Ad6 antiserum at a dilution of 1/200. Under these conditions, the hemagglutination activity was enhanced; both pentons and fibers were detected (*7*).

Indirect immunofluorescence tests were done on cell smears fixed with acetone, with the use of either specific Ad5 rabbit antiserum or immune sera raised to specific virus components.

Immune sera.—Ad5 antisera were prepared in rabbits (*6*) and in Hartley guinea pigs with purified virus replicated in HeLa cells; the antisera were absorbed on uninfected HeLa cells before use.

Two antisera against P-antigen were used: One was prepared in rabbits (*7*) by injection of P-antigen extracted from rabbit kidney cells treated with cytosine arabinoside early after infection; the other was a rabbit antiserum provided by Dr. W. C. Russell (Mill Hill, London). Both sera precip-

itated a major polypeptide 58 K but also other polypeptides (72 K and slightly 120 K).

Other antisera were obtained in guinea pigs against the structural components of Ad5 (hexon, penton, and fiber) produced in HeLa cells (6). Reference antisera were guinea pig antihexon (gift from Dr. H. G. Pereira, Mill Hill, London), rabbit antipenton, and rabbit antifiber (gift from Dr. G. Wadell, Karolinska Institute).

DNA analysis.—Labeled viral DNA was studied in infected Raji or Jijoye cells by use of an alkaline sodium iodide sedimentation gradient (*8*). Pooled fractions of each peak of DNA were dialyzed against 10 m*M* Tris and 1 m*M* EDTA buffer (pH 7.9) and hybridized on a filter with cold HeLa Ad5 DNA (*9*). Hirt supernatants were prepared from infected Raji, Jijoye, and HeLa cells. The density of viral DNA was determined by equilibrium sedimentation through CsCl gradient. Cleavage pattern of the DNA was analyzed with restriction enzymes: Kpn I, Bam I, and XBa (New England Biolabs, Beverly, Mass.) and Eco RI (Boehringer Mannheim Biochemicals, Indianapolis, Ind.). For fragment analysis, 1% agarose gels were used (*10*). The electrophoresis buffer contained 0.04 *M* Tris, 0.02 *M* sodium acetate, and 2 m*M* edetate (pH 8). The gels were immersed in buffer containing 0.5 μg of homidium bromide/ml and photographed under UV illumination.

RESULTS

Multiplication of Ad5 in Raji and Jijoye Cells

Raji or Jijoye cells infected with Ad5 yielded low amounts of infectious virus, either at the first passage (table 1, A) or after several serial passages of infected cells (table 1, B). At the first passage, in three independent experiments, the infectivity and hemagglutinating activity reached maximum levels 3-4 days post infection. Cellular growth was not inhibited and 70-100% of the cells remained viable. By indirect immunofluorescence with Ad5 rabbit antiserum only a few cells were found to contain specific Ad antigens (hexons, pentons, and fibers). The positivity to fluorescence began 2-3 days post infection and increased up to 3-4 days. Positive cells varied from 0.5 to 2% for Raji and from 1 to 5% for Jijoye cells in the different experiments. The fluorescent cells appeared to be two- to three-times larger. No fluorescence was detected in uninfected cells.

When infected cells were propagated serially in four independent experiments, the Ad5 production not only was maintained but also was enhanced until it reached a maximum level after 3-4 passages. In a typical experiment (table 1, B), in Raji cells the infectivity increased twofold to threefold, the hemagglutinating activity increased eightfold, and the number of fluorescent cells rose to 4%. For Jijoye cells, the respective values were one hundredfold, thirtyfold, and 12-13%. The rate of cellular growth slowed down, but the cells remained viable.

Reactions of immunofluorescence were positive with antibodies raised to purified hexons, pentons, fibers, and P-antigen. Virus components were unevenly distributed among the infected cells. More cells were positive with immune sera against pentons, fibers, and P-antigen than with immune sera against complete particles. In any case the fluorescence was less bright than in HeLa cells. The double-immunofluorescence reaction, with the use of fluorescein isothiocyanate-labeled EBV antibodies and rhodamine B-labeled Ad antibodies on Raji or Jijoye cells superinfected with Ad5, revealed both antigens in the same cells.

With extracts from infected cells, the Laurell technique (*11*) and immunodiffusion assays (*12*) also showed that viral antigens were present. In thin sections, virus particles were seen in the electron microscope.

The Ad5 produced in Raji and Jijoye cells was neutralized specifically by antisera raised in guinea pigs or in rabbits against purified HeLa Ad5. Hemagglutination of Raji and Jijoye Ad5 was also inhibited by these antisera.

When cells were infected at lower multiplicity (1-10 instead of 50-100 PFU/cell), the Ad5 multiplication decreased significantly. When the virus was serially propagated in Raji or Jijoye cells, the cell growth was not in-

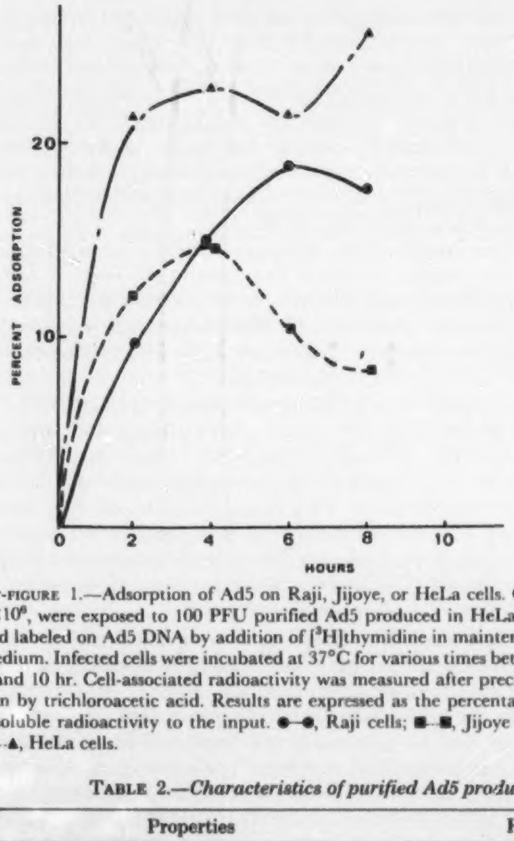
[a] Samples of 2×10^6 were infected with 50 PFU Ad5 per cell and incubated at 37°C for 2 hr. Excess virus was removed and 2 ml medium was added to each sample. Uninfected and infected cells were further incubated at 37°C for 4 days at the first passage. They were subsequently propagated every 3-4 days. At each passage, samples were adjusted to 2×10^6 cells in 2 ml medium. Samples were taken at different times. Cells were enumerated; positive fluorescent cells with specific Ad5 rabbit antiserum were counted from ≈20,000 cells/sample; infectivity was expressed in PFU/10^6 cells; hemagglutinating activity was given in U/10^6 cells. ND=not done.

[b] In each part only one typical experiment was reported.

hibited; the percentage of fluorescent cells was in the same range as the percentage in the first passage; the infectivity and the hemagglutinating activity reached maximum levels after two to three passages in Jijoye cells, whereas they decreased at the second passage in Raji cells.

The observed differences in multiplication of Ad5 in Raji and Jijoye cells were not due to variations in adsorption or to inhibitors. Control experiments with Ad5 plus radioactively labeled DNA showed that the rate of adsorption on Raji and Jijoye cells did not differ significantly from that observed with HeLa cells, but the maximum level of adsorbed radioactivity was reached at different times post infection: 2 hours for HeLa, 4 hours for Raji, and 6 hours for Jijoye cells (text-fig. 1). Adsorption on individual cells was confirmed by an immunofluorescence test developed in our previous study with HeLa cells (*6*): At 6 hours most of the cells had virus attached to them. However, when these cells were cloned, only a few cells contained viral antigens in each colony. We concluded that all the cells can adsorb virus but that only a few replicate it.



TEXT-FIGURE 1.—Adsorption of Ad5 on Raji, Jijoye, or HeLa cells. Cells, 2×10^6, were exposed to 100 PFU purified Ad5 produced in HeLa cells and labeled on Ad5 DNA by addition of [^{3}H]thymidine in maintenance medium. Infected cells were incubated at 37°C for various times between 2 and 10 hr. Cell-associated radioactivity was measured after precipitation by trichloroacetic acid. Results are expressed as the percentage of insoluble radioactivity to the input. ●—●, Raji cells; ■--■, Jijoye cells; ▲--▲, HeLa cells.

Further experiments were done to eliminate the role of inhibitors. Extracts of uninfected Raji cells did not prevent the Ad5 multiplication in HeLa cells. No interferon was ever detected in uninfected and infected Raji or Jijoye cells.

Properties of Purified Ad5 Produced in Raji and Jijoye Cells

Ad5 was purified through two CsCl gradients from pellets of infected Raji (five expts) and Jijoye cells (six expts) at the third passage. A unique band of virus was found at densities of 1.26–1.29 g/ml in four experiments with Raji cells and in three experiments with Jijoye cells. In other experiments another thin band was also detected at 1.33–1.34 g/ml similar to that obtained with Ad5 purified from HeLa cells. In some experiments, the virus was further purified on a CsCl equilibrium density gradient and no Raji or Jijoye Ad5 was recovered, indicating the virus' fragility. Under the same conditions, HeLa Ad5 was found at 1.34 g/ml. After sucrose centrifugation, Raji or Jijoye Ad5 was recovered.

In the electron microscope, the viruses banding at 1.26–1.29 g/ml were not distinguishable from the virus of HeLa cells and appeared as complete particles of similar sizes. No EBV was seen in these preparations. The usual amount of cellular contaminants was seen. The degree of purity was independent of the number of cells used per pellet or of the high content of serum in the medium. However, Ad5 from lymphoma cells differed from HeLa Ad5 in several properties (table 2). The OD ratio 260:280 nm was lower in Raji and Jijoye Ad5 than in HeLa Ad5, indicating a different ratio of DNA to proteins. The yield of infectious virus per 10^6 cells was reduced 10^5-fold in Raji and four hundredfold in Jijoye cells as compared to that in the HeLa cells. These values varied from one experiment to another as shown by the standard deviation. The infectivities expressed per unit of OD at 260 nm were two thousandfold and twelvefold lower for Raji and Jijoye cells, respectively. Similar results were obtained when expressed per unit OD at 280 nm. With the assumption that only fluorescent cells were producing virus particles, the number of PFU per cell would still be reduced by 7,500-fold and fortyfold.

TABLE 2.—*Characteristics of purified Ad5 produced after three serial passages of infected Raji and Jijoye cells*[a]

Properties	Raji cells	Jijoye cells	HeLa cells
OD ratio 260:280 nm	1.26±0.08 (5)	1.22±0.07 (6)	1.43±0.02 (17)

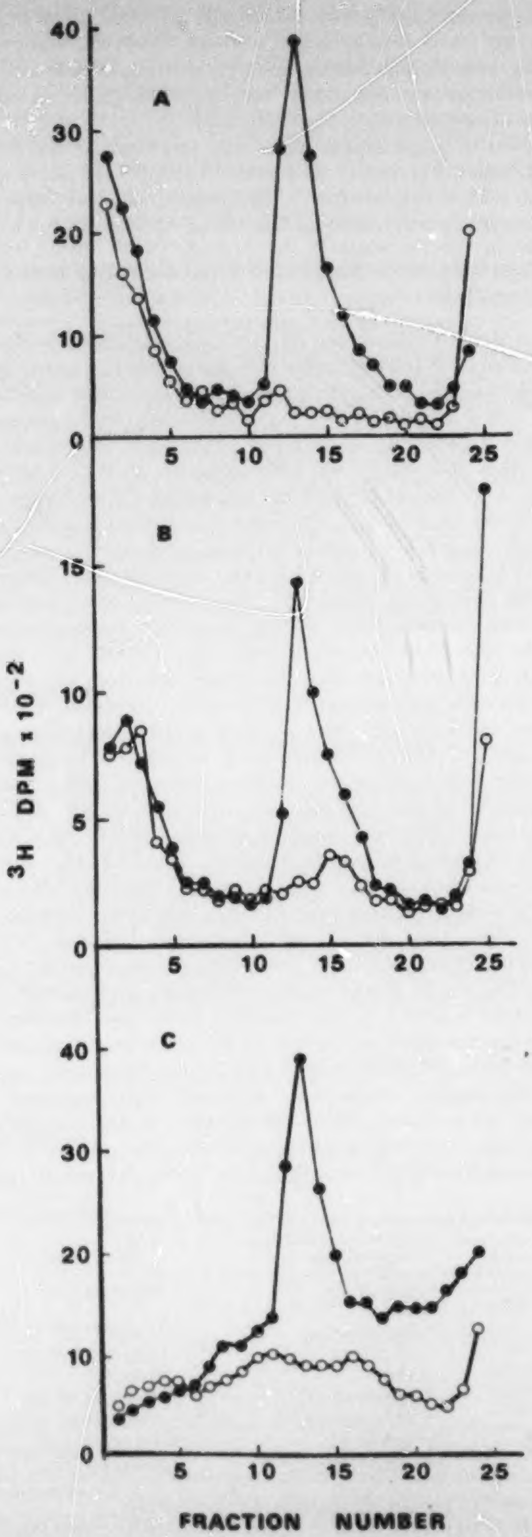
[a] Virus banding at 1.26–1.29 g/ml in CsCl gradient. Means ± SD are accompanied by number of experiments *in parentheses.*

[b] Evaluation with 4% positive fluorescent Raji cells; 10% Jijoye cells, and 90% HeLa cells obtained in indirect immunofluorescence test in the presence of specific Ad5 rabbit antiserum.

[c] The number of particles produced by 10^6 cells was estimated according to the procedures described by Maizel et al. (*13*).



TEXT-FIGURE 2.—Ad5 DNA synthesis in Raji, Jijoye, and HeLa cells. Samples of 5–6×10^6 Raji or Jijoye cells were infected with 100 PFU/cell and incubated at 37°C. On day 3 after infection, 100 μCi [^{3}H]thymidine/ml was added to the medium. After a further incubation for 5 hr at 37°C, the samples were harvested. HeLa cells infected with 100 PFU/cell were used as controls. Uninfected cells were set up in parallel. Pellets of cells were washed twice in phosphate-buffered saline, resuspended at a concentration of 2×10^6 cells/ml (equivalent to 1–2×10^3 positive fluorescent Raji or Jijoye cells), and placed in 0.2 ml lysing solution directly on top of an alkaline sodium iodide density gradient (*8*). After 1 hr at room temperature, the gradients were spun in a Beckman centrifuge (SW41 rotor) at 18,000 rpm for 18 hr at 20°C. Fractions of 400 μl were collected with a Büchler Autodensi-flow RII, and aliquots of 100 μl each were precipitated by 10% trichloroacetic acid. ●—●, DNA from infected cells; ○—○, DNA from control cells. A) Raji cells, 3 days post infection; B) Jijoye cells, 3 days post infection; C) HeLa cells, 17–22 hr post infection. The direction of sedimentation is *from left to right.* DPM=disintegrations/min.

The number of physical particles produced, estimated per 10^6 cells, was similar for Raji and Jijoye cells but one hundredfold lower than that for HeLa cells. Similar amounts of hemagglutinin were found in the three cell lines when estimated per unit OD at 260 nm. From our data of OD at 260 and 280 nm, an estimation suggested that the DNA and protein contents were higher in particles produced in Raji or Jijoye cells than in those produced in HeLa cells—fourfold and sevenfold, respectively.

Virus located in the denser band had a hemagglutinating activity similar to that of the virus in the upper band, but its infectivity remained low. The OD ratio 260:280 nm was close to that of HeLa Ad5. This observation suggested that these virus particles contained more DNA than the light ones but were still not infectious.

Polyacrylamide gel electrophoresis of standard HeLa Ad5 and of the lower and upper bands of Raji and Jijoye Ad5 showed that only upper bands from Raji and Jijoye Ad5 differed by having less hexons and an enlarged 64,000–66,000 band. This finding was similar to a previous description of the virus at the first passage (*5*). The major components were present. The modifications of the polypeptide pattern were also observed after an equilibrium sedimentation sucrose gradient.

When Raji and Jijoye Ad5 were back passed once in HeLa cells, the progeny had polypeptides similar to those of Ad5 serially propagated in HeLa cells.

We did not reduce the infectivity on HeLa cells of Raji or Jijoye Ad5 by increasing one hundredfold to 10^4-fold the number of defective particles. The production of infectious particles was similar when HeLa cells were infected with the same multiplicity of Raji or Jijoye or HeLa Ad5, although the number of particles was significantly different.

The tumor-inducing capacity of Raji and Jijoye Ad5 was tested in newborn and 3-week-old hamsters (10^6 PFU/animal). No tumor was ever observed for 10 months, indicating that the virus did not acquire a higher oncogenicity than did HeLa Ad5. In vitro, these viruses had no higher capacity than did HeLa Ad5 to transform hamster kidney cells or hamster embryo cells and to establish human cord blood lymphocytes as a cell line.

Viral DNA in Infected Raji and Jijoye Cells

DNA synthesized in infected Raji and Jijoye cells was analyzed by alkaline density gradient centrifugation of la-

TABLE 3.—*Ad5 DNA synthesis in Raji, Jijoye, and HeLa cells after three serial passages: Sequential hybridization of Raji, Jijoye, and HeLa Ad5 DNA to HeLa Ad5 DNA*[a]

Unlabeled DNA on filter	^{3}H-labeled DNA	Input, dpm	Hybridized, dpm	Percent hybridization
HeLa Ad5	Raji Ad5			
	Peak 1	15,840	841	5.3
	Peak 2	13,719	770	7.1
	Peak 3	10,332	1,357	13.1
	Peak 4	9,253	2,298	24.8
HeLa Ad5	Jijoye Ad5			
	Peak 1	5,795	1,413	24.4
	Peak 2	5,681	1,468	25.8
	Peak 3	6,420	1,515	23.6
	Peak 4	8,932	2,375	26.6
HeLa Ad5	HeLa Ad5	1,153	830	71.9

[a] Ad5 DNA synthesis was analyzed by alkaline density gradient centrifugation of labeled DNA as described in text-fig. 2. Peak 4 of DNA from Ad5-infected Raji or Jijoye cells was found in the fraction at the same density as the density for HeLa Ad5 DNA. Peaks 1–3 have a low molecular weight. When cellular DNA's were tested with HeLa Ad5 DNA, 1–5% of disintegrations/min (dpm) were hybridized with the use of empty filters that were treated identically to the other filters except that Ad5 HeLa DNA was not adsorbed to them; Raji Ad5 DNA or Jijoye Ad5 DNA hybridized to empty filters to 1–3% of the experimental values.

beled DNA. At the first passage (text-fig. 2), a single peak was observed at the same density for each batch of infected cells. At the third passage, four peaks were found and were tested by hybridization with HeLa Ad5 DNA (table 3). The extent of hybridization was lower for DNA from Ad5-infected Raji and Jijoye cells. For Raji cells only the heavy peak of DNA hybridized with HeLa Ad5 DNA, whereas for Jijoye cells the four peaks of DNA hybridized to the same extent with HeLa Ad5 DNA.

For further studies of the viral DNA, Hirt supernatants of [^{3}H]thymidine-labeled Raji and Jijoye Ad5 were prepared from infected cells at the third passage. The DNA banded at 1.690 instead of 1.715 g/ml for HeLa Ad5 in CsCl gradient centrifugation.

Cleavage by endonucleases of HeLa Ad5 DNA and Jijoye Ad5 DNA, used in equivalent amounts, showed different patterns (fig. 1). Kpn I enzyme gave eight fragments with HeLa Ad5 DNA (fig. 1, col 1) and five fragments with Jijoye Ad5 DNA (fig. 1, col 2). Generally, 10 fragments were detected with Kpn I and HeLa Ad5 DNA, but some fragments that had close molecular weights (1.5×10^6 and 1.4×10^6; 2.3×10^6 and 2.2×10^6) were not separated in our experiment. Moreover, the Jijoye Ad5 DNA was not completely digested as compared to the same amount of HeLa Ad5 DNA, so that much DNA was found at the top of the gel. Bam I endonuclease gave two similarly sized fragments with both DNA's. XBa I and Eco RI each produced four fragments for Jijoye Ad5 DNA versus 3 and 3 fragments, respectively, for HeLa Ad5 DNA.

DISCUSSION

We have shown that human B-lymphocyte lines (Raji and Jijoye), derived from human Burkitt's lymphoma replicated human Ad5, although poorly as compared to the replication by HeLa cells. Virus production was enhanced by serial passages of infected cells. These particles were intermediate between mature and empty particles: They contained less DNA, their polypeptide composition was modified, and they had a low infectivity. The virus genome was also modified. The DNA cleavage pattern by restriction enzymes of Jijoye Ad5 DNA was slightly different from that of HeLa Ad5 DNA, but there was a heterogeneous spread of small fragments throughout in the Jijoye Ad5 DNA sample. Furthermore, Jijoye Ad5 DNA was fragmented at the third passage of infected cells, whereas at the first passage it was not fragmented like the DNA from HeLa Ad5. Factors influencing the production of defective or incomplete particles were not determined.

Only a small proportion of Raji and Jijoye cells was producing Ad5, as shown by immunofluorescence with immune sera and by electron microscopy, although almost every individual cell was infectible as demonstrated by our data on adsorption. Possibly, each cell produced all viral proteins in such low amounts that they were undetectable. Also, some cells might synthesize some components but not others. This hypothesis suggests that some cellular factor(s) active in permissive cells is required for the complete Ad5 cycle and that this factor(s) was present only in a limited number of cells. Furthermore, Ad particles do not always replicate efficiently even in permissive cells that generally produce virus as shown by some enteric Ad (*14*).

It is not known why human B-cell lines were more sensitive to human Ad5 than was the primary culture of lymphocytes. Such a difference could be more general since Ad replication has been reported to be also more efficient in established continuous cultures of oral tumors than in cultures at early passages (*15*).

The yield of defective particles could be influenced by the high multiplicity of infection used. However, at low multiplicity (1 PFU) no infectious virus was detected, and at 10 PFU the virus production was low. In contrast to particles previously described by Daniell (*16*), these particles were not found to interfere with the infectious particles.

In previous experiments, our laboratory (*2*) reported that transformation by EBV of cord blood B-lymphocytes was a necessary step for Ad multiplication. The highest production of Ad5 was obtained in EBV-positive Jijoye cells. However, replication of EBV was not required since phosphonoacetic acid did not prevent replication of Ad5 (*5*). Further experiments with leukemia cell lines also suggest that the EBV genome was not necessary (Faucon N, Ogier G: Unpublished results). The important factor seems to be the state of cell differentiation either induced by EBV or present in some leukemia states or in lymphoma cells or acquired during in vitro cultivation.

The low infectivity of Ad5 produced in Raji and Jijoye cells could be due to changes in viral genome. The fragmentation of viral DNA could be related to its accessibility and its sensitivity to deoxyribonucleases from infected cells. Also, possibly some host cell DNA pieces were encapsidated into the virions. Such DNA structures have been described for Ad2 (*17*) and Ad16 (*18*).

Assuming that in vitro observed modifications of the virus could reflect variations in the expression of the virus in vivo, one may consider the possibility that in humans some pathologic conditions could induce changes in Ad5 during its latency. The modified virus could interact with other factors mainly in cancer.

Figure 1.—Cleavage by restriction enzymes of HeLa and Jijoye Ad5 DNA Hirt supernatants were prepared from infected HeLa cells (H), fro infected Jijoye cells (J) after three serial passages, and from uninfecte Jijoye cells. Viral DNA was recovered from an equilibrium sedimentati cesium chloride gradient (35,000 rpm for 60 hr). Purified DNA su pressed at 1 mg was mixed with the following restriction enzymes appropriate buffers and incubated for 1 hr at 37°C: 5 U Kpn I (1, 2), U Bam I (3, 4), 5 U XBa (5, 6), and 5 U Eco RI (7, 8). Reaction w stopped by cooling the samples in ice. Whole mixture was layered on 1% agarose gel for analysis. Controls were run simultaneously wi uncleaved HeLa Ad5 DNA, Jijoye Ad5 DNA, and Hirt supernatant Jijoye cell DNA (9, 10, 11).

Primary Liver Carcinoma and Liver Cirrhosis in Atomic Bomb Survivors, Hiroshima and Nagasaki, 1961–75, With Special Reference to Hepatitis B Surface Antigen[1]

Masahide Asano, *M.D.,*[2] **Hiroo Kato,** *M.D.,*[3,4] **Keiko Yoshimoto,** *B.S.,*[3] **Shinichi Seyama,** *M.D.,*[2]
Hideyo Itakura, *M.D.,*[5] **Tadao Hamada,** *M.D.,*[6] *and* **Soichi Iijima,** *M.D.*[7,8]

ABSTRACT—During 1961–75, 128 cases of primary liver carcinoma (PLC) in the Radiation Effects Research Foundation life-span study extended sample and 301 cases of liver cirrhosis in the pathology study sample were observed. The presence of hepatitis B surface antigen (HBsAg) was assessed in all of the cases with the use of orcein and aldehyde fuchsin stains and was confirmed by the immunofluorescence technique. The incidence of PLC was two times higher in Nagasaki than in Hiroshima, which was statistically significant, but little difference was noted in the prevalence of cirrhosis in the two cities. Findings that might possibly explain the higher PLC incidence in Nagasaki were 1) the 2.3 times higher presence in Nagasaki than in Hiroshima of HBsAg in the livers of subjects without liver disease and 2) the two times higher prevalence in Nagasaki than in Hiroshima of cirrhosis with PLC. We believe that the higher incidence of PLC in Nagasaki is attributable to hepatitis B virus infection, although other factors (e.g., immunologic competence affected by radiation) cannot be excluded. In both cities, a suggestive relationship of radiation dose to cirrhosis prevalence, but not to PCL prevalence, was noted. To clarify possible radiation effects on cirrhosis prevalence, further follow-up of the populations of these two cities is necessary.—JNCI 1982; 69:1221–1227.

A relationship between ionizing radiation and solid tumors has been found for cancers of the thyroid gland, breast, and lung from studies on atomic bomb survivors (*1*), but no suggestion has emerged of a relationship between radiation and liver tumors among the survivors (*2, 3*). However, ionizing radiation from other sources (e.g., Thorotrast) has been clinically linked to liver carcinogenesis (*4*), and atomic bomb radiation increased the incidence of liver cell carcinoma in experimental mice, even though no clear relationship between dose and tumor incidence was found (*5*). Recently, Shikata et al. (*6*) reported that orcein and/or aldehyde fuchsin stains, in the form of a surface coat, could be used to demonstrate HBV antigen in Formalin-fixed paraffin tissue sections. Several researchers, including Nayak and Sachdeva (*7*), confirmed by an immunofluorescence technique the identity of the material in liver that stained with orcein and/or aldehyde fuchsin as HBsAg.

In the present study we analyzed the relationship between the effect of ionizing radiation and the incidence of PLC and liver cirrhosis and examined the possible relationship between them and the presence of HBsAg.

MATERIALS AND METHODS

The study of PLC was made from records obtained from the Tumor and Tissue Registry Associations of both Hiroshima and Nagasaki and from surgical pathology and autopsy files at the RERF (formerly the ABCC–Japanese National Institute of Health) for 1961–75. Data for the cirrhosis study were obtained from autopsied cases in the pathology study sample[9] for the same period in both cities. All 128 PLC and 301 cirrhosis cases were histologically confirmed by the investigators upon examination of two or more tissue specimens from each subject. Samples were stained by hematoxylin and eosin, Masson's trichrome, van Gieson's elastic fiber, periodic acid–Schiff, and argyrophilic fiber techniques. Each specimen of PLC included a portion of nontumorous tissue. For assessment of HBsAg in tissue, two slides stained by orcein and aldehyde fuchsin were used. Positive cases were further confirmed by the immunofluorescence technique, in which the sections of tissue were incubated with fluorescein isothiocyanate-conjugated, anti-human HBs serum. The sections then were examined with an Olympus A-REL fluorescence microscope for deposition of HBsAg.

PLC cases were classified by Edmondson's criteria (*9*): liver cell carcinoma (grades I, II, III, and IV), bile duct carcinoma, multiple or combined primary carcinoma (carcinosarcoma, separate liver cell and bile duct carcinomas, and hepatobiliary carcinoma), and squamous cell carcinoma. For analysis, hepatobiliary carcinoma was included in the liver cell carcinoma category, as was done in (*10, 11*).

Liver cirrhosis was classified by Gall's criteria (*12*):

ABBREVIATIONS USED: ABCC = Atomic Bomb Casualty Commission; ATB = at time of bomb; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; LSS = life-span study; NIC = not in the city; PLC = primary liver carcinoma; RERF = Radiation Effects Research Foundation; T65 DR = tentative dose, 1965 revised.

[8] We sincerely appreciate the diagnostic materials contributed by the member institutions of the Tumor and Tissue Registry Associations of Hiroshima and Nagasaki, which helped to make this study possible.

[9] The pathology study sample, comprised of subjects who had died in the extended LSS, is related to two major programs: the extended LSS and the adult health study sample (*8*).

posthepatitic, postnecrotic, nutritional, congestive, obstructive, pigmentary, and mixed forms of cirrhosis. The few cases of congestive, obstructive, pigmentary, and mixed forms of cirrhosis in the present study were grouped as "other cirrhosis."

Age- and sex-adjusted prevalence rates for PLC and cirrhosis by exposure dose groups were tested for linear increase with dose and for homogeneity (*13*).

RESULTS

Incidence Difference Between Hiroshima and Nagasaki

A total of 128 PLC cases (77 in Hiroshima and 51 in Nagasaki) in the LSS extended sample[10] were examined: 103 (80.5%) liver cell carcinomas (which included hepatobiliary carcinomas), 24 (18.8%) bile duct carcinomas, and 1 (0.78%) squamous cell carcinoma. The sex ratio of males to females was approximately 2.1:1. The average PLC incidence per year was 0.76/10^4 persons in Hiroshima and 1.51/10^4 persons in Nagasaki. The average incidence in Nagasaki was two times higher ($P\leq0.001$) than in Hiroshima (table 1). The average age ATB of patients with PLC was 40.1 years. The age at death among subjects with PLC in Hiroshima ranged from 29 to 83 years (average, 65.3 yr) and from 26 to 83 years (average, 61.7 yr) in Nagasaki.

Of the 128 PLC cases, 43 (55.8%) in Hiroshima and 28 (54.9%) in Nagasaki were associated with liver cirrhosis; no difference in the proportion of cases between cities was noted. Bile duct carcinoma associated with cirrhosis was seen only in two cases (1.5%) (table 2).

TABLE 2.—*Proportion of PLC cases associated with cirrhosis, by city and histologic type, 1961–75*

Histologic type	Incidence, No. (%), in:	
	Hiroshima	Nagasaki
Liver cell carcinoma	62	41
With cirrhosis	42 (67.7)	27 (65.9)
Bile duct carcinoma	14	10
With cirrhosis	1 (7.1)	1 (10.0)
Total, all PLC	77[a]	51
With cirrhosis	43 (55.8)	28 (54.9)

[a] Total includes 1 PLC case classified "other carcinoma" (*see* table 1).

A total of 301 cases of liver cirrhosis (225 in Hiroshima and 76 in Nagasaki) were available in the autopsy series: 225 (74.8%) posthepatitic, 49 (16.3%) postnecrotic, 16 (5.3%) nutritional, and 11 (3.7%) other types of liver cirrhosis. The number of autopsied cases during 1961–75 was 4,920 [3,857 in Hiroshima and 1,063 in Nagasaki (*15*)]. The prevalence rate for cirrhosis was 5.8% in Hiroshima and 7.2% in Nagasaki, with no statistically demonstrable difference between the two cities (table 3). The average age ATB of patients with cirrhosis was 41.4 years in Hiroshima and 37.4 in Nagasaki. The average age at death of patients with cirrhosis was 63.2 years in Hiroshima and 60.5 years in Nagasaki.

Of the 301 cases of cirrhosis, 67 (22.2%) were accompanied by PLC, including 59 (26.7%) posthepatitic, 1 (7.0%) postnecrotic, 4 (25%) nutritional, and 3 (20%) obstructive type. The proportion of cirrhosis associated with PLC was two times higher in Nagasaki than in Hiroshima (table 4).

---

[10] The LSS extended sample, a matched, fixed population of ≈110,000 persons who were living in Hiroshima and Nagasaki at the time of the Atomic Bomb Survivors Survey in 1950 (*14*), is comprised of 2 groups: individuals who had been exposed to the atomic bombs and their controls who were NIC ATB.

[a] Totals for the two cities include 11 cirrhosis cases classified as "other cirrhosis" (*see* table 3).

Incidence Relationship to Radiation

In both cities the air dose estimated for each survivor was based on his or her distance ATB from the hypocenter, as modified by various transmission factors, and was expressed in terms of tissue kerma in the air. The estimated dose system was developed in 1965, was revised in 1980, and now is known as T65 DR.[11] The annual incidence rate was calculated for 5 dose groups: 0, 1–49, 50–99, 100–199, and $\geq$200 rad as shown in table 5. The nonexposed NIC group is included in this table. No relationship between radiation dose and PLC incidence (table 5) and of PLC incidence accompanied by cirrhosis was demonstrated. An association between radiation dose and cirrhosis prevalence was suggested. (Four cases in the unknown dose group were excluded.) A significant association of postnecrotic cirrhosis with radiation dose ($P\leq0.01$) was noted (table 6; text-fig. 1). No relationship was observed between radiation dose and the prevalence of cirrhosis combined with PLC.

The relationship between radiation dose and the incidence of PLC or cirrhosis was further investigated in 4 groups categorized by age ATB. However, although the prevalence of cirrhosis in the $\geq$100-rad group seems higher than that of the controls (NIC + 0-rad group) at ages 0–19 and 35–49 years ATB, the difference was not statistically significant.

HBsAg Detection in Liver Tissue

HBsAg in the livers of persons with PLC and with cirrhosis was determined with the use of orcein and aldehyde fuchsin stain, and the positive cases were confirmed with the immunofluorescence technique. Of 128 PLC cases and 301 cirrhosis cases, 106 and 231, respectively, were available for the HBsAg study. Hepatocytes positive for HBsAg were present mainly in the noncancerous areas of the liver and were unevenly distributed. Cellular deposition of orcein and aldehyde fuchsin stains appeared in the cytoplasm but rarely was found near the cytoplasmic membrane. The HBsAg-positive rate was 20.0% for PLC cases in Hiroshima and 19.6% in Nagasaki (table 7) and was 18.7% for cirrhosis cases in Hiroshima and 18.4% for Nagasaki (table 8). Con-

---

[11] A reevaluation of the atomic bomb dosimetry is in progress (*16*). Preliminary estimates suggest lower neutron and higher γ-ray doses from the Hiroshima bomb than those calculated according to the T65 DR and smaller changes in dose estimates for Nagasaki. However, because the total estimated doses are similar to those calculated according to the T65 DR system, and the dose categories used in the current analysis are broad, the conclusions reached would not be altered were the suggested new dosimetry adopted.

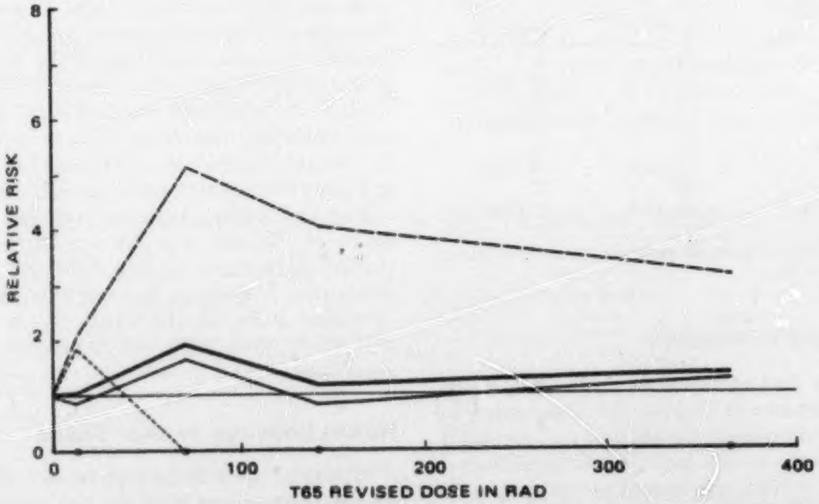
[b] H=homogeneity of dose regardless of pattern; **=$0.001<P\leq0.01$.

[c] Totals include 3 posthepatitic cases and 1 postnecrotic case classified in "unknown dose group" that were excluded from this analysis and 11 cases classified as "other cirrhosis" (*see* table 3).



TEXT-FIGURE 1.—Relative risk of liver cirrhosis, by dose and histologic type, for Hiroshima and Nagasaki combined. ▬ = total, ___ = posthepatitic, - - - = postnecrotic, ····· = nutritional.

versely, a higher percentage of positive HBsAg was detected in PLC cases with cirrhosis [35.5% in Hiroshima and 35.7% in Nagasaki (table 7)] and in cirrhosis cases with PLC [39.3% in Hiroshima and 33.3% in Nagasaki (table 8)]. The HBsAg-positive rate seemed unrelated to radiation dose in both PLC and cirrhosis (tables 7, 8).

HBsAg was positive in the cytoplasm of tumor cells in 4 PLC cases, as confirmed by orcein and aldehyde fuchsin staining and also by the immunofluorescence technique. The cytoplasm of some giant cells also was positive. The cytoplasm in most tumor cells was diffusely positive, and in some the positive material was localized as a granular mass like an inclusion body. Nuclei were never positive. The 4 HBsAg-positive cases, 2 in each city, were classified as grade III liver cell carcinoma by Edmondson's criteria (*9*).

When randomly selected livers of subjects without overt liver disease (102 in Hiroshima and 111 in Nagasaki) were examined for HBsAg, positive findings were 5.4% for Hiroshima subjects and 12.5% for Nagasaki subjects. Consequently, HBsAg was 2.3 times more common in Nagasaki than in Hiroshima; the lowest positive rate was for those persons 50 years of age or older (table 9). Positive rates tend to be lower for the older age-ATB group.

DISCUSSION

Schreiber et al. (*2, 3*) reported that the twofold difference between Hiroshima and Nagasaki in PLC prevalence was in part explained by the greater tendency in Nagasaki subjects for cirrhosis to be associated with PLC. Furthermore, no effect of radiation on the PLC prevalence was observed, but a positive association was made between radiation and cirrhosis prevalence in a study of the ABCC 1961–67 autopsy series. In the present study, the number of specimens examined was increased by inclusion of tissues obtained during surgery and the time was extended to 1975. The average PLC incidence per year was two times higher in Nagasaki than in Hiroshima, and a suggestive association existed between cirrhosis prevalence and radiation dose. The higher incidence of PLC in Nagasaki cannot be explained by an increased prevalence of cirrhosis, because no clear difference was found in the number of cirrhosis cases for the two cities (5.8% in Hiroshima and 7.2% in Nagasaki). Conversely, as pointed out by Schreiber et al. (*2, 3*), the fact that 21% of posthepatitic cirrhosis was associated with PLC in Hiroshima and 43% in Nagasaki may be a contributing factor. Lewin and Millis (*17*) reported that atrophy with lobular collapse and portal tract fibrosis occurred in a later stage of liver damage due to radiation, but that the condition was not the same as radiation-induced liver cirrhosis. Inasmuch as a tendency toward a greater incidence of cirrhosis associated with PLC was observed in the NIC and 0-rad group as well as in the 1-rad-or-more groups, some factors other than radiation probably were involved in the genesis of combined PLC and cirrhosis.

Viral hepatitis is generally accepted as being one of the more important antecedent lesions to posthepatitic or postnecrotic cirrhosis. Reports from several countries (*18*) reveal a strong correlation between HBsAg prevalence and PLC mortality. In the present study, the HBsAg-positive rate for both cities combined was about 20% for livers with PLC, 19% for livers with cirrhosis, 35.6% for livers with both PLC and cirrhosis diagnosed as PLC, and 36.4% for livers with both PLC and cirrhosis diagnosed as cirrhosis. Corresponding rates between the two cities were not significantly different. For the livers of Nagasaki subjects with PLC, HBsAg-positive rates of 54.8 and 29% were reported by Kanda (*19*) and Sato et al. (*26*), respectively. In Tokushima Prefecture, where the rate of death from PLC is the highest, HBsAg was positive for 60% of the livers of subjects with PLC (*21*). The relatively lower positive rate for HBsAg in the present study might be explained by sample bias. The sample, composed of relatively older survivors and restricted to those who lived in Hiroshima or Nagasaki, excluded individuals living in places where the positive rate is particularly high. Sakurai (*22*) reported that the HBsAg was more frequent in livers than in sera of patients with PLC and/or cirrhosis. A decrease in HBsAg prevalence was observed in the sera of older people (*23*). Such a trend also was recognized for the livers of the subjects in our study. Despite the failure to detect any difference between the two cities in the prevalence of positive HBsAg in the livers of patients with PLC and/or cirrhosis, the HBsAg-positive rates for the livers of patients without overt disease were 4.9% in Hiroshima and 13.5% in Nagasaki. Belsky et al. (*24*) reported that the occurrence of hepatitis-associated antigen in the sera of Nagasaki subjects was almost 1.4 times that of the Hiroshima subjects. Kato et al. (*25*) recently confirmed that the frequency of positive HBsAg in sera from the same sample as in (*24*) (the adult health study[12] sample) was about 1.5 times higher in Nagasaki (3.3%) than in Hiroshima (2.0%).

Thung et al. (*26*) and several other investigators (*7, 27, 28*) have reported that HBsAg was found in tumor cells. In our study, HBsAg-positive tumor cells were detected in only 4 of 128 PLC cases, and the distribution of cases was similar for the two cities.

In an international workshop on hepatitis B and liver cancer, Ziegler et al. (*29*) concluded that risk factors may include exposure to HBV, age at onset of infection (tolerance), duration of infection, immunologic determinants, nutritional status, and virus strain (virulence). Ziegler and colleagues reported evidence of HBV infection in the early life of some PLC patients, indicating perinatal infection from mothers who were carriers. Macnab et al. (*30*) described a human hepatoma cell line, PLC/PRF/5, that produces HBsAg in vitro. They also reported spherical virions (seen by electron microscope) in the supernatant tissue culture medium of the cell line. Gyorkey et al. (*31*) described multifocal PLC in postnecrotic cirrhotic nodules when juvenile monkeys were given HBV before the administration of diethylnitrosamine. Thus the high incidence of PLC in Nagasaki might be attributed to early HBV infection. The twofold difference in the prevalence of bile duct carcinoma between Hiroshima and Nagasaki subjects has not been explained. Further studies on other factors, such as nutritional status, mycotoxins, tolerance, immunologic competence, and virulence of HBV, are necessary.

Epidemiology of Familial Predisposition for Breast Cancer in Japan[1, 2]

Motoi Murata, *Ph.D.*,[3] **Keijiro Kuno**, *M.D.*,[4] **Atsuo Fukami**, *M.D.*,[4] *and* **Goi Sakamoto**, *M.D.*[5,6]

ABSTRACT—The physical and reproductive traits known to be risk factors for breast cancer were correlated with familial predisposition for this disease by the use of hospital records of 3,867 patients with breast cancer, of whom 186 had one or more relatives with breast cancer and were called "familial patients." Various characteristics in the total series of patients were compared with familial patients matched for year of birth. The mean age at menarche was significantly less in familial compared with the total series of patients, especially for premenopausal patients; however, no difference was observed in the mean age at marriage between the two groups. Familial patients were slightly taller as compared to the total series of patients, but no difference was detected in body weight between the two groups. Because age at menarche and the stature are highly correlated, they may be influenced by an underlying common hormone effect that may influence the familial nature of breast cancer.—JNCI 1982; 69:1229–1234.

The familial nature of breast cancer has been well demonstrated by a number of studies (*1–5*). So far, however, our knowledge of the nature of the genetic effect responsible for this familial observation is very poor. Studies on various genetic markers such as blood groups, serum proteins, red cell enzyme polymorphisms, cerumen type, and HLA antigens in breast cancer patients have not been revealing (*6–9*). The glutamic-pyruvic transaminase locus might be chromosomally linked to the possible dominant gene relevant to a specific hereditary type of breast cancer, but it is not necessarily linked to familial nature of breast cancer in general (*10*). Genetic control in the etiologic role of hormone factors has also been suspected. Studies on the familial relationship of breast cancer with various endocrine profiles such as the estrogen quotient (ratio of estriol to estrone plus estradiol) and prolactin level in urine or plasma have until now provided conflicting results (*11–15*).

In the present study, we attempt an epidemiologic approach to this problem by using hospital records of breast cancer patients in Japan. In discriminating a familial predisposition to breast cancer among the total breast cancer patients, we are not aware of any dominant type of hereditary breast cancer, as has been reported by other authors (*16, 17*), because patients having more than one relative with the disease are reported very rarely in this country. It is presently not clear what fraction of hereditary breast cancer is generally composed of those dominant types. Thus in this study, we define familial breast cancer as including all patients with any familial history of the disease, and we examine the association of familial history and other risk factors. Specifically, we attempt to determine whether the familial cases differ from unselected total cases in any one of those physical and reproductive traits that are generally known to be associated with breast cancer etiology (*18, 19*).

MATERIALS AND METHODS

Epidemiologic data.—Hospital records of 3,867 patients with breast cancer who were treated at the Cancer Institute Hospital, Tokyo, during 1946–77 formed the basis of the present study. The hospital records included information on the following epidemiologic properties: birth date; residence (registered domicile); age(s) at surgery, menarche, marriage, and menopause; parity; number of miscarriages; lactation, medical, and family histories; body height and weight at the time of admission; site of tumor; and histologic diagnosis. Because these demographic, reproductive, and physical traits are well known to have been changing for the last several decades in Japan (*20*), all patients were grouped into cohorts of 5-year birth periods (table 1). Among all items, information on body size was available only for patients treated between 1969 and 1977 (1,826 patients). Registered domicile is not necessarily the present address, but it is mostly that at the time of the patient's marriage and sometimes her or her husband's birthplace. Family history of cancer was obtained by a patient being asked if she ever knew about any contraction of cancer in her first- and second-degree relatives. Totally, 186 patients were recorded as having one or more relatives with breast cancer (table 2). These patients who responded affirmatively will hereafter be called "familial patients." Despite the fact that the information of family history had not been medically verified, information of a positive family history is likely to be accurate, whereas information of a negative family history may or may not be correct.

We emphasize that completion of individual items in the hospital record depended solely on the examining clinician at the time of the patient's admission; as such, the quality of some items is not necessarily homogeneous among different years. If any clinicians were not willing to obtain epidemiologic data, the individual items were left unanswered and such "unknown" items are not distinguishable from truly negative ones. Evaluation of such traits as being married or unmarried, parity, and number of miscarriages was rather ambiguous. To eliminate the instances of un-

Total	2,304 (118)	1,563 (68)	39,556

known items as much as possible, we tried to use those patients who were recorded as having a positive family history of any cancer (1,401 patients) in place of using total patients. These positive family history patients were representative of the total series with regard to such things as the distribution of birth year, age at surgery, and residence.

Because a control group matched for such characteristics as age and residence was not available, we were obliged to use as the reference population a group of women participating in a cervical cancer screening program. This group will hereafter be called the "control population." It comprises 39,556 women living in Chiba prefecture who attended the screening clinic from April 1977 to March 1978 and who were known to be healthy. Distribution of their birth dates, ages, and residences differ noticeably from those of the patient group. Information on lactation and body size was not available for the control population. In addition, marital status of the control population was dissimilar to that of the general population, single women being very rare among the control population. Data on body height and weight of healthy Japanese women can be obtained from the results of the National Survey on Nutritional Condition conducted by the Ministry of Health and Welfare for 1969–77 (*21*). This survey includes about 14,000 women randomly sampled from all over Japan every year. Accordingly, the data obtained by this survey may be regarded as the national mean value. The expected value of height and weight for breast cancer patients was calculated from the survey results by the year and age at observation being matched. It is, however, generally known that both body measurements vary by districts, especially between urban and rural areas, in Japan (*22*). Because about one-half of the patients were living in the Tokyo metropolitan area, the observed value for body size may be larger than the expected value.

TABLE 2.—*Distribution of positive familial history of breast cancer*[a]

Kinship	Premenopausal	Postmenopausal
Mother	41	11
Sister	37	34
Grandmother		
Paternal	4	2
Maternal	4	2
Aunt		
Paternal	16	7
Maternal	28	8
Daughter	0	9
Paternal uncle	1	0
Total single cases	107	62
Total multiple cases	11	6

[a] Data were derived from hospital records of patients with breast cancer who were treated at the Cancer Institute Hospital, 1946–77.

For individual items the mean values were compared, in different birth cohorts, between the patient and control groups and were further compared within the patient group between the familial and total patients. We did not use the usual method for comparison of familial and nonfamilial patients because we would need to illustrate additional comparisons between the nonfamilial and total patients, even though no differences might be expected between them because of the meagerness of the familial patient series.

Multivariate analysis.—Because the interrelatedness of some of these traits is known, association of a specific one to a familial predisposition for breast cancer should be evaluated after that trait is adjusted for the other variables. For this purpose, multiple regression analysis with a logistic model (*23*) was performed. If Y_i is a binary expression (yes–no) of family history in the ith patient, then the logit of Y_i is given by a linear combination of predictor variables X, $\log[Y_i/(1 - Y_i)] = b_0 + b_1X_{1i} + b_2X_{2i} + \ldots + b_kX_{ki}$, where b_1 to b_k are partial regression coefficients. For the X's, ages at menarche and marriage, body height and weight, residence, and parity were chosen. For postmenopausal patients only, age at menopause was included. Thus $k=6$ and 7, for premenopausal and postmenopausal patients, respectively. Lactation history was not included because of its categorical characteristic. Residence, though it is indeed categorical, was dealt with as a quantitative trait by numbers being assigned as follows: 1 for urban (special wards of Metropolitan Tokyo and large cities), 2 for smaller cities, and 3 for rural areas. Patients married longer than 40 years were counted at 40 years of age at marriage.

It is rather cumbersome to deal quantiatively with unmarried patients, especially when age at surgery was les than 40 years. We would need to introduce a function o probability of being married later than that age. Instead just arbitrarily, 3 years plus age at surgery were given fo the unmarried patients. Incidentally, of those women wh were unmarried at age 30, one-third to one-half will marr by age 40 in Japan (*24*). The concealed discrimination o unmarried and ever married was included when parity wa counted. Because a complete set of information was require for each patient, patients included in the regression analysi were restricted to those treated in 1969 and later, of whic 55 were familial premenopausal and 30 were familial pos menopausal patients, respectively.

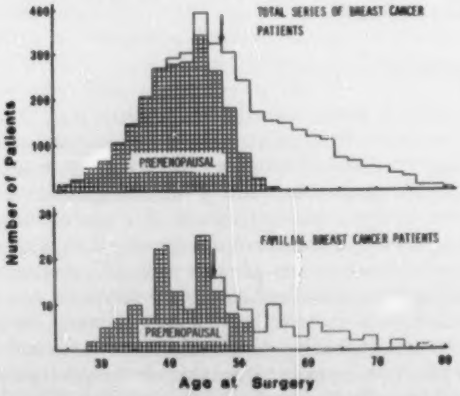
We made 10 analyses by using the same set of thes familial patients and different sets of twice as many nonfa milial patients randomly chosen every time by matchin age and birth year. We calculated the maximum likelihoo estimates of the regression coefficients by using the Newton-Raphson iterative technique. Association of a specific variable can be evaluated by a significance test of the *t*-value for the coefficient *b*.

RESULTS

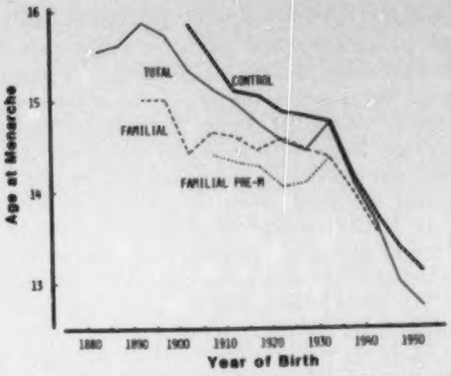
Distribution of age at surgery in the total breast cancer series as well as in the familial series of patients is shown in text-figure 1, according to menopausal status. The mean age in the total series was 48.5±0.2 years and, in the familial series, 47.2±0.7 years, with a nonsignificant difference. The distribution for familial patients appears to be bimodal. A statistical test (*25*) for "bitangentiality" indicated two peaks around the ages of 40 and 46 years, but the bimodality was not statistically significant. Familial cases were slightly more frequent in premenopausal (5.1%) than in postmenopausal patients (4.4%).

Residence of the patients was classified as urban, suburban (small cities), or rural as described in "Materials and Methods." The relative proportions of patients varied among the different residence groups, though the differences were not significant; the proportion of urban patients was highest in the familial postmenopausal patients (62.7%) and was lowest in the familial premenopausal patients (47.8%) whereas it was 54.9% in the total patients

The mean age at menarche in individual birth cohorts is given in text-figure 2. It shows a continuous decline since the early 1900's at a rate of 0.055±0.005 years/chronologic year in the control population. This decline coincides with the secular trend observed in other survey studies (*20, 22*). The leveling off seen around the 1930's probably reflects the inferior nutritional condition during the Second World War. Although not illustrated, the mean age at menarche in urban- and suburban-dwelling women was consistently less than that of rural women, the difference averaging 0.34±0.07 years ($P<0.01$). This finding suggests that the age at menarche is considerably influenced by the women's living environment and/or life-style. The age at menarche in breast cancer patients is consistently less than that of the control population, the difference averaging about 0.26±0.06 years ($P<0.01$), which in turn is smaller than the urban–rural difference. Familial patients exhibit a still younger age at menarche compared with the age at menarche of the total patients, the difference being 0.34±0.10 years ($P<0.01$). After only premenopausal patients are chosen, the disparity appears even more convincing (0.36±0.07, $P<0.01$).



TEXT-FIGURE 1.—Age distribution of breast cancer patients treated at the Cancer Institute Hospital, 1946–77. *Arrow* indicates mean age.

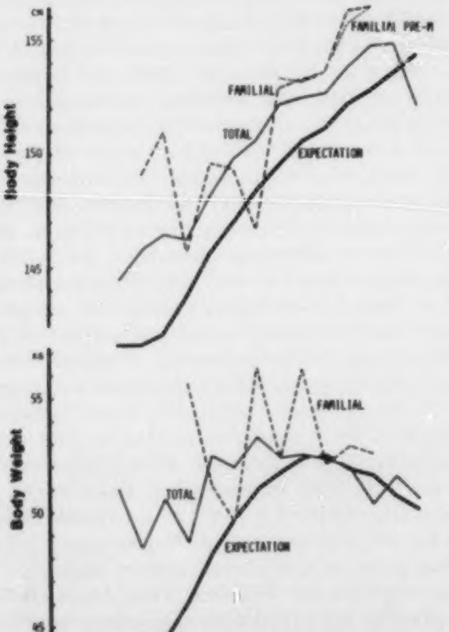


TEXT-FIGURE 2.—Changes in mean age at menarche by year of birth for total and familial series of patients and for familial premenopausal patients (PRE-M) and controls.

With respect to the age at marriage, the control population shows a gradual increase up to the 1930's, after which it declines. A consecutively older age at marriage was observed in urban and suburban residents as compared with rural residents ($P<0.01$). Breast cancer patients tended to marry about 1 year later than control women ($P<0.01$), with no difference between the total and familial series. Information on their first childbearing was not available; however, this may be related to their age at marriage. We discovered, using about 900 cervical cancer patients at the National Institute of Radiological Sciences, that the two ages (i.e., ages at marriage and first childbearing) exhibited a strict linear relationship except for marriage at ages over 32 years. Thus the difference observed above in the age at marriage seems congruent with the difference observed in the age at first childbearing (*26, 27*). The proportion of unmarried women in breast cancer patients was 8.4%, with no difference due to family history of cancer. The corresponding value in the general population was roughly 5% by age 45, though there have been some fluctuations in these decades (*24*).

The proportion of nulliparous among ever-married patients was 21.1%. The corresponding value in the general population was reported at 7–8% by a national census (*24*) or 5–6% by the Survey Study of Reproductive Force (*28*). In familial patients, nulliparous women constitued 16.5%, being not significantly different from 21.1%. The mean number of either live-born children or miscarriages per ever-married patient was 2.2±0.13 and 0.8±0.09, respectively, whereas it was 2.0±0.05 and 0.7±0.03, respectively, among ever-married familial patients. These are all smaller than the corresponding values (2.4±0.04 and 1.1±0.05, respectively) of the control population. Thus the differences observed between the patient and control groups for various reproductive traits compare well to the results reported by other authors (*18, 19*), though any conclusive remarks should not be stated because this is not a case-control study. Regarding lactation history, the proportion of patients who never breast fed as well as the proportion of patients of poor milk secretion were both slightly lower in familial patients than they were in the total series, for which we lack control data. Mean age at menopause was not different between the familial and the total series of patients, either with or without distinguishing cases of artificial menopause.

Body height and weight changes in breast cancer patients by birth cohorts are given with expected values in text-figure 3. For body height, the observed value was consistently larger than the expected in any birth cohorts. The difference was, on the average, 2.2 cm ($P<0.001$) for premenopausal and 3.0 cm ($P<0.001$) for postmenopausal patients, respectively. This taller stature might be attributable to the effect of unmatched residence. Disparity between the total and familial series of patients was also noted and, especially in premenopausal patients, was statistically significant (1.2 cm, $P<0.01$). The correlation coefficient between the stature and the age at menarche was estimated at −0.118, which is, even though very small, statistically significant ($P<0.01$). For body weight, the observed value was larger than expected only in the older cohort groups, which mostly consist of postmenopausal patients. If confined to such patients, the difference was 2.3 kg ($P<0.001$). Familial patients were only slightly heavier but were not thought to be more obese, as measured in terms of the Quetelet Index (weight/height^2) when compared to the total patients.



TEXT-FIGURE 3.—Changes in mean body height and weight by year of birth of unselected breast cancer patients in 1969–77. Expected values were calculated from National Survey data. For body weight data, dotted line includes familial patients as well as familial premenopausal patients.

TABLE 3.—*Family history of breast cancer and various risk factors for the disease*

Variable	Partial regression coefficients (*b*) and their *t*-values[a]			
	Premenopausal		Postmenopausal	
	b	*t*	*b*	*t*
Age at menarche	−0.415	2.15	0.286	1.10
Body height	0.160	0.84	0.510	1.93
Body weight	0.132	0.70	0.040	0.16
Residence	0.142	0.81	−0.203	0.75
Age at marriage	−0.143	0.66	0.377	1.40
Parity	0.023	0.12	0.465	1.56
Age of menopause	—	—	0.047	0.18

[a] Mean of 10 repeated analyses.

No disparity was observed between the total and familial series of patients in the distribution of histologic types of tumor, nor was there disparity in the family history of other cancers. Earlier benign breast disease such as mastopathy, mastitis, and benign tumor was reported in about 13% of the patients, with no difference due to the family history of breast cancer.

Results of multiple regression analysis are shown in table 3. Association of each variable with family history of breast cancer can be evaluated with the *t*-value for the regression coefficient. Values given in table 3 represent the mean of 10 estimates obtained recurrently. In premenopausal patients, only the age at menarche is significantly associated with family history; taller stature is not statistically significant in contrast with the feature observed in text-figure 3. In postmenopausal patients, however, the association of body height is very close to the significant level, whereas the age at menarche is not. Furthermore, with respect to such traits as residence, age at marriage, and parity, the association of family history is very different in premenopausal and postmenopausal patients. Although the regression coefficient is not statistically significant for any of these traits, familial postmenopausal patients seem more likely to live in an urban or Western environment in comparison to the other groups of patients.

DISCUSSION

The present results have provided some insight into the nature of the familial predisposition of breast cancer. Familial aggregation of a disease can be caused by *a*) genetic similarity, *b*) common environmental exposure within a family, or *c*) the combined effects of *a* and *b*. One of us (Murata M: Unpublished observations), by analyzing the family history of cancer in the control population, has observed a site-specific intrafamilial correlation not only in blood relatives but also in relatives by marriage for cancers of various sites including the breast. Environmental factors, such as life-style, nutritional intake, and socioeconomic status, should be adjusted so that the true genetic contributions to the etiology are clarified (*29*). Unfortunately, the present analysis lacks such information. Nevertheless, with multivariate analysis, it seems to have elucidated some interesting results regarding this point. The association of various risk factors with the familial nature of breast cancer differs according to whether this cancer occurs in premenopausal or postmenopausal patients: early menarche and/or taller stature are important characteristics of familial premenopausal patients, whereas in postmenopausal patients only body height is strongly correlated with a familial predisposition.

It might be argued that the difference observed between the total and familial series of patients in either the age at menarche (0.36 yr) or body height (1.2 cm) is too small to totally explain the twofold to threefold excess risk of familial predisposition to breast cancer among women (*18, 19*). The evidence is that both of these traits are genetically controlled: The heritability estimate from the parent–child correlation shows a considerably high value (*30–32*), and studies of twins have also revealed a marked hereditary component (*33*). However, it is also true that both traits are strongly influenced by environmental, especially nutritional, conditions. Rapid chronologic changes as well as urban–rural differences observed in the present data confirm it. If considering that such environmental effects would have concealed a possible underlying genetic contribution, the genetic correlation between the disease susceptibility and the relevant trait might become smaller. Because we know nothing about chromosome linkage between the genes controlling breast cancer susceptibility and the aforementioned trait (menarche or stature), we are not sure whether the observed correlation might be attributable to genetic or nongenetic causes. However, the discordant features observed in premenopausal and postmenopausal patients could not be explained satisfactorily by either genetic or nongenetic causes alone.

Consequently, the present results may be interpreted as follows: Familial predisposition of breast cancer in premenopausal patients is primarily attributable to genetic causes, at least a part of which should be related with body growth in infancy and childhood and thus with the age at menarche. Probably, some underlying hormone conditions are controlled by the same genetic factor, which in turn enhances the susceptibility of the mammary tissue to certain environmental carcinogens. Almost nothing is known about genetic heterogeneity among individuals of the general population with respect to various endocrine profiles. Endocrinologic control of puberty is as yet quite obscured (*34*). Thus, even though several interesting studies on the relation of the hormone factors with the family history of breast cancer have been reported recently (*12–15, 35–37*), interpretation of the present finding should wait for further accumulation of data. Familial predisposition in postmenopausal patients, however, seems to be influenced by some different factors, because early menarche does not bear any relation to familial breast cancer. If any genetic determinant of body growth is associated as a risk factor for the late-onset disease, the determinant must be of a kind that is independent of menarche-related effects. Because such nongenetic traits as residence and age at marriage are moderately related to the familial predisposition of this group, it is conceivable that stature also represents some nutritional circumstances rather than its being simply a hereditary characteristic of a family. If so, various nongenetic risk factors could be thought to cause familial predisposition of postmenopausal breast cancer.

The positive association between age at menarche and family history of breast cancer may alternatively be explained by a synergistic effect of both traits: As such, some nonhormone hereditary factor is more likely to be expressed as breast cancer in women with early menarche. Positive (*38*) and negative (*3*) findings on the synergistic effect of both traits have been reported. Such an effect could really not be clarified with the present data and probably could not be clarified by even a more refined analysis with matched controls, when consideration is given to the fact that family history of cancer is by no means independent of nongenetic risk factors as discussed above.

With respect to the age at onset of disease, it has been frequently reported that patients with a positive family history of breast cancer tend to be diagnosed from several to more than 10 years earlier than are nonfamilial patients (*39, 40*). Anderson (*2*) has proposed that the effect of a hereditary factor should be more predominant in premenopausal than postmenopausal breast cancer. Familial cases, as reported here, are also slightly more frequent in premenopausal than postmenopausal patients. Nevertheless, average age at surgery is not significantly different between the total and familial series of patients. This lack of significance may be interpreted by the fact that the relative proportion of postmenopausal breast cancer is as yet not so large in Japan (40%) as it is in the Caucasian populations (70%). Furthermore, a comparative pathology study (*41*) has demonstrated that postmenopausal breast cancer in Japanese women, as contrasted with that in American women, still has predominant characteristics of the premenopausal disease, even though it has been diagnosed after the menopause: Incidence of lobular carcinoma is quite infrequent, whereas that of papillotubular carcinoma is more common in Japanese women. The differential prognosis of premenopausal and postmenopausal patients in the United States is nonexistent in Japan. Hence it is presumed that both types of breast cancer may also resemble each other according to their etiologic aspects in Japan. However, Adami et al. (*42*) found no significant trend toward early occurrence of familial breast cancer in Sweden. In addition, we carefully reexamined Macklin's data (*43*) on the age-specific mortality rate of breast cancer in blood relatives of patients with the disease and noticed that the rate is consistently higher at all ages as compared with that in the U.S. general population, except at the perimenopausal ages, i.e., 55–59 years. Thus even with Caucasian patients, the age reduction due to the familial predisposition is not necessarily a general finding. As the age–incidence relationship could be an eloquent tool for investigating the etiologic role of the possible hereditary susceptibility in carcinogenesis (*44*), more convincing studies would be required.

Establishment and Characterization of a Human Colony-Stimulating Factor-Producing Cell Line From a Squamous Cell Carcinoma of the Thyroid Gland [1,2,3]

Tetsuro Okabe,[4] Hitoshi Nomura,[5] *and* Nakaaki Oshawa[4,5,6]

ABSTRACT—A human colony-stimulating factor (CSF)-producing cell line, T3M-5, has been established in vitro from a squamous cell carcinoma of the thyroid gland transplanted into athymic nude mice [congenitally athymic BALB/c (*nu/nu*) mice; Central Institute for Experimental Animals, Kawasaki, Japan]. Contaminating fibroblasts derived from a host nude mouse were eliminated by treatment with antiserum raised against nude mouse cells. T3M-5 cells have been continuously propagated during 3 years. The cells grew in a monolayered sheet with about 22 hours of population-doubling time and showed about 40% plating efficiency. The cells exhibited an epithelium-like morphology resembling the structure of the original tumor and showed tumor takes when inoculated into nude mice. Chromosome analysis revealed the cell line to be a human aneuploid line with a hypertriploid mode. The cells possessed the characteristic function of human CSF production in vitro and produced marked neutrophilia in tumor-bearing nude mice that were inoculated with the cultured cells. The molecular weight of the CSF was estimated at about 27,000 and was stable over the pH range 1.0–9.0 at 4°C for 21 hours. The CSF activity was destroyed by either trypsin or chymotrypsin, but it resisted neuraminidase, DNase, and RNase. The cells could be well propagated in roller bottles. About 100 liters of the conditioned medium was obtained with the roller bottle culture method, which formed approximately 500,000,000 colonies of human bone marrow cells. The rate of recovery of CSF activity from the gel-filtration column was high (68.9%). This cell line is therefore expected to aid in the large-scale preparation of human CSF.—JNCI 1982; 69:1235–1243.

Studies on thyroid cancer have been hampered by the lack of suitable experimental models. A readily available, relatively inexpensive means of growing such tumors would aid many investigations. The advent of in vitro model systems of human thyroid cancer has increased the demand for tumor cell lines from this cancer. Since the first report in 1967 by Jones et al. (*1*), few such cell lines of undisputed pedigree have been described (*2*). In an attempt to isolate a human tumor cell line, xenotransplantation of tumors seemed at first remarkably convenient for repetition of the primary culture. However, it was rather difficult to remove contaminating host fibroblasts from the cultures.

Recently, we have succeeded in the elimination of host fibroblasts for the cultivation of human tumors transplanted into nude mice (*3*). With the use of this method, a new human thyroid cancer cell line that produces human CSF has been established in vitro. Human CSF-producing cell lines have been isolated from a variety of tumors, such as squamous cell carcinoma of the oral cavity (*4*), large cell carcinoma of the lungs (*5*), carcinoma of the pancreas (*6*), hematologic cancers (*7, 8*), and transformed trophoblasts (*9*). However, until now, no thyroid cancer cell lines have been shown to produce CSF in vitro. Partial purification and characterization of the CSF are also described in this report.

MATERIALS AND METHODS

A 71-year-old Japanese female died of disseminated metastases of thyroid squamous cell carcinoma on February 2, 1978. A moderate granulocytosis and hypercalcemia persisted throughout her hospital course. At autopsy the tumor mass was transplanted into athymic nude mice and has been maintained since then by serial passages (*10*). One tumor of the second transfer generation was removed from the nude mouse on December 7, 1978, in an attempt to establish a squamous cell carcinoma cell line of the thyroid gland.

Culture medium.—The cell line was established and maintained in F-10 synthetic medium (Flow Laboratories Inc., Rockville, Md.) supplemented with 10% FBS (Flow Laboratories Inc.), 100 μg streptomycin/ml, and 100 U penicillin/ml. Cells were harvested with 0.25% trypsin (1:250; Difco Laboratories, Detroit, Mich.) and 0.02% EDTA in calcium- and magnesium-free balanced salt solution.

Elimination of fibroblasts in primary culture.—The tumor tissues were rinsed twice with F-10 medium and minced finely with small surgical scissors. The minced pieces were treated with trypsin solution and then incubated in EDTA as described previously (*3*). The treated pieces were dispersed in F-10 medium with 10% FBS, immediately dispensed into plastic culture vessels (Falcon 3002 and 3013; Falcon Plastics, Oxnard, Calif.), and incubated at 37°C in a humidified atmosphere of 5% CO_2 in air. Sparsely populated colonies of large epithelial cells attached to grow within 1–2 weeks.

ABBREVIATIONS USED: BSA=bovine serum albumin; CSF=colony-stimulating factor; FBS=fetal bovine serum; H & E=hematoxylin and eosin; MW=molecular weight; pI=isoelectric point.

[6] We thank Dr. Y. Ueyama, the Central Institute for Experimental Animals, for provision of human tumors; and Dr. N. Sato, the Third Department of Internal Medicine, Faculty of Medicine, University of Tokyo, for his support.

They were surrounded by considerable numbers of fibroblasts that were derived from stromal tissues of the tumor. To remove the fibroblasts, we treated the cultures with rabbit antiserum raised against nude mouse spleen cells in the presence of complement as described previously (*2*).

Serial subcultures.—During the subsequent 3 weeks of the primary culture, it became apparent that a heterologous population of polygonal cells with large nuclei had propagated and reached confluence. We initiated subcultures at 1:3 dilution with trypsin and EDTA solution. Adaptation to rapid growth on the medium was accomplished during the subsequent 4 months of continuous culture. At the time of the submission of this report, the cells had been subcultured to passage 112. During this period of continuous propagation, cells of different passages were stored in liquid nitrogen. After thawing, the stored cells could be propagated in culture without noticeable change in growth and CSF production.

Transplantation of cells into nude mice.—The cells (5×10^6) of passage 80 were harvested in 0.3 ml of medium and inoculated sc into the tissue on the flank of 3 nude mice. Nodules were detected in all 3 animals 2 weeks after the transplantation. Peripheral granulocyte counts were examined, and the mice were killed and submitted to histologic section.

Growth curve.—The cells of passage 60 were studied to estimate the population doubling time. The initial cell number was 5×10^4 cells per dish for a total of 16 dishes (Falcon 3001; 35×10 mm). The cells were grown in 2 ml of medium as described for serial subcultures. A cell count was taken each day in two dishes, and the growth medium was changed every day.

Histologic examination.—All the extirpated tumors from the nude mice were fixed in isotonic buffered Formalin (10%, vol/vol) stained with H & E, and examined under a light microscope. Cells in the petri dishes were photographed directly without stain with the use of a phase-contrast condenser.

Chromosome analysis.—For chromosome preparations, the cultured cells in exponential growth phase were treated with 0.2 μg Colcemid/ml (Grand Island Biological Co., Grand Island, N.Y.) for 2–3 hours at 37°C and then with hypotonic 0.5% KCl solution for 20 minutes. The cells were then fixed with methanol-acetic acid (3:1). After three changes of the fixative, the cells were dropped onto wet slides, air dried, and stained with conventional Giemsa dye.

Characterization of granulocytic CSF.—The cells were cultivated in 570-mm roller bottles at 0.5 rpm velocity. The confluent culture was incubated in serum-free medium supplemented with 1% BSA fraction V detoxicated by the method of McLeod et al. (*11*). The conditioned medium was harvested, centrifuged at 3,000 rpm for 20 minutes to remove cellular debris and precipitated material, and then stored at −20°C until used. Pooled conditioned medium was concentrated twelvefold to sixteenfold by ultrafiltration, with the use of the thin-channel apparatus with PM-10 membrane. We then transferred a 500-ml sample to a Sephadex G-75 column (35×50 cm; flow rate 700 ml/hr) equilibrated with 0.01 *M* Tris-HCl buffer (pH 7.4), containing 0.15 *M* NaCl and Tween 20. The void volume of this column was 15 liters, determined by blue dextran. The fractions containing CSF activity were pooled and concentrated twentyfold by ultrafiltration with a PM-10 membrane. The pooled fractions with CSF activity on human bone marrow cells (4 mg/ml; sp act, 2,280 U/mg) were incubated with 20 μg trypsin/ml (sp act, 1,000 U/mg), and 20 μg chymotrypsin/ml (sp act, 50 U/mg) in 0.01 *M* Tris-HCl buffer (pH 7.4) for 2 hours at 37°C. In each case the fraction-to-enzyme ratio was 1:1 and 10:1. For neuraminidase treatment, the fraction was incubated with 2 μg neuraminidase/ml (sp act, 29 U/mg) in 0.04 *M* acetate buffer (pH 5.0) for 2 hours at 37°C. For DNase or RNase treatment, the fraction was incubated with 1 mg DNase I/ml (sp act, 3,175 U/mg) or 1 mg RNase A/ml (sp act, 50 U/mg) in 0.01 *M* Tris-HCl buffer (pH 7.4) for 2 hours at 37°C. The reaction was terminated by the addition of 250 μl of FBS, and the mixture was then dialyzed against 0.01 *M* Tris-HCl buffer (pH 7.4) and assayed.

Effect of temperature on CSF activity.—The fraction containing CSF activity on human bone marrow cells (4 mg/ml; sp act, 2,280 U/mg) was heated for 30 minutes in a water bath at various temperatures up to 75°C. It was then cooled, dialyzed against 0.01 *M* Tris-HCl buffer (pH 7.4), and assayed.

Effect of pH on CSF activity.—The fraction with CSF activity on human bone marrow cells was incubated in various buffers at pH 1.0–13.0 by the addition of 1.0 *M* HCl or NaOH for 21 hours at 2°C. For adjustment we used 0.1 *M* KCl-HCl buffer (pH 1.0), citrate-phosphate buffer (pH 3.0, or 5.0, or 7.0), glycin-NaOH (pH 9.0 or 11.0), and KCl-NaOH buffer (pH 13.0). A test sample of 25 μl was incubated with 975 μl of each buffer, 10% FBS was added, and the sample was dialyzed against 0.01 *M* Tris-HCl buffer (pH 7.4) and assayed.

CSF activity.—The procedure of Bradley and Metcalf (*12*) was used with a slight modification. C3H/HeN mouse and human bone marrow cells (from healthy volunteers) were seeded at 100,000 and 200,000 per plate, respectively, after removal of adherent cells by the method of Messner et al. (*13*). The factor was added directly to the plates and always assayed at two levels, usually 0.05 and 0.1 ml per plate. We incubated the culture at 37°C in 7.5% CO_2. We determined the number of colonies (≥50 cells) on day 7 (mouse cells) and day 10 (human marrow cells) with a dissecting microscope at 25× magnification. We aspirated individual aggregates with a micropipette and stained them with 0.6% orcein in 60% acetic acid for morphologic identification. A unit of activity represents one colony formed during the time period of the assay.

Morphologic analysis of colonies—We performed routine morphologic analysis on human colonies after 14 days of culture when eosinophil, macrophage, and neutrophil colonies were enumerated. We also used the following cytochemical methods for the identification of the cells: naphthol ASD chloroacetate esterase, naphthol AS-D acetate with and without addition of sodium fluoride, Biebrich Scarlet, and acid phosphatase. We used any of these methods independently or in combination with another cytochemical method to demonstrate a particular type of cell.

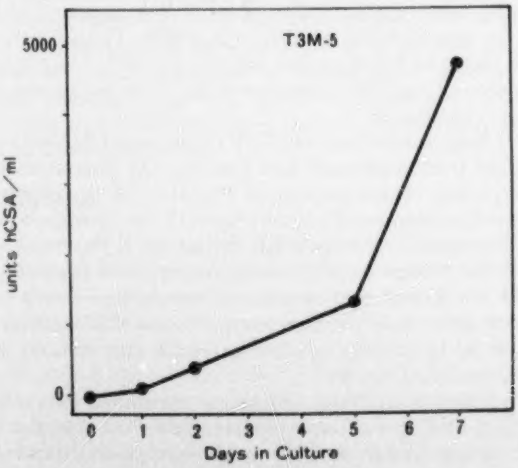
RESULTS

Isolation of the T3M-5 human thyroid carcinoma cell line.—In the primary culture of a human thyroid carcinoma transplanted into nude mice, sparsely populated colonies of large polygonal cells attached to grow slowly in 1 or 2 weeks. The colonies were usually surrounded by a considerable number of fibroblasts. The culture was then treated with a thirtyfold diluted antiserum raised against nude mouse cells in the presence of complement (fig. 1A). Mouse fibroblasts did not reappear in the post-treatment culture after the initial single treatment (fig. 1B). The cells of the original T3M-5 cell line established in this manner were characterized by large epithelial cell-like shapes with prominent nuclei (fig. 2) that were generally found in the center of the cytoplasm and were pleomorphic in shape. The cell membrane was usually rough and irregular, sometimes with one or more extending appendages. The cells formed characteristic colonies that coalesced and formed a monolayer.

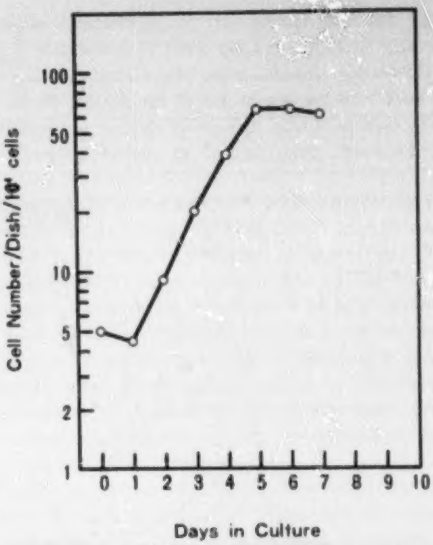
CSF production in the T3M-5 cell culture.—We incubated the confluent T3M-5 culture with the complete growth medium. The level of human CSF activity in the cultured medium was 5,000 U/ml. Of the colonies stimulated by the medium, 87.5% were granulocytic. The time course of change in human CSF activity of the medium is shown in text-figure 1. CSF activity in the cultured medium increased daily to a maximum activity on the 7th day of the culture in the roller bottles.

Growth characteristics.—A kinetic study on the in vitro growth of the cultured T3M-5 cells is shown in text-figure 2. The cells used for the study were the 60th transfer generation cells, completely adapted to the in vitro conditions, and were growing vigorously. The experimental cultures were initiated with an inoculum of 5×10⁴ cells and incubated in a 5% CO_2 chamber at 37°C. The growth curve was obtained by the number of cells per dish being counted as a function of time. Population doubling time was estimated as 22 hours from the growth curve.

Xenotransplantation of T3M-5 cells.—We tested the growth of the cultured T3M-5 cells to see whether they were able to grow in nude mice and whether a marked granulocytosis would develop. The retransplantation from tissue culture was successful in all cases; the animals showed perfect tumor takes. A remarkable granulocytosis was observed in all the animals that received xenotransplanted T3M-5 cells (table 1).



TEXT-FIGURE 1.—Changes in human CSF activities of the conditioned medium of T3M-5 cells in roller bottle culture.



TEXT-FIGURE 2.—Growth curve of cultured cells at the 60th transfer generation of T3M-5 under 5% CO_2 atmosphere. *Each point* represents the mean value from two dishes.

Figure 3 shows typical features of a tumor obtained by the inoculation of the cultured T3M-5 cells into nude mice. The histology of the tumor was similar to that of the original tumor grown in nude mice after direct transplantation from the human tumor. Both tumors were squamous cell carcinomas with occasional pearl formation (figs. 3, 4).

Chromosomal findings—The modal number of the T3M-5 cell line was 80 in the second passage and 72 in the 57th passage, with considerable scattering in the counts (table 2). Not a single normal metaphase was observed.

Characterization of CSF.—The cells propagated well in 570-mm roller bottles at the velocity of 0.5 rpm. When the cultures reached confluence, they were incubated in serum-free medium supplemented with 1% BSA. A concentrated conditioned medium (500 ml) was loaded on a Sephadex G-75 chromatography column after equilibration by dialysis with 0.01 *M* Tris-HCl (pH 7.4). We observed a broad peak of CSF activity with the use of mouse bone marrow cells as targets. The fractions of this peak region (B, C; text-fig. 3) were pooled and repeatedly chromatographed by Ultrogel AcA 54 column. Elution profile by the repeated chromatography was similar to the original one showing a broad peak of activity after the BSA region. Two small peaks were noted

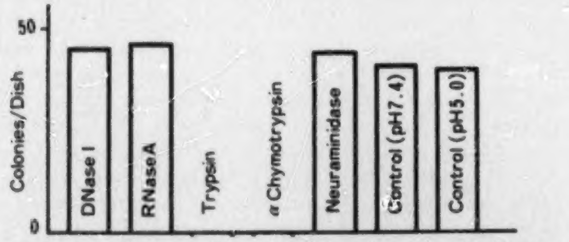
TEXT-FIGURE 3.—Gel-filtration profile of T3M-5-conditioned medium on Sephadex G-75. Activities were assayed on mouse bone marrow cells (mCSA). Different fractions of the A-, B-, and C-regions were pooled, respectively, and assayed against human bone marrow cells.

TABLE 3.—*Recovery of human CSF activity from gel-filtration column*[a]

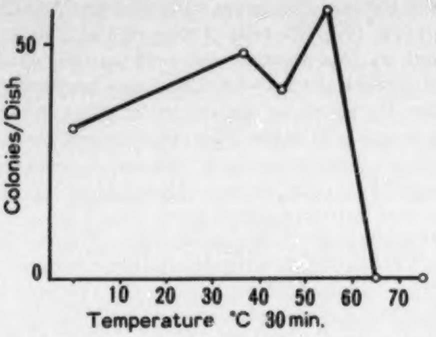
Substance assayed	Volume, ml	Protein, mg	Activity, ×10⁶ U (yield, %)	Sp act, U/mg
T3M-5 conditioned medium, 1% BSA	6,200	62,000	31.0 (100)	500
Fractions from A-region	88	8,890	6.57 (21.2)	740
Fractions from B-region	73	9,340	21.35 (68.9)	2,280
Fractions from C-region	73	4,090	6.42 (20.7)	1,570

[a] Fractions containing mCSA were pooled respectively in the regions of A, B, and C, concentrated, and assayed against human bone marrow cells. One unit represents one colony formed from 2×10^5 nonadherent human bone marrow cells.

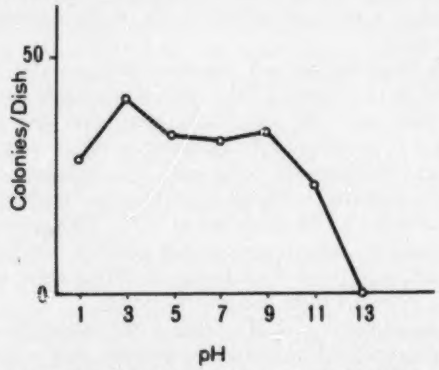


TEXT-FIGURE 4.—Treatment of concentrate from fractions of the B-region in text-fig. 3 with DNase, RNase, trypsin, chymotrypsin, and neuraminidase. *Each column* represents the mean colony No./plate (0.1 ml of stimulant) for three plates.

in the broad peak region. We estimated the MW of the proteins represented by these 2 peaks to be approximately 30,000 and 15,000, respectively, with the use of BSA, cytochrome c, and ovalbumin as protein markers. Only a small amount of protein was associated with the first peak, and the specific activity increased to 2,280 U/mg protein on human bone marrow cells (table 3). The recovery of CSF activity was 68.8% in the first peak region. The second small peak showed a lower specific activity of 1,570 U/mg protein. The recovery of CSF activity was 20.7% in the second peak region (text-fig. 3).



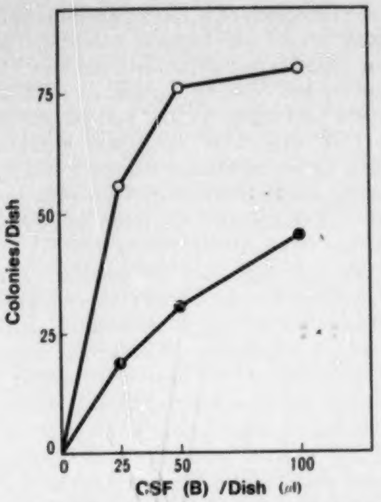
TEXT-FIGURE 5.—Heat inactivation of CSF from fractions of the B-region in text-fig. 3.



TEXT-FIGURE 6.—Stability during pH change of CSF fractions of the B-region in text-fig. 3.

Partially purified human CSF from pooled fractions from the first peak region (B) was used for the characterization experiments. The resistance of human CSF to RNase and DNase is demonstrated in text-figure 4. No biologic activity was lost when active purified DNase or RNase was incubated for 2 hours at 37°C with concentrated fractions (B), under conditions that caused the enzymes to break down rapidly their respective substrates. Human CSF activity was destroyed by trypsin or chymotrypsin, but resisted neuraminidase (text-fig. 4).

To examine the effects of heat, we incubated the partially purified CSF at various temperatures for 30 minutes. CSF activity was stable at 4°C, at room temperature, and at 45°C, but it was lost completely within 30 minutes at 65°C (text-fig. 5).



TEXT-FIGURE 7.—Relative stimulation of human and mouse cell colonies by CSF from fractions of the B-region in text-fig. 3.

TABLE 4.—*Morphology of human marrow colonies stimulated by different sources of CSF*[a]

Sources of CSF	Colonies, %			
	Neutrophil	Neutrophil-macrophage	Macrophage	Eosinophil
T3M-5 conditioned medium	41.7	29.2	12.5	16.7
GCT conditioned medium	33.3	35.3	21.6	9.8
Placental conditioned medium	58.0	7.0	22.0	13.0
T3M-5 high-MW CSF	56.3	37.5	3.1	3.1

[a] Colonies were stained after 14 days of culture.

CSF activity was stable over the pH range of 1.0–9.0. At pH 13, however, the activity was completely lost (text-fig. 6).

Cell populations of the colonies.—High-MW T3M-5 CSF from pooled fractions of the first peak region (B) was more active against human bone marrow than against mouse marrow cells and stimulated predominantly neutrophilic colonies (text-fig. 7; table 4). Crude and partially purified CSF stimulated the formation of both neutrophil and eosinophil colonies on day 14.

DISCUSSION

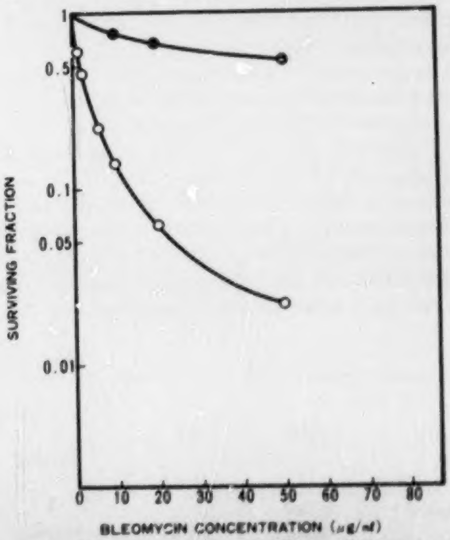
We have described the establishment of a human CSF-producing cell line derived from a squamous cell carcinoma of the thyroid gland, and the characterization of the CSF. The original cell line designated T3M-5 has been propagated continuously by serial passages during the past 34 months, and it has been producing human CSF in vitro.

Squamous cell carcinoma is rare among primary thyroid cancers. It has been shown to account for only 1% of all the neoplasms of this gland. Since there are no squamous cells in intact thyroid glands, the origin of this tumor remains unclear. One theory is that the tumor may originate from the follicular epithelium of the gland through squamous metaplastic alteration. T3M-5 cells produce a squamous cell carcinoma in athymic nude mice, thereby providing a clue to the understanding of the pathogenesis of this thyroid cancer. Prognosis for patients with this tumor is very poor, since the tumor resists radiation and chemotherapeutic agents.

For examination of the sensitivity of this type of tumor to antineoplastic agents, the T3M-5 cell line is expected to serve as a useful in vitro experimental model in culture and in vivo experimental model in nude mice. T3M-5 cells reveal a high colony-forming capacity in vitro and show perfect tumor takes when inoculated into nude mice. Recently, T3M-5 cells have been shown to be extremely sensitive to bleomycin in vitro (text-fig. 8), which is usually effective against a variety of squamous cell carcinomas. Bleomycin may be a potential choice for the treatment of squamous cell carcinoma of the thyroid gland.

A moderate leukocytosis is often observed in patients with squamous cell carcinoma of the thyroid gland (*14–16*). The precise mechanism of this phenomenon, however, remains unexplained in most cases. In 1977, we described a poorly differentiated squamous cell carcinoma of the lung that produced human colony-stimulating factor(s) in nude mice (*17*). Recently, a human CSF-producing cell line was isolated from a squamous cell carcinoma of the oral cavity (*4*). T3M-5 cells possess a characteristic function of human CSF production in vitro; a marked granulocytosis developed in nude mice bearing the tumors produced by inoculation with the cultured cells. Leukocytosis often seen in patients with squamous cell carcinoma of the thyroid gland may be due in part to CSF production by the tumor cells themselves.

In the conditioned medium of T3M-5 cells, gel column chromatography showed a broad peak of CSF activity with two small peaks indicating substances with MW of about



TEXT-FIGURE 8.—Effect of various concentrations of bleomycin on survival of dividing T3M-5 cells. Survival response of L-929 cells treated for 1 hr with bleomycin is shown for reference. *Each point* represents the mean values for 4 dishes from 3 expts. Plating efficiency of T3M-5 cells was 33–48% throughout the experiments.

30,000 and 15,000. To estimate the accurate MW of the high-MW CSF, we pooled the first peak region (B) obtained from the Sephadex G-75 fractionation and chromatographed it again on an AcA 54 column after fractionation under dissociating conditions with the use of phenyl-Sepharose CL-6B and 6 *M* guanidine hydrochloride (*18*). The CSF obtained from the phenyl-Sepharose fractionation eluted from Ultrogel AcA 54 column with an apparent MW of 27,000 (data not shown). The pI of this CSF was 5.5 with a relative narrow half-width or a half a pH unit. Wu and Yunis (*19*) and Wu et al. (*20*) described two common types of CSF in several human sources, one of which was purified and had a MW of about 50,000, stimulating only mouse marrow cells, but not human cells (mouse-active CSF). This type of CSF was polydisperse on isoelectrofocusing and showed multiple peaks with a pI between 3.6 and 4.7 and stimulated the formation of predominantly macrophage colonies in mouse bone marrow culture.

Activities that stimulate mouse macrophage colony formation were not demonstrated in any of the fractions obtained by Sephadex G-75 column chromatography. As described above, further characterization of the high-MW CSF in T3M-5 conditioned medium showed that this form of CSF had an apparent MW of 27,000 and pI of 5.5 with a relative narrow half-width or a half a pH unit, and exhibited higher activity in human bone marrow than in mouse marrow, yielding predominantly granulocytic colonies (text-fig. 7). These observations suggest that the high-MW CSF in T3M-5 conditioned medium was functionally and structurally distinct from the mouse active CSF. The CSF from human sources has been shown to stimulate human granulocytic colony formation (human active CSF). Most of the colonies grown in the presence of this type of CSF were granulocytic. These two types of CSF were demonstrated in the conditioned media from leukocytes, lungs, placenta, and cancer cells.

A previous study demonstrated that in a squamous cell carcinoma cell line, T3M-1, the mouse active factor was not detected in the conditioned medium (*21*). To compare the subtypes of these CSF produced by malignant cell lines, further purification studies are required (*22*).

Table 5 shows a summary of the properties of the CSF from malignant cell lines. Human active CSF from all the cell lines had an approximate MW of 30,000; the activity was destroyed by trypsin but resisted neuraminidase. With the exception of the CSF with 34,000 MW released from a T-lymphoblastoid cell line, all human active CSF, including T3M-5 CSF, have failed to bind concanavilin A–Sepharose (*23*). With the exception of a T-lymphoblastoid cell line, all human sources of CSF also support mouse marrow growth. From human leukocyte-conditioned medium, Price et al. (*24*) separated three types of human active CSF with approximate MW of 14,700, 36,500, and 96,000. Several human active CSF with MW of 25,000–40,000 have been isolated from a variety of human tissues (*25–27*). For studies to determine the similarities and differences between cancer-derived CSF and the other CSF, large quantities of highly purified CSF are required (*21, 23, 28, 29*).

Nicola et al. (*18*) suggested the possible existence of at least three forms of human active CSF in placental conditioned medium, one of which stimulated predominantly neutrophil colony formation. Most of the colonies in the presence of this form of CSF were neutrophilic at all dilutions of stimulus. Another form of human active CSF preferentially stimulated macrophage colony formation. Since this form of CSF was not separable from eosinophil CSF, it also stimulated eosinophil colony formation. Human active CSF obtained from a lymphoblastoid cell line or a monocyte-like cell line also stimulated eosinophil colony formation. In T3M-1 conditioned medium stimulation of eosinophil colony formation or macrophage colony formation was not demonstrated (*21*).

To establish whether T3M-5 conditioned medium contained neutrophil CSF, macrophage CSF, or eosinophil CSF, we performed morphologic subtyping of the colonies with the use of conventional Wright-Giemsa stain and special cytochemical stain (nonspecific esterase, naphthol AS-D chloroacetate esterase, and Biebrich Scarlet). Morphologies of colonies stimulated by conditioned media from T3M-5, GCT, and human placenta, and those by high-MW T3M-5 CSF are summarized in table 4. Eosinophil colonies were demonstrated in all of the conditioned media. Although T3M-5 conditioned medium seems to contain not only neutrophil CSF but also eosinophil CSF, high-MW T3M-5 CSF stimulated a few eosinophil colonies (<5%). Most of the colonies were neutrophilic, and the percentage of macrophage colonies was low (<3%).

Both T3M-1 and T3M-5 CSF were destroyed when kept at 65°C for 30 minutes. CSF from GCT or Mo cells was not destroyed at 65°C but was inactivated at 90°C (table 5). T3M-5 CSF differed from T3M-1 CSF in neuraminidase sensitivity (*21*). In T3M-1 CSF, partial loss of the activity occurred with neuraminidase treatment, whereas T3M-5 CSF activity was not destroyed.

To remove sialic acid from the high-MW CSF, we performed selective acid cleavage (*18*). Recovery of T3M-1

TABLE 5.—*Sources of human active CSF*[a]

Cell line	MW	pI	Effect of:			Inactivation at:		Eosinophil CSA	Presence of neutrophilia in patient
			Trypsin	Neuraminidase	Con A binding	Heat, °C	pH		
MiaPaca-2	27,000	5.7	?	?	?	?	?	?	?
GCT	30,000	5.0	Sensitive	Resistant	−	90	?	+	?
Mo	34,000	4.0–5.2	Sensitive	Resistant	+	90	3–10	+	?
T3M-1	30,000	5.5	Sensitive	Partially sensitive	−	65	1–11	−	+
T3M-5	27,000	5.5	Sensitive	Resistant	−	65	1–9	+	+

[a] ?=not known; +=present; −=absent.

CSF was less than 20% after this procedure, in contrast to the complete recovery of T3M-5 CSF (data not shown). Relationships between the sialic acid content and the functional properties of these tumor-derived CSF remain unclear. Differences and similarities among these CSF will be elucidated by the further purification studies.

At any rate, it is essential to obtain material sources with high biologic activities in extraordinarily large quantities, since multistep purification procedures of human active CSF usually yield low recoveries of active materials. T3M-5 cells can be well propagated in roller bottles and produce large quantities of human active CSF. The cells have the advantage of being able to produce significantly larger quantities of human active CSF than the other cell lines. The conditioned medium obtained from roller bottle cultures exhibited a greater activity (5,000 U/ml) than that from T3M-1 cells (1,440 U/ml) or that from GCT cells (1,300 U/ml). Within 1 month, 45 570-mm bottles yielded about 100 liters of conditioned medium that stimulated approximately 500,000,000 human granulocytic colonies. The recovery of the activity from a gel-filtration column was high (68.9%). This cell line is therefore expected to provide a superior starting material for purification, which facilitates greatly the studies on this granulopoietic factor.

In Vitro Studies on the Cell-Mediated Immune Response to Human Brain Tumors. I. Requirement for Third-Party Stimulator Lymphocytes in the Induction of Cell-Mediated Cytotoxic Responses to Allogeneic Cultured Gliomas[1,2]

Maurice K. Gately,[3,4] Moshe Glaser,[3] Steven J. Dick,[3] Ray W. Mettetal, Jr.,[3] *and* Paul L. Kornblith[3,5]

ABSTRACT—For study of those properties of human gliomas that might contribute to their ability to escape cell-mediated immune attack, cultured human glioma cells were examined for their ability to elicit allogeneic cytolytic lymphocyte responses in vitro. Of 9 glioma lines, 5 were unable to elicit allogeneic cytolytic lymphocyte responses in mixed lymphocyte–tumor cultures although the concentration of stimulating glioma cells was varied over a fortyfold range. However, lymphocytes specifically cytolytic for 4 of the nonstimulatory lines could be generated if irradiated, third-party stimulator lymphocytes were added to cultures containing responder lymphocytes and glioma cells. The specific cytolytic lymphocytes produced in these cultures were inactivated by treatment with the monoclonal anti-T-cell antibody OKT3 plus complement and were thus identified as T-cells. However, nonspecific, non-T-lytic effectors were also generated. The results of these experiments demonstrated that certain cultured gliomas possessed a defect in immunogenicity that can be overcome by "help" from an allogeneic mixed lymphocyte reaction. The possible nature of this help and the potential implications of these results for the immunotherapy of human gliomas are discussed.—JNCI 1982; 69:1245–1254.

In contrast to the many chemical- or virus-induced tumors that are able to elicit strong immune responses, most spontaneously arising tumors have been found to be only weakly immunogenic or nonimmunogenic (*1–5*). The factors contributing to this lack of immunogenicity are poorly defined. In our current studies we have examined the ability of one class of human neoplasms, the astrocytomas, to elicit cellular immune responses in an attempt to delineate those properties of astrocytoma cells that might contribute to their escaping cell-mediated immune attack. We approached this investigation by examining the ability of cultured glioma cells to induce cytolytic lymphocyte responses in vitro. Such glioma lines were previously shown to possess both common and highly restricted glioma-specific antigens (*6–9*) as well as HLA antigens (*10*) and in some cases Ia-like (*11, 12*) antigens. Nevertheless, initial attempts to elicit autologous tumor-specific CTL responses were unsuccessful. To define properties of glioma cells that might contribute to their failure to stimulate *autologous* responses, we have examined their ability to elicit *allogeneic* CTL responses. Since allogeneic reactions should be substantially stronger than tumor-specific autologous responses, it seems likely that factors impeding allogeneic responses should be at least equally effective in abrogating autologous sensitization to tumor-specific antigens. These experiments have led to the identification of several properties of human glioma cells that interfere with their ability to stimulate CTL responses in vitro. In this report we demonstrate that certain human glioma lines possess a defect in immunogenicity such that they are unable by themselves to elicit an allogeneic CTL response in MLTC but can elicit a response in the presence of "help" from an allogeneic MLR.

MATERIALS AND METHODS

Cell lines.—Portions of tumor samples obtained by biopsy at craniotomy were minced into 1-mm^3 pieces and explanted into 75-cm^2 Falcon flasks (Falcon Plastics, Oxnard, Calif.) in F-10 nutrient medium containing 10% FBS (Grand Island Biological Co., Grand Island, N.Y.). After tumor outgrowth began, the medium was changed regularly, and the cells were subcultured when needed with 0.25% trypsin. The sources and properties of the astrocytoma lines used in this study are summarized in table 1. Histologic diagnosis was made by Dr. Paul McKeever (Surgical Neurology Branch, NINCDS). The Kernohan grading of astrocytomas from grades I to IV denotes an increasing histologic scale of anaplasia (*13*). The malignant and glial properties of these lines were established by ultrastructural (*14, 15*), biochemical (*16*), and biophysical (*17*) techniques. The cell lines were routinely examined for mycoplasma contamination by Dr. Richard Del Guidice (NCI-Frederick Cancer Research Facility, Frederick, Md.) and were negative for mycoplasma at all times.

Fibroblasts were cultured from skin biopsies or from fragments of galea taken at operation. Cells of the erythroleukemia line K562 were donated by Dr. John Ortaldo, the

[5] We are grateful to Mrs. Martha Johnson for her excellent technical assistance and to Dr. Henry McFarland for his help in performing the indirect immunofluorescence studies.

National Cancer Institute, Bethesda, Md., and were maintained by passage in RPMI-1640 medium with 5% FBS.

Patients.—Lymphocytes from 9 astrocytoma patients were studied as part of this investigation. One patient's tumor was diagnosed histologically as astrocytoma grade II; all other patients had grade III or IV astrocytomas. Patients' ages ranged from 27 to 64 years (mean: 41 yr). All patients received therapy appropriate for their grade of tumor within the Surgical Neurology Branch, NINCDS. Patient #10, who was unique in the ability of his lymphocytes to lyse allogeneic glioma cells (*see* "Results"), was a 41-year-old male from South America who had a grade IV astrocytoma. He was studied immunologically at regular intervals beginning 5 months after his tumor had been surgically removed.

Sensitization of lymphocytes in MLTC.—Blood from tumor patients and from normal blood bank donors was drawn into syringes containing preservative-free heparin, 5 U/ml. Mononuclear cells were isolated by centrifugation on discontinuous Ficoll-Hypaque gradients (*18*) followed by centrifugation through 20% sucrose in RPMI-1640 with 1% human blood type AB serum for removal of contaminating platelets (*19*). Final cell pellets were resuspended in TCM consisting of a 1:1 mixture of RPMI-1640 and Dulbecco's modified Eagle's minimum essential medium supplemented with 5% human blood type AB serum, 5×10^{-5} *M* 2-mercaptoethanol, nonessential amino acids, 2 m*M* L-glutamine, 100 U penicillin/ml, and 100 μg streptomycin/ml (Grand Island Biological Co.).

Cytolytic lymphocytes were generated by incubation of responder lymphocytes with stimulator lymphocytes and/or glioma cells in 2 ml TCM in the wells of Costar 3524 tissue culture plates (Costar, Cambridge, Mass.). Stimulator lymphocytes received 2,000 R of γ-radiation prior to culture, and glioma cells received 10,000 R of γ-radiation. Responder and stimulator lymphocytes were each cultured at a density of 2×10^6 cells/well. Optimal glioma cell density was found to be $0.5\text{–}2\times10^5$ cells/well (*see* "Results"). Responder lymphocytes were harvested from primary sensitizing cultures after 7–12 days and were assayed for cytolytic activity. Alternatively, responder cells were harvested from primary MLTC after 13–16 days and reexposed to fresh stimulator lymphocytes and/or glioma cells with the use of culture conditions identical to those described above. Cytolytic activity was measured 3–4 days after the initiation of these secondary MLTC. Whereas early experiments involved the use of primary MLTC only, in later experiments both primary and secondary sensitizations were carried out because the ratio of specific to nonspecific effectors (*see* "Results") was increased in secondary cultures. Nevertheless, gliomas, which by themselves were nonstimulatory in primary MLTC, failed to elicit a response in secondary MLTC also (*see* "Results").

Cytolytic assays.—Freshly trypsinized glioma cells or fibroblasts to be used as targets in lytic assays were incubated with 100 μCi sterile [^{51}Cr]sodium chromate (New England Nuclear Corp., Boston, Mass.) in 0.5 ml TCM for 1 hour at 37°C. The cells were then washed three times and resuspended at a concentration of 5×10^4 cells/ml. Aliquots (0.1 ml) of this suspension were added to wells of Costar 3696 "half-area" MicroTest plates. The plates were incubated at 37°C for 18 hours for the cells to adhere and spread on the floors of the wells. The culture medium was then aspirated from each well and replaced with 0.1 ml of lymphocyte suspension. Lymphocytes were incubated with target cells for 18–24 hours at 37°C. At the end of this time, 0.05 ml culture medium was withdrawn from each well, and the amount of ^{51}Cr in each sample was measured in a gamma counter. The total amount of ^{51}Cr in the glioma cells was determined by addition of 1% sodium dodecyl sulfate to control wells. The percent specific ^{51}Cr release was calculated as $[(e-c)/(100-c)]\times100$, where e is the percentage of ^{51}Cr released from glioma cells incubated with lymphocytes and c is the percentage of ^{51}Cr released spontaneously from glioma cells incubated alone. All assays were performed in triplicate, and values given in tables represent the means ± 1 SE of replicate samples. Lytic activity of similar specificity could be observed when assays were terminated after 6 hours rather than 18 hours; however, effector:target ratios approximately fivefold greater were required to yield similar levels of lysis (Gately MK, Glaser M: Unpublished data).

Lymphocytes to be used as targets in cytolytic assays were incubated at a density of 1×10^6 cells/ml in 2 ml TCM containing 1 μg "PHA-L"/ml (E-Y Laboratories, San Mateo, Calif.) at 37°C for 3–4 days. [^{51}Cr]sodium chromate (100 μCi) was added 18 hours prior to the assay. The ^{51}Cr-labeled, PHA-activated cells were washed three times with 0.1 *M N*-acetyl-D-galactosamine (Sigma Chemical Co., St. Louis, Mo.) in TCM and then twice in TCM alone. The final cell pellet was resuspended in TCM at a concentration of 2×10^4 cells/ml. K562 cells to be used as targets were likewise labeled overnight with [^{51}Cr]sodium chromate, washed three times with TCM, and adjusted to 2×10^4 cells/ml. Then 0.1-ml aliquots of ^{51}Cr-labeled PHA blasts or K562 were mixed with 0.1-ml aliquots of effector cells in the wells of Linbro 76-311-05 round-bottom MicroTest plates. The microplates were centrifuged at $500\times g$ for 5 minutes at room temperature and then incubated for 4 hours at 37°C. At the end of this time, the MicroTest plates were again centrifuged, and supernatants containing released ^{51}Cr were harvested with the use of a Titertek supernatant collection system (Flow Laboratories, Inc., McLean, Va.). The percent specific ^{51}Cr release was calculated as above.

Treatment of cells with OKT3 plus complement.—Effector cells were suspended at 5×10^6 cells/ml in a 1:50 dilution of the monoclonal anti-T-cell antibody OKT3 (Ortho Pharmaceutical Corp., Raritan, N.J.) in L-15 medium with 1% FBS. After incubation for 15 minutes at 37°C, the cell suspensions were mixed with an equal volume of rabbit complement, which had been obtained from 6-week-old New Zealand White rabbits and stored at −80°C until use. The mixtures were incubated for 1 hour at 37°C, after which the cells were washed twice in TCM, and the number of viable cells remaining was determined by trypan blue dye exclusion. Treatment of cells with complement alone reduced the number of viable cells by 10% or less.

Indirect immunofluorescence.—The presence of HLA or Ia-like antigens on the glioma lines was examined by indirect immunofluorescence with the use of xenogeneic monoclonal anti-HLA-A, -B, -C and anti-HLA-DR antibodies directed at nonpolymorphic determinants. Glioma cells adherent to glass cover slips were incubated with monoclonal anti-HLA-A, -B, -C (clone 61D2; Bethesda Research Laboratories, Inc., Gaithersburg, Md.) or with monoclonal anti-HLA-DR (clone L243; Becton, Dickinson & Co., Sunnyvale, Calif.) for 45 minutes at room temperature. The cover slips were then rinsed in PBS, and the cells were further exposed for 45 minutes to fluorescein-labeled goat anti-mouse IgG (Cappel Laboratories, Cochranville, Pa.). The cover slips were rinsed again, mounted, and examined for the presence of surface fluorescence on the glioma cells. Controls in which the glioma cells were first incubated with PBS and then with fluorescein-labeled anti-mouse IgG were in all cases negative. These tests were performed and scored by Dr. Henry McFarland of the Neuroimmunology Branch, NINCDS.

RESULTS

Requirement for Third-Party Stimulator Lymphocytes in the Generation of Lymphocytes Specifically Cytotoxic for Certain Glioma Lines

Freshly isolated peripheral blood lymphocytes from 7 glioma patients failed to cause lysis of autologous glioma cells in vitro to an extent significantly greater than that caused by lymphocytes from normal donors (data not shown). These results were obtained in 18-hour ^{51}Cr release assays with the use of an effector-to-target cell ratio of 100:1. Likewise, peripheral blood lymphocytes from 7 of 8 glioma patients failed to cause substantial lysis of allogeneic gliomas when assayed in a similar manner (for the one exception, *see below*). These results led us to initiate a series of experiments to examine those properties of human glioma cells that might contribute to their ability to escape cell-mediated immune attack.

As an approach to this problem, we examined the ability of human glioma cells to elicit cytolytic lymphocyte responses in MLTC. Despite serologic evidence from two separate laboratories (*7, 9*) that human glioma lines possess tumor-specific surface antigens, initial attempts to elicit tumor-specific CTL with the use of autologous combinations of lymphocytes and glioma cells from 5 different patients were unsuccessful. Therefore, to define those properties of human glioma cells that might contribute to their failure to stimulate *autologous* responses, we examined their ability to stimulate *allogeneic* CTL responses, for which sufficient reagents to permit detailed studies were more readily available. Of the 9 glioma lines studied, 5 were unable by themselves to elicit such responses (tables 1–3). However, 4 of the nonstimulatory lines could elicit the generation of lymphocytes specifically cytolytic for the glioma if sensitization was carried out in the presence of third-party stimulator lymphocytes (tables 1, 2). When added to a mixture of responder and stimulator lymphocytes, the 5th nonstimulatory line termed "GB" did not elicit a cytolytic lymphocyte response but rather suppressed the MLR that would otherwise have occurred. This suppression was due to the secretion of a macromolecular, nonspecific immunosuppressive substance (*20*).

Several types of targets were used to examine the specificity of the cytolytic lymphocyte responses induced in these experiments. In addition to being assayed against one or more glioma lines, effectors were also assayed for their ability to lyse K562, an erythroleukemia line that lacks HLA and Ia-like antigens (*21*) but is highly susceptible to lysis by NK and "NK-like" effectors (*22–24*), and for their ability to lyse PHA-activated stimulator lymphocyte blasts. These blast targets were used to monitor the level of cytolytic activity directed against alloantigens on the third-party stimulator lymphocytes; however, the lysis of PHA blasts may, to a lesser extent, reflect the activity of NK-like cells as well (*24*).

Since the various targets differed in their susceptibility to lysis, the specificity of effectors generated in these experiments could not be determined by simple comparisons of absolute levels of lysis of the different targets. Rather, the specificity of effectors was evaluated by examination of the *ratio* of the lytic activity generated in the presence of glioma stimulators to the lytic activity generated in their absence and then comparison of the ratios observed for the different targets. For example, in table 2, experiment 1, incubation of responder lymphocytes in MLTC with NN glioma alone led to little or no generation of cytolytic activity. Culture of responder lymphocytes with stimulator lymphocytes resulted in the generation of cytolytic effectors capable of

[a] +=present in MLTC.

[b] Values are means ± 1 SE of replicate samples.

[c] In expt 1, glioma cells were added to the MLTC at a concentration of 5×10^4 cells/well. Cytolytic activity was assayed on day 7 of the primary MLTC with the use of effector-to-target cell ratios of 6:1 for glioma targets and 15:1 for PHA blasts. Spontaneous ^{51}Cr release was 26, 22, and 35% from NN glioma, LM glioma, and PHA blasts, respectively.

[d] In expt 2, concentrations of glioma cells in MLTC were 5×10^4 RB cells/well or 1×10^5 NN cells/well. Responders were harvested from primary MLTC on day 13 and reexposed to fresh stimulator lymphocytes and/or glioma cells. Cytolytic activity in the secondary MLTC was assayed after 3 days. Effector-to-target cell ratios in cytolytic assays were 5:1 both for glioma targets and for PHA blasts. Spontaneous ^{51}Cr release was 28% from NN glioma, 34% from RB glioma, and 7% from the PHA blasts.

[e] In expt 3, both NN and RF gliomas were added to MLTC at 5×10^4 cells/well. Effectors were harvested on day 12 of primary MLTC and assayed for lytic activity at effector-to-target cell ratios of 20:1 for NN glioma and 5:1 for RF glioma. Spontaneous ^{51}Cr release was 27 and 21% from the NN and RF gliomas, respectively.

TABLE 3.—*Lack of requirement for third-party stimulator lymphocytes in the generation of lymphocytes specifically cytotoxic for allogeneic AB and LH gliomas*

[a] +=present in MLTC.

[b] Values are means ± 1 SE of replicate samples.

[c] In expt 1, glioma cells were added to MLTC at 5×10^4 cells/well. Cells were harvested on day 15 of the primary MLTC and boosted in secondary MLTC. Cytolytic activity was assayed 4 days later. Effector-to-target cell ratios were 7:1 for both targets, and the spontaneous ^{51}Cr release was 29% for AB glioma and 28% for K562.

[d] In expt 2, concentration of glioma cells in MLTC was 5×10^4 cells/well, and cytolytic activity was assayed on day 12 of the primary MLTC. Effector-to-target cell ratios in the cytolytic assays were 24:1 for glioma targets and 40:1 for PHA blasts and K562. Spontaneous ^{51}Cr release was 15, 28, 29, and 10% from LH glioma, K562, LM glioma, and PHA blasts, respectively.

causing significant lysis not only of the stimulator PHA blasts but also of the glioma targets. The lysis of glioma targets by these effectors might have resulted from the action of specific cytolytic lymphocytes recognizing antigens on the glioma cells that were identical to or cross-reactive with antigens on the stimulator lymphocytes. Alternatively, lysis could have been caused by nonspecific "anomalous" or NK-like effectors that are generated in such cultures (*22–24*). In fact, as shown below, probably the NK-like effector was responsible for most glioma cell lysis produced under these conditions.

In table 2, experiment 1, when MLTC contained NN glioma stimulators as well as responder and stimulator lymphocytes, the resulting lysis of NN glioma targets was increased 2.6-fold over that caused by effectors generated from responder cells incubated with stimulator lymphocytes alone. In contrast, lysis of the LM glioma targets and of stimulator PHA blasts did not increase but rather decreased when NN glioma stimulators were included with responder and stimulator lymphocytes in the MLTC. Likewise, lysis of K562 was not increased when effectors were from such cultures (*see* table 4, expt 1). Thus in MLTC containing responder lymphocytes, stimulator lymphocytes, and NN glioma cells, a mixture of cytolytic effectors was produced. Substantially enhanced lysis of the NN glioma but not of the LM glioma or of stimulator PHA blasts provided clear evidence for the generation of a population of effectors capable of specifically recognizing and lysing the NN glioma cells. However, this lysis was superimposed on the lysis caused by nonspecific effectors that were produced as a result of the interaction between the responder and stimulator lymphocytes, regardless of whether or not NN glioma cells were present in the mixed leukocyte cultures. Further evidence of the phenotypic distinction between these two types of effectors is presented below (*see* table 4). Results similar to those of table 2, experiment 1, are presented for the NN, RB, and RF gliomas in experiments 2 and 3, table 2. In addition, experiments 2 and 3 contain *reciprocal specificity* controls, which clearly established that effectors specific for antigens on the glioma cells were generated when glioma cells were cultured with responder and stimulator lymphocytes in MLTC.

Although the nature of the antigens recognized in these experiments was not rigorously defined, most likely they were alloantigens. In experiments (not shown) in which fibroblasts autologous to the glioma stimulators were included as targets, lysis of the fibroblasts paralleled that of the corresponding glioma targets. However, lysis of fibro-

[a] In both experiments, NN glioma cells were added to MLTC at 1×10^5 cells/well. Cells were harvested from primary MLTC on day 14 and boosted in secondary MLTC. After 4 days, cells were harvested from the secondary MLTC and treated with medium, complement (C) alone, or OKT3 plus C as described in "Materials and Methods." The remaining viable cells were then enumerated and assayed for lytic activity. Spontaneous ^{51}Cr release from the NN glioma was 20% in expt 1 and 28% in expt 2. Spontaneous ^{51}Cr release from K562 in expt 1 was 28%. Results shown for expt 1, parts A and B, represent the results of a single experiment in which various untreated and treated effector populations were assayed for lytic activity on two separate targets. R=responder lymphocytes; S=stimulator lymphocytes.

[b] Values are means ± 1 SE of replicate samples. E:T=effector-to-target cell ratio.

[c] One lytic unit was defined as the number of viable effectors required to cause 30% specific ^{51}Cr release from the targets. Values for specific ^{51}Cr release were graphed on a semi-log plot in which the *ordinate* was 100 minus the percent specific release and the *abscissa* was the effector-to-target cell ratio (25). Such plots were linear for values of percent specific release <50%. In the case of effector populations for which the maximum percent specific release was <30%, the effector-to-target cell ratio required to give 30% specific release was extrapolated, with linearity assumed.

TABLE 5.—*Ability of lymphocytes from a patient with evidence of in vivo sensitization against antigens on the NN glioma to respond to the NN glioma in vitro in the absence of third-party stimulator lymphocytes*[a]

Contents of MLTC[b]			Percent specific ^{51}Cr release from:[c]			
Lymphocytes of patient #10 with NA glioma	Stimulator lymphocytes	Glioma	NN glioma	Autologous NA fibroblasts	K562	Stimulator PHA blasts
+			2.4±5.8	−0.6±0.8	6.3±3.2	1.7±1.9
+		NN	37.6±2.5	7.5±0.9	23.4±0.3	14.6±1.8
+	+		11.8±4.8	30.9±3.1	59.7±1.3	48.6±1.1
+	+	NN	37.8±2.6	25.4±1.4	73.8±4.8	56.5±1.0

[a] Effector cells were harvested from primary MLTC on day 10 and assayed for cytolytic activity. Effector-to-target cell ratios were 20:1 for glioma and fibroblast targets and 10:1 for K562 and PHA blasts. Spontaneous ^{51}Cr release was 36, 29, 17, and 15% from NN glioma, NA fibroblasts, K562, and PHA blasts, respectively.

[b] +=present in MLTC.

[c] Values are means ± 1 SE of replicate samples.

blasts autologous to the responders paralleled the lysis of K562 (table 5).

When the AB or LH gliomas were incubated with responder lymphocytes from normal donors, they directly elicited allogeneic cytolytic lymphocyte responses in the absence of any third-party stimulator lymphocytes (table 3). The cytolytic lymphocyte response elicited by the LH glioma appeared to be highly specific. In contrast, the AB glioma seemed to elicit a mixture of specific and nonspecific (lytic for K562) effectors; however, it is unclear from the data in table 3 to what extent each of these two types of effectors contributed to the lysis of AB targets.

From among the nonstimulatory gliomas, the NN glioma was selected for further studies regarding the nature of its immunogenic deficit. This line was chosen both because its rapid doubling time of 3–4 days permitted the growth of many cells for use in experiments and because it had previously been studied in detail with the use of serologic techniques and had been shown to possess both common and restricted glioma-specific antigens (*9*) as well as HLA antigens (this report). To determine whether the inability of this line to directly elicit a cytolytic lymphocyte response was due simply to an inappropriate choice of the concentration of glioma cells to be added to the MLTC, we performed two experiments in which the concentration of NN glioma cells in the MLTC was varied over a fortyfold range. These experiments yielded similar results, and one of them is summarized in table 6. In this experiment, incubation of responder lymphocytes from a normal donor with NN glioma at concentrations varying from 1.25×10^4 to 4×10^5 glioma cells/well did not lead to the generation of a significant amount of cytolytic activity. When more than 4×10^5 glioma cells were added per well, the glioma monolayers became overly dense and retracted off the floor of the well. Optimal glioma concentration for eliciting a cytolytic lymphocyte response in the presence of help from an allogeneic MLR was 5×10^4 to 2×10^5 cells/well. At higher concentrations suppression of the response was observed. It is unclear whether this resulted from the secretion of some immunosuppressive entity or simply from overcrowding and competition for critical nutrients. Thus the NN glioma was unable to elicit a cytolytic lymphocyte response in the absence of allogeneic help at all cell concentrations tested; however, at high cell concentrations weak immunogenicity could have been masked by an overriding immunosuppressive effect.

T-Cell Nature of Specific Cytolytic Lymphocytes Generated in the Presence of Allogeneic Help

Zarling and Kung (*26*), Zarling et al. (*27*), and Platsoucas and Good (*28*) demonstrated that specific cytolytic T-cells can be distinguished from nonspecific NK-like cells, which are likewise generated in MLR, by treatment of effector cells with the monoclonal anti-T-cell antibody OKT3 plus complement. Such treatment abolishes the activity of CTL but not that of NK-like cells. In the two experiments shown in table 4, this approach was used to determine the identity of the glioma-specific effectors generated in the presence of third-party stimulator lymphocytes.

In both experiments responder lymphocytes from normal donors were incubated with either stimulator lymphocytes or stimulator lymphocytes plus NN glioma. Effectors harvested from MLTC containing stimulator lymphocytes plus NN glioma were threefold- to fourfold-more effective in lysing the NN glioma than were effectors from cultures containing only responder and stimulator lymphocytes. OKT3 and complement treatment of effectors from responder and stimulator lymphocyte cultures caused only a minimal decrease in the lytic units per culture and increased the lytic units per viable cell. In contrast, similar treatment of effectors that had been sensitized against the NN glioma in the presence of allogeneic help reduced the lytic units per culture threefold to fivefold to a value essentially identical to the number of lytic units remaining in cultures of responder plus stimulator lymphocytes after treatment with OKT3 and complement. Thus these results provided phenotypic evidence that in MLTC containing responder lymphocytes with glioma cells and third-party stimulator lymphocytes at least two types of effectors were generated: CTL specific for antigens on the glioma cell and nonspecific, non-T-effectors, presumably NK-like cells. Non-T-effectors were produced to the same extent as in cultures containing responder and stimulator lymphocytes without glioma cells.

As a specificity control, the lysis of K562 by the various untreated and treated cell populations was also examined

TABLE 6.—*Effect of number of glioma cells in MLTC on generation of lymphocytes cytotoxic for allogeneic NN glioma*[a]

Contents of MLTC:[b]			Percent specific ^{51}Cr release from NN glioma[c]	Difference between percent specific release: (R+S+glioma)−(R+S)[d]
Responder lymphocytes	Stimulator lymphocytes	NN glioma/culture		
+		0	−2.8±1.8

+	+	1.25×10^4	27.6±3.4	5.8

[a] Effector cells were harvested from primary MLTC after 7 days and assayed for cytolytic activity at an effector-to-glioma ratio of 5:1. The spontaneous ^{51}Cr release from NN glioma was 22%.

[b] +=present in MLTC.

[c] Values are means ± 1 SE of replicate samples.

[d] R=responder lymphocytes; S=stimulator lymphocytes.

in experiment 1, table 4. Consistent with the results in table 2, addition of NN glioma to cultures of responder and stimulator lymphocytes did not lead to any increase in the generation of lytic activity as assayed on K562 (in contrast to the threefold to fourfold enhancement of lytic activity as assayed on the NN glioma). Likewise, in accordance with the results of previous authors (*26–28*), treatment of effectors with OKT3 and complement did not appreciably alter the lytic units per culture as assayed on K562; i.e., lysis due to the action of NK-like cells was unaffected.

Ability of Lymphocytes From a Glioma Patient With Evidence of In Vivo Sensitization Against Antigens on the NN Glioma To Respond to the NN Glioma in MLTC in the Absence of Third-Party Stimulator Lymphocytes

One patient (#10) with NA glioma has been unique among the glioma patients studied to date in that freshly isolated peripheral blood mononuclear cells from this patient caused substantial lysis of all three allogeneic glioma lines tested [NN, LM (table 7), and GB] and of 1 of 2 allogeneic fibroblast lines (NN but not GB fibroblasts were lysed). However, lymphocytes of patient #10 lysed neither autologous cultured glioma nor autologous fibroblasts, and they caused no greater lysis of an allogeneic colon adenocarcinoma than did lymphocytes from normal controls (data not shown). The ability of this patient's lymphocytes to lyse allogeneic glioma cells did not correlate with their NK activity as measured on K562 targets (table 7); in contrast to NK-mediated lysis of K562, lysis of allogeneic gliomas was virtually abolished by treatment of the effectors with OKT3 and complement (table 7). Thus patient #10 with NA glioma had apparently made a CTL response in vivo against some antigen present on the NN and other glioma lines. It is not known whether this was an antigen cross-reactive with some environmental antigen, an alloantigen against which sensitization had occurred as a result of blood transfusion, or some tumor-related antigen that had been lost from the patient's own cultured glioma line. However, this patient's lytic activity against allogeneic glioma cells remained at essentially constant levels during serial assays over a 10-month period, and similar reactivity was not observed for lymphocytes from any of 6 other glioma patients or 34 normal donors.

When lymphocytes from patient #10 with NA glioma were incubated with NN glioma cells in MLTC, an enhanced cytolytic lymphocyte response occurred in the absence of third-party stimulator lymphocytes (table 5). This observation was in contrast to the inability of lymphocytes from four other glioma patients or nine normal donors to make any direct response to the NN glioma in MLTC (cf. tables 2, 4, 6). As in experiment 1, table 3, the cytolytic response appeared to consist of a mixture of specific and nonspecific elements, since exposure of NA lymphocytes to NN glioma in MLTC resulted in enhanced lysis not only of the NN glioma but also of K562. Nevertheless, effectors generated in an allogeneic MLR containing NA lymphocytes as responders and allogeneic stimulator lymphocytes lysed K562 to a substantially greater extent than the NN glioma, whereas effectors generated by the incubation of

TABLE 7.—*Presence of T-cells capable of lysing allogeneic NN and LM gliomas in freshly isolated peripheral blood mononuclear cells from patient #10 with NA glioma*[a]

Expt No.	Lymphocyte donor	Treatment of lymphocytes	Percent specific ^{51}Cr release from:[b]		
			NN glioma	LM glioma	K562
1	Normal #1	Medium	3.8±2.7		13.8±2.2
	Normal #2	Medium	5.2±1.5		4.6±1.1
	Patient #10	Medium	52.0±2.0		25.9±1.7
	Patient #10	C	50.3±1.3		22.7±0.6
	Patient #10	OKT3+C	7.2±2.2		23.2±1.3
2	Normal #3	Medium	15.2±2.2	10.8±1.9	77.8±6.0
	Normal #4	Medium	8.9±0.7	4.4±0.6	61.5±4.4
	Patient #10	Medium	39.6±1.0	41.8±0.3	73.7±0.5
	Patient #10	C		44.5±6.6	
	Patient #10	OKT3+C		7.3±1.6	

[a] Freshly isolated peripheral blood mononuclear cells were treated with medium, complement (C), or OKT3 plus C as described in "Materials and Methods" and then assayed for their ability to lyse NN glioma, LM glioma, and K562. Treatment with OKT3 and C caused a 67% reduction in viable cells in expt 1 and a 74% reduction in expt 2. Treatment with C alone lysed ≤10% of cells in both experiments. Effector-to-target cell ratio was 50:1 in expt 1 and 70:1 in expt 2. The spontaneous ^{51}Cr release was 27% from NN glioma and 29% from K562 in expt 1 and 27, 23, and 13% from NN glioma, LM glioma, and K562, respectively, in expt 2.

[b] Values are means ± 1 SE of replicate samples.

responders with NN glioma were more highly lytic for the NN glioma than for K562. These observations suggested that the increased lysis of the NN glioma caused by the effectors generated by incubation of responders with NN glioma was due to the action of specific cytolytic lymphocytes rather than to an unusually high sensitivity of the NN glioma to lysis by NK-like cells. In a separate experiment it was found that NA lymphocytes, in contrast to lymphocytes from other glioma patients or from normal donors, also could react directly against the LM glioma in MLTC in the absence of allogeneic help (data not shown). Thus it appeared that, if sensitization to antigens on a normally nonstimulatory glioma cell line such as NN had occurred in vivo, such a cell line could elicit an enhanced cytolytic lymphocyte response in vitro in the absence of allogeneic help if responders were from the sensitized individual.

Ability of Glioma Cell Lines To Directly Stimulate an Allogeneic CTL Response; Lack of Correlation With the Presence of Ia-Like Antigens on the Glioma Line

In collaboration with Dr. McFarland, we examined the glioma lines used in these studies for the presence of HLA and Ia-like antigens by means of indirect immunofluorescence employing xenogeneic monoclonal anti-HLA-A, -B, -C and anti-HLA-DR antibodies recognizing nonpolymorphic determinants. As indicated in table 1, only one line, GB, reacted with the anti-HLA-DR antibody. However, that line, because of its production of an immunosuppressive substance, could not elicit cytolytic lymphocyte responses. Rather, GB glioma cells inhibited MLR to which they were added (20). Thus there was no correlation between the presence of Ia-like antigens on these lines, at least as determined by the anti-HLA-DR antibody used in these experiments, and the ability of these lines to elicit a CTL response.

DISCUSSION

The immune response to astrocytomas may be of particular interest to tumor immunologists for several reasons. Since these tumors arise in a location, the brain, which has traditionally been regarded as an "immunologically privileged site" (*29*), one might expect that in the absence of selective pressure from a hostile immune system such tumors would have a higher probability of expressing strong tumor-specific antigens than tumors arising in the periphery. Nevertheless, as these tumors grow, the blood-brain barrier is breached (*30*), so that interactions between the tumor and the host's immune system can occur. Substantial evidence indicates that most astrocytoma patients do make humoral immune responses to their own tumors (*7, 9*). These studies likewise provide evidence for the existence of both common and restricted glioma-specific antigens on these tumors. The evidence that astrocytoma patients make significant cellular immune responses to their own tumors is, however, more tenuous and controversial (*8, 31*). Because conventional therapy, consisting of surgery, irradiation, and chemotherapy, has had only a minor impact in improving the prognosis of patients with high-grade gliomas (*32*), interest in the use of less conventional therapeutic modalities, including immunotherapy, has risen. Although astrocytomas display extensive local growth and infiltration, they rarely metastasize; thus elimination of the tumor at its site of origin should be curative. Current technology permits the successful growth of astrocytomas in culture in over 90% of cases (*33*); hence detailed studies on the properties of glioma cells in vitro and of their potential for use in immunotherapy are readily feasible.

We have examined the ability of human glioma cells to elicit allogeneic CTL responses in vitro so that we could define those properties of glioma cells that may contribute to their ability to escape cellular immune attack. In addition to the defect in immunogenicity described in this paper, two other escape mechanisms have been identified: *a*) the production by certain glioma lines of an immunosuppressive substance and *b*) the secretion by some glioma lines of a protective mucopolysaccharide coat that impedes contact between lymphocytes and glioma cells (*20*). The experiments reported in this paper demonstrate that certain cultured glioma lines possess a defect in immunogenicity such that they are unable by themselves to elicit an allogeneic cytolytic lymphocyte response in MLTC but can elicit a response in the presence of help from an allogeneic MLR. Whether this defect exists in gliomas in vivo or represents a characteristic acquired in vitro is unclear. There was no obvious correlation between the inability to stimulate CTL responses and the length of time the lines had been in culture (table 1). It is unclear what property of a glioma line determines its ability to directly elicit a CTL response. Stimulatory capacity was not correlated with the presence of Ia-like antigens, as determined by the ability of the glioma lines to react with a xenogeneic monoclonal anti-HLA-DR antibody (table 1). However, it is well documented, at least in murine systems, that I-region differences in MLR are not necessarily required for the generation of a CTL response (*34, 35*). Preliminary experiments suggest that the ability of at least some glioma lines to directly stimulate cytolytic responses could relate to the acquisition of fetal calf serum components during culture. The LH line (table 3) was divided into two portions, one of which was cultured in TCM with human blood type AB serum for more than 2 months while the other was cultured in medium containing FBS. LH cells grown in human blood type AB serum lost the ability to directly elicit cytolytic responses, although LH-specific responses could still be generated in the presence of third-party stimulator lymphocytes (Gately MK, Dick SJ: Unpublished results). LH cells grown in FBS retained the ability to directly elicit cytolytic responses as shown in table 3 (the same normal donor was used as the source of responder cells in all experiments).

Third-party stimulator lymphocytes have been used by others to facilitate the induction of CTL responses to autologous human leukemias (*36–38*), to autologous human trinitrophenyl-modified lymphocytes (*39*), and to UV-irradiated murine lymphocytes (*40–42*). Our experiments extend this approach to a class of *human solid* tumors, the gliomas. The ability of NA lymphocytes to respond directly to the NN glioma establishes a further parallel with observations on the CTL response to UV-irradiated lymphocytes. UV-irradiated murine lymphocytes have been observed to stimulate CTL responses in the absence of allogeneic help when responder cells have been previously sensitized to antigens carried by the stimulator lymphocytes (*43–45*). It has been shown that the inability of UV-irradiated murine lymphocytes to elicit primary CTL responses is due to an inability to stimulate helper T-cells and that the mechanism of help provided by allogeneic MLR involves the secretion of a nonspecific helper factor identical to IL-2 (*46–48*). Possibly, the mechanism of allogeneic help in the human glioma system is similar.

Alternatively, the mechanism of allogeneic help in the glioma system could involve the production of lymphoid cells or soluble factors that act directly upon the glioma cells to alter their properties as stimulators. Such alteration could involve either a reduction or counterbalancing of suppressive influences exerted by the glioma cells or changes that directly enhance their immunogenicity. We are currently attempting to circumvent the requirement for third-party stimulator lymphocytes in our experiments by the use of lymphokine-containing supernatants. If successful, we could better define the mechanism of allogeneic help in the human glioma system.

Injection of irradiated autologous glioma cells into patients with high-grade astrocytomas has been reported neither to prolong patient survival nor to elicit cell-mediated antiglioma immunity, as determined by intradermal skin testing (*49*). The results of our experiments provide one possible explanation for the failure of this type of specific immunotherapy in glioma patients. If cultured glioma cells, such as NN glioma cells, are to be used effectively in specific active immunotherapy, they most likely will need to be modified by chemical, enzymatic, or other means for the enhancement of their immunogenicity. Alternatively, patients' lymphocytes might be sensitized in vitro to the autologous tumor and the sensitized cells grown in IL-2 for use in adoptive immunotherapy. Attempts in our laboratory to sensitize patients' lymphocytes to autologous tumor in the presence of allogeneic MLR have, in general, been unsuccessful (Gately MK, Glaser M: Unpublished results). However, since such autologous reactions would be expected to be substantially weaker than the allogeneic reactions described in this paper, the generation of small numbers of specific CTL in the autologous MLTC might have been obscured by the presence of the nonspecific, non-T-effectors, which are likewise produced in such cultures (cf. table 4). The possible generation of such nonspecific effectors, which are only poorly capable of lysing normal lymphocytes (*22–24*), clouds the interpretation of some of the previous reports (*36, 37, 50*) in which cytolytic lymphocytes specific for autologous human tumor cells were thought to have been produced but in which failure of effectors to lyse normal lymphocytes constituted the primary specificity control. To use allogeneic MLR to facilitate the induction of autologous tumor-specific CTL, one will likely need to find ways of inactivating or depleting the nonspecific effectors while leaving specific CTL functionally intact. Studies on these problems are in progress.

Isozymes of Acid Esterase and Acid Phosphatase in Permanent Human Hematopoietic Cell Lines[1,2]

Christer Sundström,[3] **Heinz J. Radzún,**[4] *and* **Mohammad R. Parwaresch**[4,5]

ABSTRACT—Net enzyme activities of normal human blood cells were measured, and isoelectric focusing patterns of acid esterase (AcE) (EC 3.1.1.6) and acid phosphatase (AcP) (EC 3.1.3.2) were compared with corresponding data obtained for two acute T-lymphoblastic leukemia cell lines (JM, Molt-4), one acute B-lymphoblastic leukemia cell line (Ball-1), one acute non-B-non-T-lymphoblastic leukemia cell line (KM 3), and one promyelocytic leukemia cell line (HL-60). The AcE isozymes, found in the individual blood cell types, were regularly expressed by the corresponding cell lines. AcP was regularly expressed by lines HL-60 and KM 3, but lines JM, Molt-4, and Ball-1 showed additional isozymes and/or reduction of the intensity of the typical isozymes found in the presumed normal counterparts. This phenomenon resulted partly in an obscuration of the typical isozyme patterns. Our study documents the applicability of isozyme mapping to the characterization of permanent hematopoietic cell lines. The results suggest that long-term culture conditions can repress phenotypic properties and/or derepress gene activities.—JNCI 1982; 69:1255–1260.

Normal human blood cells are distinguished by cell-specific isozymes of their lysosomal acid phosphatase (EC 3.1.3.2) and acid esterase (EC 3.1.1.6). The isozyme patterns remain detectable during neoplastic and functional transformations. With the use of the isoelectric focusing technique, we have been able to describe distinct AcP and AcE isozyme patterns for different subsets of lymphocytes, myeloid cells, and monocytes, and for different categories of non-Hodgkin's lymphomas (*1–5*).

In the study reported here, we extended our investigation of AcP and AcE heterogeneity to include a panel of permanent human hematopoietic cell lines established from several acute leukemias. These cell lines are ideal for such studies inasmuch as they are monoclonal expansions of tumor cells without the presence of contaminating normal cells (*6*). The study of the isozyme heterogeneity of these cell lines adds further knowledge to that obtained in previous functional studies (*7–10*) and provides clues to the understanding of the biology of the malignant diseases from which these cells were derived.

MATERIALS AND METHODS

Cell lines.—Five hematopoietic cell lines were studied, the origin of which is given in table 1. The cell lines were grown with a cell concentration never exceeding 5×10^5 cells/ml to ensure logarithmic growth. Ham's F-10 tissue culture medium (GIBCO, Grand Island, N.Y.), supplemented with 10% fetal calf serum and antibiotics (100 IU penicillin/ml, 50 µg streptomycin/ml, 1.25 µg amphotericin B/ml), was changed twice a week (*8*). Cells (total, 1×10^9) were harvested at regular intervals from logarithmically growing cultures, washed twice in phosphate-buffered saline (pH 7.4), and kept frozen at −70°C until further analyses.

Separation of normal blood cells.—For comparison, normal human granulocytes and T-lymphocytes were separated from heparinized fresh venous blood, as described elsewhere (*1, 2*). After centrifugation on a one-step Ficoll-Urografin gradient (Pharmacia Fine Chemicals, Uppsala, Sweden; Schering Aktiengesellschaft, Berlin, Federal Republic of Germany), granulocytes were obtained from the bottom fraction (*15*). T-lymphocytes were enriched from the nonadherent fraction of the interphase by passing the lymphocyte fraction over an immunoglobulin-anti-immunoglobulin C3 column (*16*). In addition, B-lymphocytes were separated from minced and sieved specimens of tonsil tissue, and the contaminating T-lymphocytes were excluded by means of rosetting with sheep red blood cells and by sedimentation (*17, 18*). Only highly purified viable cell fractions, as checked by cytochemical and immunological tests and trypan blue exclusion, were used (*1, 2*).

Activity assay and isoelectric focusing of AcE.—For extraction of the lysosomal hydrolases, cell pellets were incubated with 1% (vol/vol) Triton X-100 solution (Serva Feinbiochemica GmbH, Heidelberg, Federal Republic of Germany) for 30 minutes at room temperature and then ultracentrifuged (100,000×*g* for 60 min at 4°C). [In preliminary experiments no substantial differences appeared in the isoelectric focusing patterns, whether whole cells or the separated lysosomal fraction for enzyme extraction was used (*2, 4*).] AcE activity was measured in the clear supernatant, with α-naphthyl acetate (Sigma Chemie GmbH, Munich, Federal Republic of Germany) as substrate and fast blue RR (Sigma Chemie GmbH) as coupler at pH 5.8. The activity was spectrophotometrically evaluated at 500 nm and related to 1×10^7 cells.

On 4.3% polyacrylamide (Canalco, Rockville, Md.) slabs, 60 mU AcE activity in 20 µl sample volume was subjected to isoelectric focusing with the use of the multiphor system 2117 from LKB-Produkter AB (Bromma, Sweden). The gels contained 13.3% (wt/vol) sucrose, 1% (wt/vol) Triton X-100, 0.057% (wt/vol) riboflavin (Canalco), and, for maintenance of the pH gradient, 5% (vol/vol) ampholine, pH 3.5–10.0 (LKB-Produkter AB); 0.036% (vol/vol) ampholine,

TABLE 1.—*Analyzed hematopoietic cell lines*

Cell line	Original diagnosis	Reference
HL-60	Promyelocytic leukemia	Collins SJ et al. (*11*)
Ball-1	B-ALL	Hiraki S et al. (*12*)
JM	T-ALL	Schneider U, Schwenk HU (*13*)
Molt-4	T-ALL	Minowada J et al. (*14*)
KM 3	0-ALL	Schneider U, Schwenk HU (*13*)

pH 4.0–6.0; and 0.036% (vol/vol) ampholine, pH 5.0–7.0. As anolyte and catholyte, 1 *M* phosphoric acid and 1 *M* sodium hydroxide were used (*19*). After a running time of 4 hours at 4°C, during which the initial voltage of 200 V was raised to a terminal level of 1,200 V, the AcE enzyme bands were visualized with α-naphthyl acetate as substrate and hexazonium pararosanilin as coupler at pH 5.8, according to the histochemical method described by Mueller et al. (*20*). The gels were photographed, scanned at 537 nm (flying spot, TLD-100; Vitatron, Cologne, Federal Republic of Germany), and the pI of the bands were determined by measurement of the pH of aliquots of gel strips.

Activity assay and isoelectric focusing of AcP.—The procedures for enzyme extraction and isoelectric focusing were identical to those described above for AcE. For the AcP assay we used commercial kits (Boehringer Mannheim GmbH, Mannheim, Federal Republic of Germany), with *p*-nitrophenylphosphate as substrate (*21*). A minimum of 8 mU of enzyme activity, which prevented overlooking weak bands and gave optimal resolution, was subjected to isoelectric focusing. For visualization of AcP variants, the histochemical method as described by Barka and Anderson (*22*) was applied, with naphthol-AS-BI phosphate as substrate and hexazonium pararosanilin as coupler at pH 5.0.

In parallel runs all samples were studied after neuraminidase (type V; Sigma Chemie GmbH) treatment (2 hr at 37°C, pH 5.5) as described in (*3*).

RESULTS

AcE and AcP Activities

Table 2 gives a survey of the activities of the analyzed lysosomal hydrolases per 1×10⁷ cells.

The acute lymphoblastic leukemia lines of the B- and T-cell type (Ball-1, JM, Molt-4) revealed similar AcE activities, exceeding the value for the promyelocytic leukemia line (HL-60) by a factor of two. Granulocytes isolated from normal human peripheral blood showed a net enzyme activity of 0.9±0.5 mU/1×10⁷ cells, whereas B- and T-lymphocytes had a sixfold higher AcE activity value (table 3).

TABLE 2.—*Activities of AcE and AcP in the analyzed cell lines*[a]

Cell line	AcE	AcP
HL-60	6.1	25.6
Ball-1	12.9	21.2
JM	11.2	18.6
Molt-4	12.4	15.6
KM 3	6.3	8.6

[a] mU/1×10⁷ cells.

TABLE 3.—*Activities of AcE and AcP in normal blood cells*[a]

Cell population	AcE	AcP
Granulocytes	0.9±0.5 (*n*=5)	5.8±3.4 (*n*=6)
B-lymphocytes	5.5±3.3 (*n*=6)	1.8±1.3 (*n*=6)
T-lymphocytes	5.3±1.8 (*n*=4)	2.8±1.2 (*n*=4)

[a] mU/1×10⁷ cells.

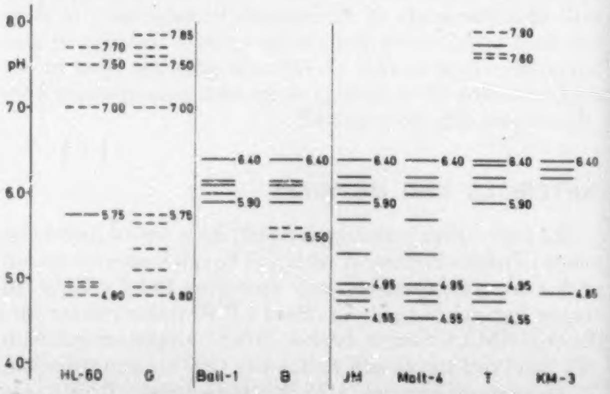
The acute lymphoblastic leukemia lines of the B- and T-cell type displayed AcP values of nearly the same order: 21.2, 18.6, and 15.6 mU/1×10⁷ cells (table 2). The promyelocytic cell line HL-60 showed only slightly higher AcP values. Corresponding values for AcP of normal human blood cells were 5.8±3.4 for granulocytes, 1.8±1.3 for B-lymphocytes, and 2.8±1.2 for T-lymphocytes (table 3). Line KM 3 showed values of 6.3 and 8.6 mU for AcE and AcP, respectively.

AcE Isoelectric Focusing Patterns

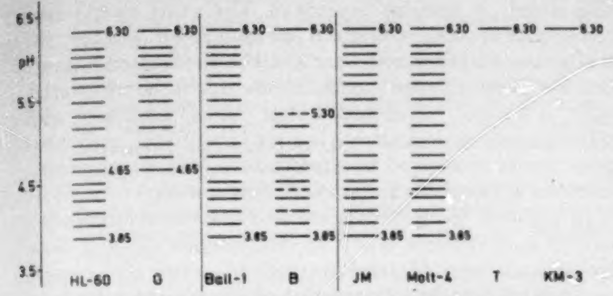
The AcE isoelectric focusing patterns for the individual permanent cell lines and for the corresponding normal human blood cell types are shown in figures 1A and 1B. A schematic comparison of the analyzed cell lines and the normal counterparts is shown in text-figure 1.

HL-60 displayed three AcE bands between pH 5.0 and 4.8 and an additional band at pH 5.75. In the cathodal region of the gel, three weak bands with pI values of 7.7, 7.5, and 7.0 could be seen. Ball-1 was characterized by four AcE bands with strong activity between pH 6.4 and 5.9. The AcE activity in JM was localized in two complexes between pH 6.4 and 5.9 and pH 5.0 and 4.5, with five and four bands, respectively. Two additional bands were detectable at pH 5.7 and 5.3. The same isoelectric focusing pattern was observed in Molt-4, but with only four AcE bands between pH 6.4 and 5.9. KM 3 showed three AcE bands, with pI values of 6.4, 6.3, and 6.2, and one band at pH 4.85.

In comparisons with the normal counterparts (text-fig. 1), a good correlation was found between Ball-1 and normal human B-lymphocytes. The five typical bands of normal B-



TEXT-FIGURE 1.—Schematic AcE isoelectric focusing patterns in the analyzed hematopoietic cell lines matched with the corresponding patterns of the presumed normal counterparts. G=granulocytes, B=B-lymphocytes, T=T-lymphocytes. *Interrupted lines* stand for bands with weak activity.



TEXT-FIGURE 2.—Schematic AcP isoelectric focusing patterns in the analyzed hematopoietic cell lines matched with the corresponding patterns of the presumed normal counterparts. G=granulocytes, B=B-lymphocytes, T=T-lymphocytes. *Interrupted lines* stand for bands with weak activity.

lymphocytes were also detectable in the Ball-1 line. In HL-60, some of the AcE bands of normal granulocytes were expressed. JM and Molt-4 clearly showed two of the three AcE complexes found in normal T-lymphocytes between pH 6.4 and 5.9 and between pH 5.0 and 4.5. KM 3 displayed only a few of the AcE bands seen in the middle and anodal AcE complexes of normal T-lymphocytes.

AcP Isoelectric Focusing Patterns

Figures 2A and 2B show the original AcP isoelectric focusing patterns for the permanent cell lines and their normal counterparts, which are matched schematically in text-figure 2.

The AcP isoelectric focusing patterns for normal human blood cells were clearly shared by HL-60 and KM 3. HL-60 expressed the main activity between pH 6.3 and 6.0, with three bands also characteristic for normal granulocytes. The nine bands of normal granulocytes between pH 5.9 and 4.65 showed only weak intensity. An additional six AcP bands could be seen, with pI values extending from 4.5 to 3.8. Like normal T-lymphocytes, KM 3 displayed one band at pH 6.3. The other 3 cultured cell lines (Ball-1, Molt-4, JM) revealed regularly arranged AcP bands between pH 6.3 and 3.8, separated by pH distances of 0.1–0.2 and without any characteristic distribution pattern in the pI values or in the intensity. In Ball-1, the typical AcP pattern of normal B-lymphocytes—1 band at pH 6.3 and 11 bands between pH 5.3 and 3.85—could not be verified.

Samples of cell lines as well as of normal cells treated with neuraminidase showed in some cases a cathodic shift of individual enzyme bands. The distribution pattern and the number and intensity of the bands, however, remained unaltered.

DISCUSSION

The lysosomal hydrolases AcE and AcP have often been studied in investigations of normal and neoplastic blood cells (*23–26*). In recent reports we demonstrated that the different cytochemical patterns of AcE and AcP activity in normal human blood cells are associated with blood cell-specific isozymes, as analyzed by isoelectric focusing (*1, 2*). Using the cell-specific isozyme pattern as a biochemical blood cell marker, we were able to trace the B-cell origin of human malignant lymphomas (*3*) as well as the cellular derivation of different leukemias (*5*). Furthermore, the monocytic origin of resident human peritoneal macrophages could be established by the blood cell-specific AcE isoelectric focusing patterns (*4*). These results demonstrated that the isozyme patterns of AcE and AcP can be regarded as reliable blood cell markers, in terms of physicochemical properties and antigenicity (*27*), and that they resist functional alterations and neoplastic transformations.

Attempts to relate enzyme banding patterns obtained by isoelectric focusing to the isozyme distributions obtained by conventional standard electrophoresis (*28, 29*) failed to demonstrate a clear correlation (*30, 31*). The main difficulty arose in relating certain standard electrophoresis patterns or bands to individual cell types. In contrast, with the use of isoelectric focusing, we were able to establish a clearly defined cell-specific pattern for the individual blood cell types (*1, 2*). This certainly is due to the far better resolution capacity of isoelectric focusing than that of standard electrophoresis. In addition, isoelectric focusing seems to circumvent difficulties expected from the microheterogeneity of the enzyme proteins. Treatment of crude samples with hydrolytic enzymes (e.g., neuraminidase) does not alter number, intensity, and distribution pattern of the individual bands (*3*). For the human system, however, no information is available as to the genetic control of the individual enzyme protein variants that are neither resolved by standard electrophoresis nor by isoelectric focusing. Nevertheless, no significant variations were observed in intensity, number, and location of the bands among normal human donors (*1, 2*).

We thought it of interest to study the expression of isozymes in different blood cell types also under long-term cell culture conditions. Thus we analyzed AcE and AcP in five well-defined permanent cell lines derived from human leukemias.

A direct comparison of the total enzyme values of normal and neoplastic cells is not possible, inasmuch as the exact normal cellular counterparts of the analyzed neoplasias are not available. All 5 cell lines analyzed in this study displayed considerably higher activities for both enzymes (table 2) than did the normal cells (table 3). Enzyme inductions have been shown for a panel of lysosomal hydrolases during different growth phases of lymphoid cell line culture (*32*). A similar phenomenon repeatedly has been reported to occur during cultivation of monocytes and macrophages (*33*). Thus culture conditions seem to stimulate lysosomal enzyme production. Furthermore, neoplastic cell lines have been found to develop a higher synthetic activity for lysosomal enzymes under culture conditions than do cultured normal cell lines. Sippell et al. (*34*) encountered a significantly higher rise in the activities of α-glucosidase, β-glucosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, and AcP in malignant lymphoid cell lines than in cultured normal lymphocytes. The differences were attributed to the higher general metabolic activity as well as to the growth rate of neoplastic cells in cultures.

The results of isoelectric focusing of AcE in the analyzed cell lines (fig. 1A) showed that the banding patterns of normal cells (fig. 1B) were basically detectable in the corresponding neoplastic cell lines. The two acute T-lymphoblastic leukemia lines (JM, Molt-4) and KM 3 displayed two of the three AcE complexes found in normal T-lymphocytes (text-fig. 1). Whether these cell lines are derived from different T-cell subpopulations, which are known to differ in their Fc receptor for immunoglobulins as well as in their cytochemical AcE and AcP reaction patterns (*35, 36*), remains to be determined. Another possibility as the underlying reason for the observed differences in isozyme patterns could be the immaturity of the cultured cell lines as compared to the mature state of normal T-lymphocytes of peripheral blood. The promyelocytic leukemia line HL-60 expressed only 7 of the 11 AcE isozymes found in normal granulocytes (text-fig. 1). This is probably due to the relative immaturity of HL-60 as compared with normal mature granulocytes of the peripheral blood. In cytochemical terms, typical patterns of activity of lysosomal enzymes have been found for the individual maturation stages of human granulocytes (*37–39*), which might reflect the phenotypic expression of repression or derepression of the corresponding genes.

In contrast to AcE, the classification of the analyzed cell lines by AcP isozymes was only possible for two lines (fig. 2A, 2B; text-fig. 2). For line KM 3, reliable assertion could be made only for lymphocytic origin. This cell line showed the typical intense single AcP band at pH 6.3, as in the B- and T-lymphocytes (*1*). The granulocytic derivation of HL-60 was documented by the occurrence of the 12 typical AcP bands seen in normal granulocytes. A similar conclusion could not be made for lines Ball-1, JM, and Molt-4 because of the uncharacteristic distribution pattern of AcP isozymes.

Several investigators have studied enzyme activity and polymorphism under in vitro conditions, by cytochemical as well as electrophoretic methods, and have found a good correlation between normal cells and malignant cell lines with respect to cytochemical behavior and isozyme patterns. Some results, however, indicated the possibility that in vitro culture might lead to quantitative and qualitative alterations of enzyme expression. This was specifically the case for the cytochemical behavior of AcE in neoplastic T-lymphocytes (*40*) and β-glucuronidase in neoplastic B-lymphocytes (*8*), as compared to the behavior of their normal counterparts. Conversely, Povey et al. (*41*) demonstrated typical electrophoretic patterns of enzyme phenotypes that resisted culture manipulations. In other studies Wright et al. (*42, 43*) reported isozyme stability after malignant transformation of normal cells in vivo and long-term culture of neoplastic cells in vitro. Although the stability of banding patterns in long-established cell lines also was demonstrated by Hunter (*44*), he pointed out that under different culture conditions as well as during long-term culture, changes in cell population composition or cell characteristics were detectable. Furthermore, the isozyme expression of cultured cell lines may be the result of facultative hybridization, as proposed by Heyden et al. (*45*).

Our results mainly confirm that culture conditions leave the basic patterns of isozymes unaltered. Isozyme mapping, therefore, can be applied to problems concerning derivation of a given cell type. In some instances of AcP activity, culture conditions seem to exert stimulatory and/or repressive effects on isozyme expression. The exact mechanisms responsible for such alterations are not known. Not only the malignant transformation but also the accelerated cell replication under culture conditions are apt to be influential. Also, it cannot be excluded that minor subclones with different enzyme expression, not yet identifiable, may overgrow under prolonged in vitro culture (*46*). Furthermore, isozymes might differ in terms of their stability.

In addition to morphological and functional studies (*6*), as well as cytochemical (*8*), surface receptor (*7*) and chromosome analyses (*47*), and the study of surface glycoprotein patterns (*9, 10*), the investigation of enzyme polymorphism seems to be a reliable method for the characterization of cell lines and for the monitoring of their population composition. Whether all or which of these isozymes might represent distinctive cell-specific markers in biochemical (*1, 2, 4*) and immunological terms (*27*) has yet to be determined. Further systematic investigations, are required to extend our thinking on the diversity of cell surface properties (differentiation antigens, cell cycle antigens, tissue antigens, fetal antigens, tumor antigens, etc.) to include the enormous body of intracytoplasmic enzyme proteins and their polymorphic subtypes. We are, therefore, currently studying cell-specific isozymes of AcE as intracytoplasmic targets for corresponding monoclonal antibodies.

Subpopulations of Human T-Lymphocytes. XIX. T-Cells and T-Cells With Receptors for IgMFc ($T\mu$), IgGFc ($T\gamma$), or IgAFc ($T\alpha$) in the Peripheral Blood and Regional Lymph Nodes of Patients With Untreated Breast Cancer[1,2,3]

Sudhir Gupta[4,5] *and* **Susanna Cunningham-Rundles**[4]

ABSTRACT—Peripheral blood and regional lymph node mononuclear cells from 43 untreated patients with breast cancer were analyzed for the proportions of total T-cells and T-cells with receptors for the Fc portion of IgM ($T\mu$), IgG ($T\gamma$), or IgA ($T\alpha$). Proportions of total T-cells and $T\mu$ cells both in peripheral blood and lymph nodes from breast cancer patients were comparable to those from health controls. The proportion of $T\gamma$ cells, however, was significantly ($P<0.01$) increased in the peripheral blood and lymph nodes from breast cancer patients as compared to that from controls. The proportion of $T\alpha$ in the peripheral blood was comparable; however, when compared to the number of $T\alpha$ cells in control lymph nodes, $T\alpha$ cells were increased ($P<0.025$) in the regional lymph nodes from patients with breast cancer. When data on the proportions of T-cells and T-cell subsets were analyzed according to the presence or absence of metastatic disease in the regional lymph nodes, the proportion of $T\gamma$ cells was significantly ($P<0.025$) higher in the peripheral blood from patients with metastatic disease than in patients with nonmetastatic disease. This study demonstrates an abnormality of T-cell subsets in the peripheral blood and the regional lymph nodes from patients with breast cancer. The significance of these observations is discussed—JNCI 1982; 69: 1261–1264.

Several studies have reported immunologic abnormalities in patients with breast cancer. These abnormalities include impairment of proliferative response to mitogens, depressed delayed cutaneous hypersensitivity, alterations in NK and antibody-dependent cellular cytotoxicity, and increased levels of circulating immune complexes (*1–10*). Data regarding absolute lymphocyte counts and total T-lymphocytes in breast cancer are, however, conflicting (*10–15*). Furthermore, in most of these reports simultaneous immunologic studies have not been done in the peripheral blood and regional lymph nodes in patients with breast cancer. It is now well recognized that T-lymphocytes are heterogeneous with regard to their effector and immunoregulatory functions (*16*). Therefore, altered immune response in breast cancer could be a consequence of change in the proportions of distinct subsets of T-lymphocytes. Recently, functionally distinct subpopulations have been classified on the basis of the presence of receptors for immunoglobulin isotypes (*16–19*) and differentiation antigens as defined with monoclonal antibodies (*20*). T-cells with receptors for IgMFc ($T\mu$) have been shown to provide help in the differentiation of B-cells to plasma cells in a pokeweed mitogen-driven system, whereas T-cells with receptors for IgGFc ($T\gamma$) suppress the differentiation of B-cells to plasma cells in a similar system (*21*). Reinherz et al. (*22*) using monoclonal antibody analysis demonstrated that the $T\gamma$ cells reacted with the OKM1 antibody that is said to define the antigen present on cells of the monocyte–myeloid lineage. However, Fox et al. (*23*) and others [reviewed in (*16*)] using monoclonal antibodies and other criteria have shown that $T\gamma$ cells belong to the T-cell lineage. Heterogeneity of $T\mu$ cells (*16*) has been demonstrated by the presence of concanavalin A-inducible suppressor cells in $T\mu$ cells. Similar heterogeneity exists in monoclonal antibody-defined T-cells as well. Thomas et al. (*24*) have demonstrated the presence of suppressor cell activity in OKT_4^+ cells. T-cells with receptors for IgAFc ($T\alpha$) have been shown to be distinct from $T\mu$ or $T\gamma$ cells (*25–27*) and appear to contain cells with immunoregulatory activity for an IgA-specific response (*28*). We have shown that $T\gamma$ cells also mediate natural killing and antibody-dependent cytotoxicity (*29*). Natural killing has been suggested to play an important role in immune surveillance against tumors (*30*). Therefore, in this study we examined the proportions of total T-cells and $T\mu$, $T\gamma$, and $T\alpha$ cells in the peripheral blood and regional lymph nodes from patients with untreated breast cancer and correlated them with the presence or absence of metastatic disease. At the time this study was initiated, monoclonal antibodies defining T-cell subsets were commercially unavailable.

MATERIALS AND METHODS

Peripheral venous blood and regional lymph nodes from 43 women with breast cancer were studied. Analysis of peripheral blood and lymph nodes from each patient was done on the same day. The entire section of lymph node (not the fragments) was used. Eighteen patients had metastatic disease, whereas 25 patients had no evidence of metastasis. All lymph nodes from patients with metastatic

disease were tumor bearing. Forty healthy age-matched women served as controls for peripheral blood. Analysis of normal lymph nodes obtained from 15 subjects with nonmalignant disease at the Memorial Hospital was performed at different times. Total peripheral blood lymphocyte counts in patients and controls were similar; therefore, data will be presented for the percentage of lymphocyte subpopulations.

Isolation of mononuclear cells.—Lymph node tissues were gently teased with sterile 18-gauge needles and were washed twice by centrifugation. One-half of each lymph node was retained for histopathologic examination. Mononuclear cells from peripheral venous blood were isolated on an FH density gradient. Blood and lymph node mononuclear cells were washed three times in HBSS. A small sample of mononuclear cells was incubated with latex particles (The Dow Chemical Co., Indianapolis, Ind.) for the identification of contaminating monocytes and was used for the enumeration of total T-cells. For the analysis of T-cell subsets, mononuclear cells were resuspended in medium containing 20% FCS at 4×10^6/ml. To this suspension was added carbonyl iron (Lymphocyte Separator Reagent, Technicon Instruments Corp., Tarrytown, N.Y.) at a ratio of 2:1 (vol/vol), followed by incubation on a rotator at 37°C for 30 minutes. Phagocytic cells were depleted on another FH gradient (*31*). Phagocytic cell-depleted lymphoid cells were washed three times in HBSS and resuspended at a concentration of 4×10^6/ml. This preparation contained less than 2% monocytes. The viability was greater than 98% as tested by the trypan blue dye exclusion test. These cells were used to separate T- and non-T-cells.

Purification of T-cells.—Aliquots (1 ml) of phagocytic cell-depleted lymphoid cell suspensions were mixed with an equal volume of 1% neuraminidase-treated SRBC, incubated at 37°C for 5 minutes, centrifuged at $200\times g$ for 5 minutes, and incubated further on ice for an additional 1 hour. Pellets were gently resuspended, and rosetting T-cells were separated from nonrosetting non-T-cells on an FH gradient (*31*). SRBC attached to T-cells were lysed with Tris buffer containing ammonium chloride (pH 7.2). Cells were washed three times in HBSS, resuspended in medium containing 20% FCS, and incubated overnight at 37°C. Following incubation, T-cells were washed with HBSS, resuspended in HBSS at 3×10^6/ml, and assayed for T-cell subsets. These preparations contained greater than 97% T-cells, as determined by rosette formation with SRBC and lack of cells with readily demonstrable surface immunoglobulins.

Enumeration of total T-cells.—One hundred microliters of latex-ingested mononuclear cell suspension were mixed with an equal volume of 1% SRBC and 25 μl of heat-inactivated SRBC-absorbed human AB serum. The mixture was incubated at 37°C for 5 minutes, centrifuged at $50\times g$ for 5 minutes, and further incubated overnight on ice. The pellet was gently resuspended, a drop of trypan blue was added, and rosette-forming cells were counted in a hemacytometer. The results are expressed as percent of total lymphocytes.

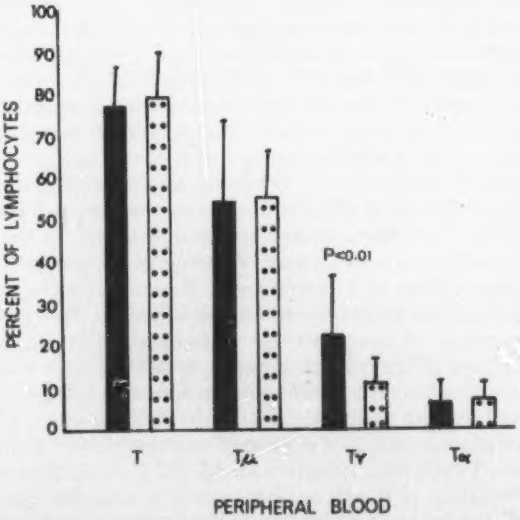
Determination of T-cell substrates.—T-cell subsets were assayed by rosette formation with OXRBC-IgM anti-OXRBC (EA_M), OXRBC-IgG anti-OXRBC (EA_G), or trinitrophenyl-coated OXRBC-MOPC-315 IgA myeloma (EA_A) complexes. Preparation of these complexes is described elsewhere (*31, 32*).

Purified T-cell suspensions (100 μl) were mixed with an equal volume of 1% EA_M (for Tμ), EA_G (for Tγ), or EA_A (for Tα) complexes and centrifuged at $200\times g$ for 5 minutes, followed by incubation on ice for 1 hour. Pellets were resuspended and rosette-forming lymphocytes counted. A lymphocyte with three or more OXRBC attached was considered a rosette. Tμ and Tγ cells were counted with a light microscope. Cytocentrifuge preparations of Tγ cells were stained with nonspecific esterase to exclude any contamination of monocytes. In a Tα cell suspension, a drop of 0.01% euchrysine was added and rosette-forming Tα cells were counted with a Leitz Orthoplan fluorescence microscope equipped with epi-illumination. T-cell subsets were expressed as percent of total T-cells. Statistical analysis was performed by the Student's *t*-test.

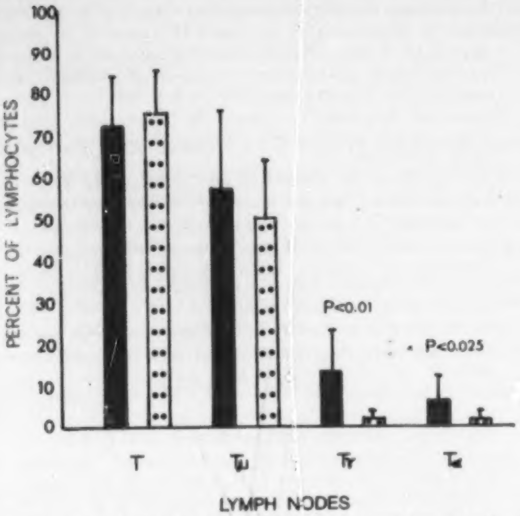
RESULTS

Data for T-cells and T-cell subpopulations in the peripheral blood from patients with breast cancer and healthy controls are shown as means plus or minus standard deviations in text-figure 1. The proportions of total T-cells, Tμ cells, and Tα cells were comparable in 2 groups; however, the proportion of Tγ cells in the patient group was significantly ($P<0.01$) increased when compared to that in the controls. The ranges for total T-cells, Tμ cells, Tγ cells, and Tα cells in the patient group were 54–92, 22–87, 6–54, and 0–32%, respectively; in controls, they were 60–93, 25–75, 6–20, and 2–22%, respectively.

Results obtained with T-cells and T-cell subsets in the regional draining lymph nodes from patients with breast cancer and normal lymph nodes are shown in text-figure 2. The proportions of total T-cells and Tμ cells were comparable in the 2 groups; however, the proportions of Tγ cells



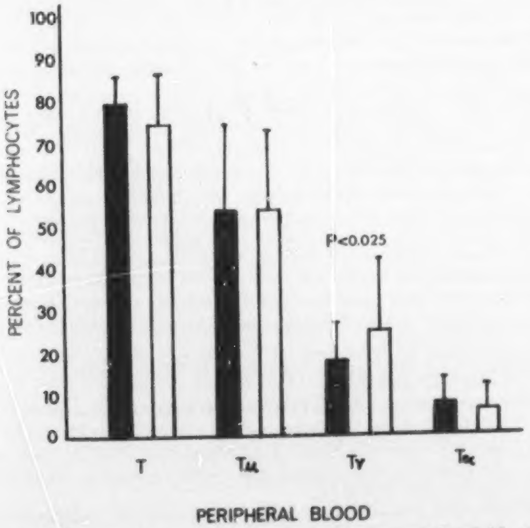
TEXT-FIGURE 1.—T-cells and T-cell subpopulations in the peripheral blood of patients with breast cancer (■) and healthy controls (⊡). Results are means ± SD.



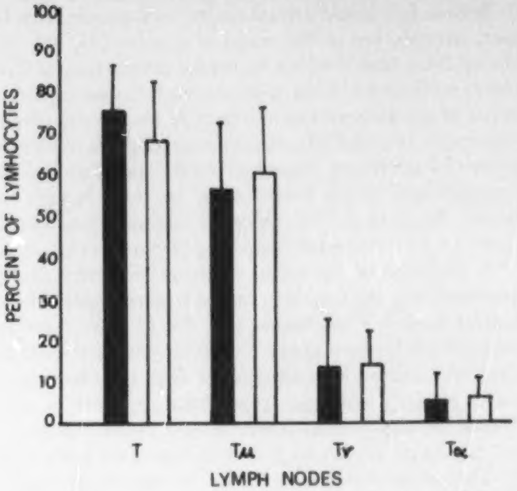
TEXT-FIGURE 2.—T-cells and T-cell subsets in regional lymph nodes from patients with breast cancer (■) and cervical lymph nodes from subjects with nonmalignant disease (▨). Results are means ± SD.

and Tα cells were significantly ($P<0.01$; $P<0.025$) increased in the lymph nodes from cancer patients as compared to the proportions in normal lymph nodes. The ranges for total T-cells, Tμ cells, Tγ cells, and Tα cells in lymph nodes from cancer patients were 50–90, 20–87, 2–43, and 0.5–25%, respectively; in control lymph nodes, ranges were 56–84, 22–79, 0–6, and 1–7%, respectively.

Data on T-cells and T-cell subsets in patients with or without metastatic disease were compared. Results of such an analysis in the peripheral blood are shown in text-figure 3. The proportion of Tγ cells was significantly ($P<0.025$) increased in the blood of patients with metastatic disease (range 6–54%) when compared to that in the blood of patients without metastatic disease (range, 6–34%). The proportions of T-cells, Tμ cells, and Tα cells in the group with metastatic disease (range, 70–92, 22–83, 2–25%, respectively) were comparable to values in the group without metastatic disease (range, 54–90, 21–87, 0–32%).



TEXT-FIGURE 3.—T-cells and T-cell subsets in the peripheral blood of patients with (□) or without (■) metastatic breast cancer. Results are means ± SD.



TEXT-FIGURE 4.—T-cells and T-cell subsets in the regional lymph nodes from patients with (□) or without (■) metastatic breast cancer. Results are means ± SD.

Text-figure 4 shows no significant difference in the proportions of T-cells, Tμ cells, Tγ cells, and Tα cells in the lymph nodes from patients with metastatic disease (range, 50–90, 20–84, 2–43, 0.5–25%, respectively) or without metastatic disease (range, 50–86, 20–87, 2–28, and 0–18%, respectively).

DISCUSSION

In this study, we have demonstrated a significant increase in the proportion of Tγ cells in the peripheral blood and regional lymph nodes from patients with breast cancer and a significantly increased proportion of Tα cells in the regional lymph nodes from patients with breast cancer when compared to the values in controls. When data were analyzed according to the presence or absence of metastasis, Tγ cells were increased in the peripheral blood of patients having lymph nodes with metastatic disease. Cunningham-Rundles et al. (*7*) have reported an increase in NK function in lymph nodes from a *subset* of patients with breast cancer. Since Tγ cells have been shown to contain NK function, it remains to be determined whether the increase in Tγ cells in the peripheral blood represents a subpopulation that contains suppressor activity or NK activity. In a few patients in whom both NK activity and T-cell subset analyses were done on the same samples, a correlation between increased Tγ cells and increased NK activity was observed in only 50% of the cases studied (data not shown). Ermin et al. (*8, 10*) reported variable but prominent NK function in patients with breast cancer. Tα cells have been shown to contain immunoregulatory functions for an IgA-specific response

(*28*). Serum IgA levels are increased in patients with breast cancer, irrespective of the stage of disease (*33, 34*). In this study we have observed an increased proportion of $T\alpha$ cells in the lymph nodes from patients with breast cancer, irrespective of the presence or absence of metastatic disease. It is reasonable to speculate that increased levels of serum IgA in patients with breast cancer could be due to an increase in the proportion of $T\alpha$ helper cells in their lymph nodes. Recently, Pucci et al. (*35*) reported increased proportions of $T\alpha$ cells in patients with bronchogenic and colon carcinomas. A number of investigators have reported decreased proportions of total T-cells in breast cancer, especially in the advanced stage of the disease (*11, 13, 14*). We have found normal proportions of total T-cells in patients with breast cancer; this finding is in agreement with the observation of Goust et al. (*15*) who have reported a decrease in a subset of T-cells in patients with metastatic breast cancer. This subset has been shown to inversely correlate with $T\gamma$ cells (*36*). This relationship would be in agreement with our observation of increased $T\gamma$ cells in metastatic breast cancer. Studies are required of lymphocyte subpopulations in the peripheral blood, regional lymph nodes, and primary tumor tissue with the use of monoclonal antibodies to understand the mechanism(s) for immune alterations in patients with breast cancer.

Epidemic Curve of Respiratory Cancer Due to Chloromethyl Ethers[1,2]

William Weiss, M.D.[3]

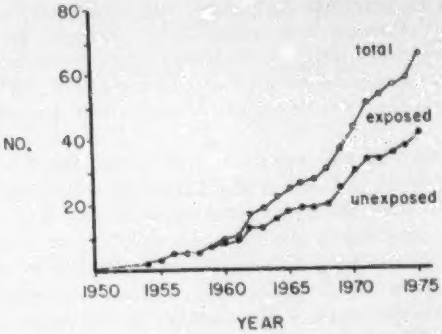
ABSTRACT—In 1962, suspicion arose that an excess of lung cancers was developing in a chemical plant. A prospective cohort study of 125 male workers was begun, and the group was followed from January 1963 to the end of 1979. A small epidemic of respiratory cancer evolved, including 14 cases of lung cancer (13 were the small cell type) and 2 cases of laryngeal cancer among 91 men exposed to chloromethyl ethers in the 17-year period, as compared to 2 cases of lung cancer among 34 unexposed men. The lung cancer epidemic peaked 15–19 years after onset of exposure and began to subside thereafter.—JNCI 1982; 69:1265–1270.

In parallel with the rising incidence of lung cancer in the U.S. male population, cases of lung cancer began to appear in the work force of approximately 2,000 employees at a large chemical plant in the 1950's. The cumulative number of lung cancer cases (text-fig. 1) rose steadily at a rate of 1–2 per year until 1962 when 7 cases developed. During the next 5 years, the annual number of lung cancers ranged from 1 to 4, averaging 2.2. By use of the scan statistic for detection of clustering over time (*1*), the incidence of 7 cases in 1962 did not prove to be a cluster that was statistically significant at the 0.05 level. Therefore, an ongoing program of annual surveillance might not have uncovered the onset of a microepidemic if statistical evaluation alone had been used as the criterion for significance.

However, among the 7 cases were 3 characterized by their occurrence in men 33–39 years old, all of whom worked in a single building (building B) which housed approximately 45 employees. This cluster of cases attracted the attention of the plant physician and stimulated further investigation in December 1962.

In January 1963, a semiannual screening study of all 45 men who had been working 3 months or more in the building in question and 80 men in other buildings was begun. Four cases of lung cancer, all small cell carcinomas, developed in this cohort during the next 5 years, but only 1 of these occurred in the suspect building. In 1968, animal studies by Van Duuren et al. (*2*) provided information indicating that BCME was carcinogenic for mouse skin and when injected sc in rats. In the suspect building at this plant, CMME was being used as an alkylating agent in the production of various organic chemicals. It was contaminated with small amounts of BCME, but Van Duuren had not found CMME to be carcinogenic in animals. This fact and the observation that only 1 of 4 cases of lung cancer in the cohort had worked in the suspect building where CMME was being made suggested that CMME was not causing cancer in this cohort.

In 1971, a preliminary report by Laskin et al. (*3*) indicated that BCME is a very potent carcinogen when inhaled by rats. Since CMME in the industrial setting was contaminated with small amounts of BCME, the CMME process was promptly eliminated until it could be completely automated, and an epidemiologic investigation of the entire plant was initiated. Hereafter, industrial CMME will be called CME.



TEXT-FIGURE 1.—Cumulative number of lung cancer cases (1950–75) by exposure to chloromethyl ethers, in a large chemical plant. *Upper curve* is total No. of cases, *lower curve* is No. among unexposed workers, and intercurve area is No. among exposed workers.

CME had first been used in the plant in 1948. It was produced and used in two other buildings, hereafter called buildings A 1 and 2. A retrospective assessment of exposure on a semiquantitative scale in every plant worker over the 24 years from 1948 to 1971 was initiated, and it became clear that the 3 men who developed lung cancer in 1963–68 but were not working in the suspect building, hereafter called building B, had been exposed earlier in buildings A 1 and 2.

In 1973, a preliminary report of the microepidemic in the cohort of 125 men established in 1963 was published (*4*). The further development of exposure data led to publication of a series of papers on various aspects of the cohort study (*5–9*) as well as of reports on a historical prospective study of all workers at the plant (*10, 11*).

The purpose of this paper is to update the results of the cohort study begun in 1963, to report the results of 17 years of follow-up (1963–79), and to document the epidemic curve of respiratory cancer in this group of 125 chemical workers.

METHOD

A group of 125 male production workers was assembled in January–March 1963 and screened with 70-mm chest

photofluorograms and questionnaires regarding age, smoking habits, and respiratory symptoms. These men included 45 who had worked 3 months or more in building B and 80 from other buildings. Among the 80 men were 18 who had worked in building B in previous years and 28 who had worked in buildings A 1 and 2 and had been exposed to CME. Follow-up was maintained through semiannual screening for 5 years and thereafter by periodic tracing. Vital status was determined as of December 31, 1979, for all but 3 members of the cohort. These 3 were assumed to be alive.

For the 116 men who were white and the 9 who were black, 1,869.5 man-years of observation were available for 1963–79. SMR for lung cancer were calculated by comparing the observed to the expected numbers of lung cancer deaths. The expected number was estimated by applying Philadelphia 5-year age-specific and period-specific white male mortality rates to the number of man-years of observation in each 5-year age group in each 5-year period (except for the initial period of 1963–64). White male rates were used because 93% of the cohort was white. These rates were derived from official population estimates and numbers of deaths reported for 1960–64, 1965–69, 1970–74, and 1975–79. Because the Philadelphia population figures for the years 1971–79 have proved to be overestimated in comparison with the overall population count of the 1980 census and because, for 1980, counts by age, race, and sex are not yet available (November 1981), estimates of the age-, race-, and sex-specific population bases for 1971–79 were obtained from the Population Division, U.S. Bureau of the Census. The method for making these estimates is described in (*12*). Population estimates for 1972 were combined with 1970–74 death counts to obtain white male age-specific mortality rates for the 1970–74 period, and population estimates for 1977 were similarly used for the 1975–79 period.

Inasmuch as the chemical plant was located in an area of Philadelphia (Health District No. 7) that had relatively high lung cancer mortality rates in 1968–72 (*13*), the SMR was also calculated from Health District No. 7 data. Although these rates included only part of the follow-up period 1963–79, they dealt with data from approximately the middle 5 years in the 17-year follow-up period. Therefore, despite the changing lung cancer mortality rates, the use of these rates is reasonable.

An SIR was also separately calculated for lung cancer and for laryngeal cancer by use of the average white male cancer registry data reported by Waterhouse et al. (*14*) in the San Francisco Bay, Alameda, and Detroit registries for 1969–73, the middle 5 years of the 17-year observation period. The number of attributable cases was calculated as the difference between the observed and expected numbers of cases.

The development of exposure data was difficult because CME had been manufactured and used in three buildings at different times, changes of employees relative to the chemical processes had been frequent, and employee exposure to CME had diminished as a result of process improvements over time. Because suitable workplace chemical determinations of CMME or BCME concentrations had not been made in the study period before automation of the process, supervisory personnel associated with the manufacture and use of CME during 1948–72 were asked to rank the exposure for all job classifications. This was done retrospectively on an arbitrary scale from 0 to 6. Work histories and exposure ratings for each job at every important stage in the development of the process were used to calculate the time-weighted average exposure ratings and total exposure times for each employee. An exposure index was calculated for each man by cumulation of the total exposure.

In the group of 125 men, 34 had had no exposure to CME whereas 91 had had varying cumulative exposures. The temporal trends in exposure on a population basis were calculated from a mean annual exposure index for a given group of men for each year of exposure, as follows: For each man per group per year, the number of months spent at each exposure rating was multiplied by that rating, and the results were summed. The annual exposure thus calculated was summed over all the men exposed in that year and divided by the number of men in the group living in that year, whether exposed or not in that year. Although the distribution of annual exposures was not Gaussian, this calculation provided an annual per capita exposure which gave a rough estimate of population exposure for any group of ever-exposed men.

The pattern of CME exposure differed in two groups. One group of 28 men was exposed more intensely and for a shorter time in buildings A 1 and 2 during 1948–54 when the process was being developed, whereas the other group of 63 men was exposed to a lesser degree over a more prolonged period in building B during 1954–71. From 1962 on, the latter group received decreasing exposures because control procedures were instituted in the manufacturing process. There was very little overlap between these 2 groups because employees usually did not transfer when a process was moved. In this cohort only 4 of the 91 exposed men were exposed at both plant sites, and these doubly exposed men were allocated arbitrarily to the group for which exposure was limited to building B. None of those 4 developed cancer.

All CME-exposed men were assigned to groups according to the total cumulative exposure index (dose) attained by the time of death or by 1971, whichever came first, for the purpose of calculating crude 17-year respiratory cancer risks on a percentage basis. These groups were delineated by dose as follows: less than 10.0, 10–24.9, and 25 U or more. These doses were based on estimates of exposure to CME. In 1948–50, several batches of BCME were made in building A 1, but no attempt was made to account for this type of exposure when the rating system was developed because the greater potency of BCME compared to CMME as a carcinogen was uncertain at the time the rating system was devised, the exposure to BCME batches was limited, and there are no records as to who was exposed to the batches of BCME; therefore, no correction was feasible retrospectively.

Microscopic sections of all but 1 of the cancers were reviewed by Dr. Oscar Auerbach, Distinguished Physician, East Orange Veterans Administration Hospital, East Orange, N.J. Each tumor was typed according to a modification of the World Health Organization classification of lung cancer (*11*).

RESULTS

Incidence and Mortality

The cohort of 125 men experienced 37 deaths in the 17 years 1963–79. The expected number of deaths from all causes on the basis of Philadelphia white male age- and period-specific rates was 22.02; therefore, the overall SMR was 1.68. Fifteen of the 37 deaths were due to lung cancer, and 13.23 were attributable to exposure to CME. Thus lung cancer accounted for almost all the excess mortality.

The incidence of respiratory cancer in the whole cohort during the 17-year observation period was 18, including 16 lung cancers and 2 laryngeal cancers. Fifteen of the 16 men with lung cancer died during the period, whereas 1 was diagnosed in 1979 but was still alive at the end of the period. Among the 15 lung cancer deaths, all but one were attributed to this disease on the death certificate; the certified cause of death in the single exception was "undifferentiated malignancy" in 1 of the 4 men who died in the most recent 5-year period. The clinical records in this case confirmed the diagnosis of bronchogenic carcinoma.

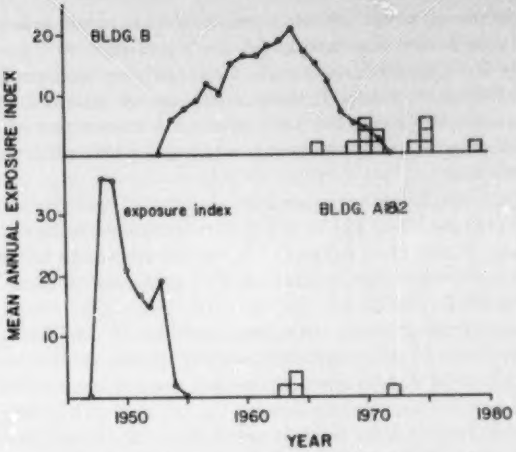
The SMR for lung cancer was 8.45, from the use of Philadelphia white male lung cancer death rates, and 13.23 cases were attributable to chemical exposure. The figures were almost the same when lung cancer mortality rates for Health District No. 7 (the area surrounding the plant) in 1968–72 were utilized: The SMR was 7.43 with 12.98 attributable cases. Likewise, the SIR of 8.52, as based on male cancer registry rates in 1969–73, was almost identical with the SMR based on Philadelphia mortality rates, although the attributable number was a little higher, 14.12, on the basis of incidence. All of the ratios were elevated statistically to a highly significant degree, as determined by the Poisson distribution ($P<0.001$).

There were 2 cases of laryngeal cancer in 1974 and 1975; both were squamous cell carcinomas. The expected number on the basis of registry rates was 0.28; the resultant SIR of 7.09 was almost as high as that for lung cancer. This elevation, however, was not quite statistically significant ($P=0.08$). Inasmuch as a large proportion of men with laryngeal cancer do not die of their disease, the SMR was not calculated.

Two cases of lung cancer (5.9%) developed among 34 men who had not been exposed to CME, whereas 14 cases of lung cancer and 2 cases of laryngeal cancer (total of 17.6%) occurred among 91 men who were exposed.

Temporal Trends

Text-figure 2 shows the temporal relationship of cancer cases to exposure in the two different plant sites: building B and buildings A 1 and 2. The curves for the mean annual exposure index, on a group basis, show that the population exposure was more intense over a shorter and earlier period for the men who worked in buildings A 1 and 2 than for those who worked in building B. Correspondingly, the cancer cases occurred earlier among the former group, the last case appearing in 1972. There was a large gap between last exposure and the first cancer case in this group. In contrast, there was overlap of exposure and cancer appearance in the group exposed in building B. The frequency of cases in this group was highest in the first half of the decade of the 1970's, and only 1 case occurred in the last 4 years, 1976–79.



TEXT-FIGURE 2.—Mean annual exposure index among 91 employees exposed to chloromethyl ethers and the occurrence of respiratory (lung and laryngeal) cancer cases, 1948–79. *Each block* represents 1 cancer case. Data are divided by building in which exposure occurred.

The latent period, herein defined as the interval from onset of exposure to time of disease, in the 4 cases of lung cancer among men exposed in buildings A 1 and 2 ranged from 16 to 25 years, with a median of 17 years. Among men exposed in building B, the latent period in the 10 cases of lung cancer ranged from 10 to 23 years, with a median of 15.5 years. The latent periods in the 2 men who developed laryngeal cancer among the men exposed in building B were 16 and 17 years. The potential duration of the latent period which could be observed was constrained by the length of follow-up. Among the 91 exposed men, 93% could have been followed 20 years or more, but only 68% could have been followed 25 years or more. These percentages varied very little in subgroups of differing CME doses.

Among the 34 unexposed men, 2 cases of lung cancer occurred; 0.51 had been expected ($P>0.05$). The facts that both cases occurred in men who were cigarette smokers and that one man had a squamous cell carcinoma and the other had a large cell carcinoma suggest that these cases were not attributable to any undocumented exposure to CME.

All but 1 of the 13 lung cancer deaths in the exposed men were due to small cell carcinomas. The single exception, approximating the expected number of 1.26 cases, was a large cell carcinoma. Of the 13 men who died of lung cancer, 7 were current cigarette smokers in 1963 when observation began, 2 were ex-smokers of cigarettes, 1 smoked an occasional cigar, and 3 had never smoked.

Because all 16 respiratory (14 pulmonary and 2 laryngeal) cancer cases among the 91 exposed men occurred only among the 58 men with moderate-to-heavy CME exposure (cumulative dose index, ≥10 U), the remaining analysis will be limited to this group. Text-figure 2 shows that exposure patterns were quite different according to site of CME exposure. Because the median and the range of latent periods were similar for both groups, the epidemic curve can be examined in all 58 men, provided that other potential risk factors were also similar for the 2 groups.

Age is a potential risk factor. Thirteen men were exposed in buildings A 1 and 2; their mean age at onset of CME exposure was 33.15 (SD=3.85). Forty-five men were exposed in building B; their mean age was almost identical: 33.16 (SD=7.70).

The cumulative exposure index was also very similar for the 2 groups: 22.66 (SD=10.71) for the 13 men in buildings A 1 and 2 and 23.27 (SD=11.21) for the 45 men in building B. This difference is not statistically significant (Student's *t*-test=0.17, $P>0.05$).

The smoking factor was examined by the building in which the men were exposed to CME (table 1). While the proportion of nonsmokers was higher among the 13 men in buildings A 1 and 2 than among the 45 men in building B, the numbers of men were so small that this factor had no discernible effect on the crude respiratory cancer risk in the 2 groups. Table 1 shows that the crude 17-year cancer incidence was about twice as high among the nonsmokers as among the smokers in each group, but the overall crude incidence in each group was about the same.

Table 2 shows that the SMR were almost the same for the 2 groups. Therefore, it seems likely that the difference in dose rate experienced in the 2 groups shown in text-figure 2 had no discernible effect on risk.

TABLE 1.—*Distribution of and respiratory cancer incidence in men occupationally exposed to CME*[a]

Groups by workplace and cigarette habit in 1963	Distribution		Respiratory cancer	
	No. of men	Percent	No. of men	Percent of group
Buildings A 1 and 2	13	100	4	31
Nonsmokers	7	54	3	43
Smokers	6	46	1	17
Building B	45	100	12	27
Nonsmokers	7	16	3	43
Smokers	38	84	9[b]	24
Total	58	100	16[b]	28
Nonsmokers	14[c]	24	6	43
Smokers	44	76	10	23

[a] Crude 17-yr (1963-79) cancer incidence was determined for 58 men with moderate-to-heavy CME exposure.

[b] Includes 2 cases of laryngeal cancer.

[c] The 14 nonsmokers included 9 men who had never smoked any form of tobacco, 3 ex-smokers of cigarettes of >1 yr duration at registration, and 2 cigar smokers.

[a] Values were obtained from 1963-79 data for 58 men moderately to heavily CME exposed.

[b] From Philadelphia lung cancer 5-yr age-specific and period-specific mortality rates.

[c] From the Poisson distribution.

In view of this lack of differences by age, cumulative CME exposure, or smoking habit between the 2 groups and in view of the failure of dose rate to influence overall risk of respiratory cancer, the 2 groups have been combined for an examination of the epidemic curve from onset of exposure. Table 3 presents a distribution of the 58 men by age at onset of exposure and the distribution of man-years of observation in 1963-79 by years from onset of exposure. Observation for the 13 men exposed in buildings A 1 and 2 began 15 years after the onset of exposure, inasmuch as the earliest exposure occurred in 1948 and observation started in 1963. Observation for the 45 men in building B was possible beginning not more than 9 years after onset of exposure, inasmuch as the earliest exposure occurred in 1954.

Table 4 shows data for the epidemic curve limited to the 13 lung cancer deaths so that SMR could be calculated. The SMR peaked 15-19 years after onset of exposure when 7 cases were observed, 32 times the expected number. The SMR fell markedly in the two later periods. The attributable number of deaths also peaked at 15–19 years and fell to an even greater extent than the SMR. At 25–29 years, there was only one death, and the SMR was no longer statistically significantly elevated; however, the numbers are small.

DISCUSSION

The degree to which this cohort of 125 men was representative of either the entire plant population or the general population is unknown, except for the men's smoking habits. The percentage of current cigarette smokers in the cohort was 77% in 1963. Age-specific prevalence rates in U.S. males reported for 1966 (*15*) were used to calculate the expected number of current cigarette smokers in the cohort, 56%. Thus smoking was considerably more common in the chemical workers. This complicates an interpretation.

Another potential problem in assessing the results of this cohort study concerns the possibility for some selection bias. The cohort included all men working in building B at the end of 1962. Inasmuch as CME was made and used in the building for 8 years before this time, some men who had been exposed earlier might have failed to be registered in the cohort because of transfers or terminations. It may be possible to investigate the degree to which this happened and to determine whether these individuals differed in certain ways from those who were included in the cohort. In addition, the method by which men from other buildings, some of whom had been exposed to CME in buildings A 1 and 2, were selected for the cohort is uncertain.

A final problem in this research has been the lack of data on CME concentrations in the workplace. This problem has necessitated semiquantitative estimates of dose. These estimates are based on assumptions as to the relationship between the estimates and the actual exposures, and this relationship may not be linear. In addition, the degree to which CMME was contaminated by BCME, a much more potent carcinogen than CMME in animals, may have varied. Neither this factor nor the exposure of certain employees to several batches of pure BCME in building A 1 was taken into consideration in the dose estimates.

Because lung cancer is a common disease in males of the general population as a result of the high prevalence of cigarette smoking, the epidemic curve was described not only in terms of the number of cases observed among the exposed workers but also in terms of relative risk and the attributable number of cases. It is heartening to see that the curves in terms of both methods are subsiding 20–24 years after onset of exposure. It is possible that the descending limb of a curve may be skewed into a long tail because *a*) low doses may be associated with longer latent periods (*10*), *b*) a previous study of this plant suggests (*11*) that low doses may be associated with adenocarcinoma of the lung rather than with small cell carcinoma, and *c*) adenocarcinomas tend to grow more slowly than small cell carcinomas (*16*). Further follow-up is indicated.

The results of this investigation are particularly interesting because the epidemic curve of lung cancer has seldom been described. Several examples come to mind. The cohort study of British physicians by Doll and Peto (*17*) contains significant data showing that the risk of lung cancer in ex-smokers drops slowly but dramatically over 10–15 years.

A more clear-cut example of an epidemic curve for this disease is provided by the follow-up of atom bomb survivors in Hiroshima and Nagasaki. Data published by Beebe et al. (*18*) show that the ratio of observed to expected lung cancer deaths was elevated significantly only among those people exposed to 100 rad or more at the time of the bomb. In this group, lung cancer began to occur 9–12 years after the bomb, with an observed-to-expected ratio of 3.3, but the ratio subsided thereafter to 2.2 at 13–16 years and to 1.7 or less at 17–28 years.

Enterline and Marsh (*19*) have likewise found among employees of a copper smelter that "workers who worked 10 years or less showed large relative excesses in respiratory cancer in the decade following termination of employment and these relative excesses all but disappeared in the next 20 years."

In each of these studies, the decline in risk was related to cessation of exposure. In a situation, such as that described in the present report, in which the pattern of exposure varied by intensity and duration, the description of the epidemic curve in relation to only cessation of exposure may be unrewarding.

In a recent analysis of lung cancer mortality results at the same plant in which the present cohort study was done, Pasternack and Shore (*20*) reported no decrease in relative risk as a function of years since last exposure. Their data showed a relative risk of 2.3 at 1–4 years after exposure stopped, 0.7 at 5–9 years, 1.0 at 10–14 years, and 1.5 at 15–25 years. The trend was irregular, but it may have been confounded by the pattern of exposure.

In the present cohort study, examining crude risk by pattern of exposure (*see* text-fig. 2: short, intense exposure vs. prolonged, less intense exposure) suggests that excess risk began to subside more than 20 years after onset of exposure, regardless of exposure pattern. An examination of the crude risk of respiratory cancer by the interval from cessation of exposure confirmed the observation of Pasternack and Shore: There was essentially no change in the percentage of men who developed cancer. Inasmuch as other important risk factors were similar in the 2 groups with different exposure patterns and inasmuch as the overall SMR were also similar, the observations reported herein suggest that earlier exposures to CME were more important in the eventual development of lung cancer than were the later ones. The importance of early exposures to cigarette smoke in determining the eventual risks of lung cancer has been stressed by Doll and Peto (*21*). Further study of this point is needed.

Epithelial Line From Normal Human Colon Mucosa[1,2,3,4]

B. Shannon Danes[5] *and* **E. Sutanto**[5,6]

ABSTRACT—An epithelial line was established from an explant culture derived from human colon mucosa exhibiting a normal phenotype by taking advantage of two differences in in vitro cell behavior of mixed cell (epithelial-fibroblast) monolayer [rate of adherence to a plastic surface from a suspension and toxicity to collagenase (25 U/ml medium) in the culture medium]. Cells with an epithelial morphology could be identified at all times throughout the first 5 culture months— first as epithelial sheets migrating from explants, then as small clusters within the fibroblast monolayer, and finally after 5 months of selective culturing as the only cell type present. The line maintained an epithelium-like morphology and growth pattern through 27 continuous culture months (35 subcultures) and was clearly distinguishable from colon fibroblast cultures grown under the same conditions. The ultrastructural features of this line that grew as a continuum included extensive membrane interdigitations with intercellular junctions, tonofilaments, mucus droplets, no Weibel-Palade bodies (characteristic of endothelial cells), and microridges uniformly covering the cell surfaces; all of these features were absent in colon fibroblast cultures. Growth kinetics (generation time, saturation density, and life-span) were distinctly different from those of colon fibroblast cultures grown under the same conditions. During 27 continuous culture months, the cells remained diploid (2-3% hyperdiploidy) and showed no evidence of senescence.—JNCI 1982; 69:1271-1276.

Since human colon pathology is predominantly expressed in the mucosa, normal colon mucosal lines are needed for in vitro studies on pathogenesis. Although short-term cultures have been established from normal colon (*1, 2*) and colon adenocarcinoma tissue (*3, 4*), there have been no epithelial lines derived from normal human colon mucosa.

The purpose of this paper was to describe the establishment of a human colon mucosal line that exhibits a normal phenotype and has grown in continuous culture for 27 months.

MATERIALS AND METHODS

Establishment of primary mixed (epithelial-fibroblast) cultures.—A biopsy (1×1 cm) sample was taken from the mucosal surface of a surgical colon specimen obtained at surgical resection for trauma to the colon from a 37-year-old male (blood group O) who had had no family history of colon cancer. This biopsy sample was placed in chilled culture medium [modified EMEM with 10% (vol) FBS containing 50 μg gentamicin and Fungizone/ml medium (pH 7.4)] to be taken to the laboratory. It was then cut into small pieces (1×1 mm), placed in a culture tube containing the same medium, and kept at 4°C for 12 hours. The mucosal pieces were then cut into smaller fragments and washed in fresh medium.

The culture vessel used was a double petri dish (a 60/15-mm dish in a 100/20-mm dish as isolation against external contamination). Four such fragments were placed in the inner dish containing approximately 1 ml medium [EMEM with 25% (vol) FBS without any antibiotics (pH 7.4)]. Optimal migration of epithelial cells was obtained when a 1-ml/28-cm^2 surface area was used to just cover the fragments and floor of the culture dish. The culture vessel was then placed in an incubator having a humidified atmosphere of 5% CO_2 in air at 37°C and left undisturbed for 10 days. At that time each culture was examined microscopically for epithelial migration. Fragments that showed no epithelial migration were removed. Three milliliters of medium was added to the culture with care being taken not to loosen the fragments. The medium was completely changed twice each week.

After the culture floor was completely covered by cells, the mixed cell population was subcultured. The culture was rinsed twice with a trypsin-Versene solution (0.5% trypsin-0.02% Versene, sodium ethylenediaminetetraacetate, in Hanks' balanced salt solution without calcium and magnesium) and then incubated in 1 ml of the same solution for 3-5 minutes at 39°C. After the cells had rounded up but were still adhered, the solution was removed, medium was added, and the cells were loosened into suspension by gentle pipetting by means of a Pasteur pipette. One-half of the cell suspension was put into each of two new culture dishes, which were then placed in a humidified CO_2 incubator. One hour later the medium was changed to remove any cellular debris and traces of the trypsin-Versene solution.

Selection of epithelial cells from mixed monolayer culture.—At each subculture two differences in cell behavior were utilized: 1) rate of adherence to a plastic surface from a suspension and 2) toxicity to the addition of collagenase to the culture medium (*5*).

There was an observed difference in the rate of readherence of cells to the plastic floor. When the cell suspension was introduced into the new dishes, the subcultures were kept at room temperature for 15 minutes. The medium containing the nonadherent cells was transferred to another

dish, and both dishes were incubated. If the predominant cell type in the subcultures containing the cells that adhered in the first 15 minutes were fibroblasts, these dishes were then identified as fibroblasts and used to establish colon fibroblast cultures so that their characteristics could be compared with those of the epithelial line.

Fibroblast growth was suppressed by the incorporation of 25 U collagenase/ml medium (collagenase source— *Clostridium histolyticum*; Grand Island Biological Co.). Collagenase-containing medium was used in cultures for 3 days after subculture followed by 11 days of growth in medium without collagenase and then subcultured into two petri dishes.

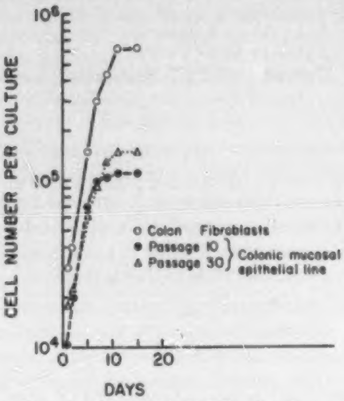
These two procedures were repeated at each subculture (every 2 wk) until the morphology of the total cell population was epithelial. From then on the line was grown in double petri dish cultures containing EMEM with 25% (vol) FBS without antibiotics (pH 7.4) in humidified 5% CO_2 in air at 37°C. Every 2–3 weeks the line was subcultured (1:2 split). Cultures were routinely checked for bacteria and mycoplasma and found to be uncontaminated.

Characterization of epithelial line—Morphology was examined under light, phase, transmission (*6*), and scanning electron (*7*) microscopies. Growth kinetics of both the colon epithelial line and colon fibroblasts were compared by methods previously described in detail (*8*). Every month after the establishment of the line (5–35 subcultures), chromosome preparations were made, stained in acetic orcein, and examined for variations from diploidy. Growth of cells in the nude mouse was determined for evidence of tumorigenicity (*8*).

RESULTS

The sheets of epithelium, observed in the migration zone around each explant during the 1st culture week, increased in surface area gradually over the next 2 months. Such sheets occasionally dispersed into small islands or clumps. Migration of fibroblasts from the explant started in the 2d culture week and continued as long as the explant was present. After the first subculture (after 2 culture mo), several islands of cells with epithelial morphology were observed in the predominantly fibroblast monolayer. With the elimination of fibroblasts by selection (differential adherence to plastic surface and incorporation of collagenase in the medium) at each subculturing, there was a gradual shift in the proportion of epithelial cells to fibroblasts. By the 5th culture month, all cells in the monolayer had an epithelial morphology (fig. 1).

At the 10th and 30th subcultures, the cultures were examined for ultramicroscopic epithelial structures. Numerous intercellular junctions were observed (fig. 2A). Some had the characteristics of desmosomes, and others were nonspecific intercellular junctions, perhaps intermediary in type. Cytoplasmic tonofilaments (9.6 nm in diameter) were also observed. Edges of adjoining cells were connected by extensive membrane interdigitations in which intercellular junctions were frequently seen (fig. 2A). Other structures present were mucus droplets and pinocytotic vesicles (fig. 2C). Microridges uniformly covered the cell surfaces exposed to the culture medium (fig. 3). Weibel-Palade bodies (*9, 10*) and bundles of fine filaments (*10*) as seen in human endothelial cells were not observed.



TEXT-FIGURE 1.—Growth of the epithelial line from normal human colon mucosa at passages 10 (5th culture mo) and 30 (23d culture mo) and a colon fibroblast culture at passage 10 (5th culture mo). Cell samples were plated into plastic petri dishes (growth surface, 28 cm^2) containing EMEM with 25% (vol) FBS and grown in a humidified atmosphere of 5% CO_2 in air at 37°C (pH 7.4). Cell counts were done and medium was changed every 3 days for 15 days.

During logarithmic growth (text-fig. 1), the generation time for this cell line was 31 hours at the 10th subculture and 28 hours at the 30th subculture; colon fibroblast cultures had a generation time of 25 hours at the 10th subculture and had ceased to grow and had been discarded by the 25th subculture. Saturation density occurred at 1.1×10^3 cells/cm^2 growth area, which was at a lower cell density than that for colon fibroblasts (2.2×10^4 cells/cm^2 growth area).

The karotype was 46,XY without obvious chromosome aberrations. The chromosome frequency distribution at the 10th subculture was 99% diploid and 1% hyperdiploid. By the 35th subculture (after 27 continuous culture mo), there had been little change in this distribution (97% diploid and 3% hyperdiploid). Metaphases with diplochromosomes indicating endoreduplication were observed occasionally throughout the 27 culture months. Tumorigenicity was not observed because none of the samples from the cell line inoculated sc into athymic nude mice produced tumors in a 6-month period.

DISCUSSION

In the human colon the epithelial cells are arranged as a single layer of columnar cells lining indentations (crypts of Lieberkühn) into the colon wall. Because replicating colon epithelial cells are found only in the lower two-thirds of the crypt (*11*), it was assumed that the epithelial cells constituting the original cells of this line came from this region.

Lasfargues and Moore (*12*) introduced the incorporation of collagenase into the culture medium to discourage fibroblast growth and thus enhance growth of epithelial cells. Webber (*5*) utilized this selective process to establish short-term cultures of normal and benign human prostate epithelia. If this technique was combined with the difference in the rate of adherence of different cell types from a cell suspension from a mixed (epithelial–fibroblast) monolayer, it was possible to select an epithelial cell population from a mixed fibroblast–epithelial monolayer derived from a colon mucosal biopsy specimen. Cells with an epithelial morphology were identifiable at all times throughout the culture period (5 mo) to establish this line. Initially, the epithelial cells were in sheets migrating from explants, then they were present as small clusters within the fibroblast monolayer, and later, by selection, they were the only cell type present (fig. 1). During the establishment of the cell line, there appeared to be some cell-to-cell interaction and cooperation between the fibroblast and epithelial populations which may have been essential to the epithelial cells. Primary cultures that showed only epithelial migration and no subsequent fibroblast growth grew poorly and failed to subculture.

The culture properties of this cell line met the criteria for cultured epithelium. This line maintained an epithelium-like morphology and growth pattern through 35 subcultures and was clearly distinguishable from fibroblast-like cultures derived from the colon and grown under the same conditions. The line grew as a sheet (fig. 1), whereas the monolayer of colon fibroblasts grew as swirls, the usual pattern for cultured fibroblasts.

Intercellular junctions were numerous (fig. 2A, 2B). In vivo colon epithelial cells are coupled by junctions having three components (tight, intermediary, and desmosome) in apical-basal sequence (*13*). Short-term cultures (up to 8 wk in culture) have shown all three components in sequence (*2*). In this line cell junctions appeared to be single and randomly distributed (fig. 2). Some of the junctions had the morphologic features of desmosomes (*13*) (fig. 2B), but others appeared to be nonspecific intercellular junctions, perhaps intermediary. In this line there was no evidence of a basal-apical orientation. In electron micrographs the cell surface did not have a brush border (fig. 2); in scanning electron micrographs the nonadherent cell surface was covered with microridges (fig. 3) and was quite distinct from the smooth surface of the cultured colon fibroblast. Numerous membrane interdigitations between adjoining cells were present (figs. 1B, 1C, 2A).

Culture senescence was not observed throughout 27 months of continuous culture. The extended life-span of this line was not related to the presence of adventitious agents because routine examinations of cultures for the presence of mycoplasma, bacteria, fungi, protozoa, and viruses were negative. Constancy of culture conditions appeared essential for such continuous growth. A constant pH 7.4, complete medium change twice each week, and subculture (1:2 split) every 2–3 weeks were essential for sustained growth.

On the basis of the definitions adopted by the Terminology Committee of the Tissue Culture Association (*14*), this continuous culture was designated a line even though all cell types present at the first subculture of the primary explant culture were not present. The designation of strain was withheld until specific colon mucosal markers, such as colon-specific antigens, have been identified (*15*). Other mucosal lines have been established with the use of the methodology described for this line, and their properties are currently being characterized.

DNA Content of Liver Cell Nuclei of *N*-2-Fluorenylacetamide-Induced Altered Foci and Neoplasms in Rats and Human Hyperplastic Foci[1,2]

Hideki Mori,[3] Takuji Tanaka,[3] Shigeyuki Sugie,[3] Masayoshi Takahashi[3] *and* **Gary M. Williams[4]**

ABSTRACT—The DNA content of cell nuclei of liver lesions induced in inbred male ACI rats by administration of 0.02% *N*-2-fluorenylacetamide (2-FAA) diet was measured with a microspectrophotometer in Feulgen-stained specimens. Altered liver foci of the eosinophilic, clear, and simple basophilic (toluidine blue weakly positive or negative) types had modal DNA values with a wider deviation (2C–10C) than the euploid pattern of normal hepatocytes (2C–6C). However, the DNA histograms of cells in hyperbasophilic (intensely toluidine blue-positive) foci were aneuploid (2C–18C) and resembled those of cells in hepatocellular carcinomas (2C–23C). Conversely, the modal DNA values of neoplastic nodules showed a narrower range (2C–12C). These results confirm that the hyperbasophilic foci may be a population similar to carcinoma in situ or may be a direct precursor lesion of hepatocellular carcinoma. In the livers from 4 humans, 3 of whom had a history of long-term use of some drugs, multiple hyperplastic foci resembling eosinophilic or clear cell foci in rats were identified. The modal DNA values of the cell nuclei in these foci showed a wider deviation (2C–10C) than in surrounding hepatocytes (2C–6C). In 2 patients, the lesions contained neoplasms and, therefore, hyperplastic foci in humans may be related to tumor development.—JNCI 1982; 69:1277–1282.

In experimental hepatocarcinogenesis in the rat, the altered focus (enzyme-altered focus), which appears soon after exposure to carcinogens, is a proliferative lesion that has been regarded as a precursor of hepatocellular neoplasms (*1–9*). These altered foci are histologically classified as eosinophilic, basophilic, and clear cell in H & E-stained preparations (*10*). Basophilic foci can be subdivided into two types on the basis of staining with toluidine blue (*4, 11*). Hyperbasophilic foci, which are intensely toluidine blue-positive, have been suggested to be related to cancer development (*4, 11, 12*) or even to be microcarcinomas (*13*). Foci have been found to display a number of abnormal properties (*14–19*) that could reflect genetic aberrations (*9*). Morphologic abnormalities in the nuclei of cells in foci have been described (*20*), but genotypic alterations have not been documented. One means of studying the genotype of cells is by measurement of their DNA content (*21–23*).

The amount of DNA in nuclei of neoplastic cells is higher and more variable than that in nuclei of normal cells (*24–30*). Correlations between DNA content and histologic type of cancer or degree of malignancy of tumors have also been documented (*23, 31, 32*). Inui et al. (*33*) reported differences between the modal DNA values of cell nuclei of liver cell adenomas or hepatocellular carcinomas experimentally induced in mice and those of normal hepatocytes. Therefore, the DNA content of the early-appearing altered foci in rat liver that were induced by a hepatocarcinogen was analyzed to further clarify the basic nature of these foci and to determine their potential as precursors of carcinomas.

In the present study, microspectrophotometric estimations of the nuclear DNA content of foci altered by 2-FAA in rats were performed and compared with those of normal liver, neoplastic nodules, and hepatocellular carcinomas. In addition, the DNA values of human hyperplastic liver foci resembling some of the altered foci in rats were also measured. The possible significance of these human liver lesions is discussed.

MATERIALS AND METHODS

Twenty inbred male ACI rats 1.5 months old were fed a 0.02% 2-FAA diet for 15–19 weeks. Twelve of these rats were killed at the termination of feeding. The remaining 8 rats were then transferred to the basal diet CE-2 (Japan Clea Co., Tokyo, Japan) for 10 weeks after which they were killed. Four rats 5–7 months old were used as controls. At necropsy of the animals, each liver lobe was sliced at 4-mm intervals and fixed in Carnoy's solution. The embedded liver slices were cut as three serial sections and stained with H & E (first section) and toluidine blue (second section) and by the Feulgen reaction (third section).

In the liver sections, 28 altered foci [7 eosinophilic foci, 7 clear cell foci, 7 simple basophilic foci (toluidine-blue-negative or weakly positive), and 7 hyperbasophilic foci (intensely toluidine blue-positive)] were obtained in the rats killed at the termination of the 15- to 19-week 2-FAA diet. Seven neoplastic nodules and 5 hepatocellular carcinomas were found in rats given 2-FAA for the same period and then given basal diet for 10 more weeks.

Among recent autopsies of human patients performed at Gifu University Hospital, we encountered 4 cases in which the liver contained multiple hyperplastic hepatocellular foci resembling the altered foci in rats. The morphology and speculated etiology of the liver foci in 1 case have been reported (*34*). In the present study, 20 hyperplastic liver foci were analyzed.

For the measurement of DNA content in cell nuclei, a microspectrophotometer MMSP (Olympus Co., Tokyo, Japan) was used at 545 nm on interphase nuclei. Random samples of 50 Feulgen-reacted nuclei contained within a

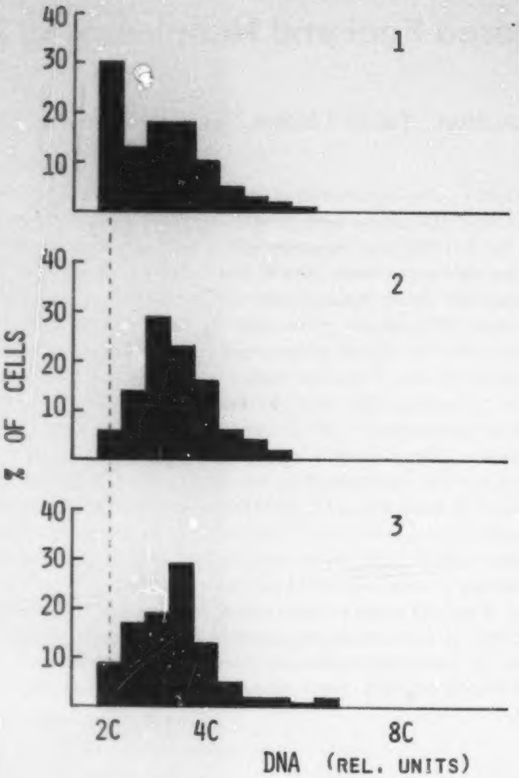
liver section were counted with the use of small lymphocytes as a diploid (2C) control.

RESULTS

The modal DNA values of hepatocellular nuclei of the normal rats and nonlesional portions of the liver in rats given a 2-FAA diet are shown in text-figure 1. The values of hepatocellular nuclei of the normal liver exhibited a fairly sharp modal peak in the diploid region, whereas a secondary peak appeared in the hypotetraploid region with limited deviations around these two modes. About 97% of the cells in the normal liver had DNA values below 5C (table 1). The DNA histograms of hepatocytes in the nonlesional portions of the livers in rats killed after 15–19 weeks on the 2-FAA diet or killed after being fed the 2-FAA diet followed by the basal diet for 10 weeks differed from those of normal liver (text-fig. 1). The modal DNA values of hepatocytes in these livers were slightly deviated to the multiploid range.

Altered foci displayed an architectural pattern that was different from normal, but the plates of hepatocytes were as a rule in continuity with those of surrounding parenchyma and the foci never compressed the surrounding hepatic plates. The DNA patterns of the cell nuclei of hepatocytes in the altered foci induced by 2-FAA administration are shown in text-figure 2. Generally, the DNA values of foci with the exception of hyperbasophilic foci were alike. The DNA histograms of cells in the altered foci of the three types usually ranged between 2C and 8C with a wider spread than those of control hepatocytes. In some cells, the DNA values reached 10C. About 20–30% of hepatocytes in these foci exhibited DNA values above 5C with major peaks around 3C.

The hyperbasophilic foci had more irregular nuclei and prominent nucleoli than other types of foci. The DNA histograms of cell nuclei of the hyperbasophilic foci were all quite different from those of cell nuclei of other types of altered foci. The values ranged between 2C and 18C and showed an aneuploid pattern without a detectable stem cell line (text-fig. 2). Of the cells in the hyperbasophilic foci, 77% were multiploid (exceeding 5C), whereas only 1% had DNA values below 2.5C (table 1).



TEXT-FIGURE 1.—Nuclear DNA content of control liver. Each histogram is from averaged values of five sites. 1) Normal liver from control rats. 2) Nonlesional portions of the liver in rats killed after 15–19 wk on the 2-FAA diet. 3) Nonlesional portions of the liver in rats given the 2-FAA diet for 15–19 wk and a normal diet for 10 more wk.

Neoplastic nodules observed in this study were all sharply demarcated from the surrounding parenchyma. They were generally composed of acidophilic cells, and the cell plates of the nodules were discontinuous from those of adjacent liver tissue and compressed the hepatic plates. Modal DNA values of cells in the neoplastic nodules showed a wider deviation than altered foci like the eosinophilic type, but the range was narrower than that of hyperbasophilic foci (text-fig. 2). The DNA histograms of neoplastic nodules revealed basically polyploid patterns; 48% of cells exceeded 5C, and 45% were between 2.5C and 5C (table 1).

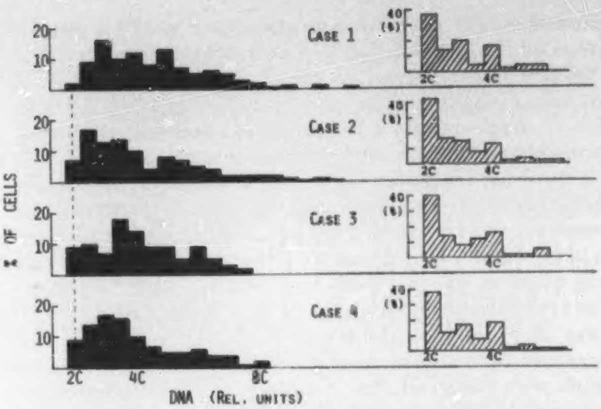
TEXT-FIGURE 2.—Average histograms from different rat liver lesions. 1) Eosinophilic foci. 2) Clear cell foci. 3) Simple basophilic foci. 4) Hyperbasophilic foci. 5) Neoplastic nodules. 6) Hepatocellular carcinomas.

The hepatocellular carcinomas used in this study were of the well-differentiated or moderately differentiated trabecular type. The histograms of cells in hepatocellular carcinomas showed an aneuploid pattern with widespread DNA values. Moreover, the ploidy distribution was different in each carcinoma. Some of the histograms of carcinoma cells were narrower than that of hyperbasophilic foci, and some of were extremely wide with a range between 2C and 23C (text-fig. 2).

Hyperplastic human liver foci were found in the livers from 4 aged people, 3 of whom had a history of long-term drug use for hyperlipidemia or hypertension. The foci were sharply demarcated from the surrounding hepatocytes, and their plates merged imperceptibly with those of adjacent hepatocytes (figs. 1, 2) similar to what was seen in the altered foci in rats. As a rule, these lesions did not compress the surrounding parenchyma. The cells in foci had clear or acidophilic cytoplasms, and the cytoplasms were strongly PAS-positive (fig. 3). The frequency of these foci was approximately 1.0–3.4/cm^2 of the liver. Of the 4 cases, 3 had the focal lesions in the absence of other changes, such as cirrhosis or severe bile duct proliferation. One of the cases also had adenomatous nodular lesions in the liver, and another had cirrhosis and hepatocellular carcinoma (table 2). The modal DNA values of the cell nuclei in the human hyperplastic foci were similar to those in the altered foci of the eosinophilic or clear cell type of rats. They ranged between 2C and 10C with major peaks around 3C (text-fig. 3). Unlike the surrounding normal hepatocytes that scarcely possessed DNA values exceeding 5C, about 23% of these cells fell into the range above 5C.



TEXT-FIGURE 3.—Histograms of nuclear DNA content of human hyperplastic foci in the livers of 4 patients. Each histogram is obtained from five sites of foci. *Inserted histograms with oblique lines* are those from the corresponding surrounding hepatocytes.

DISCUSSION

The studies reported here document a number of abnormalities in the DNA contents of carcinogen-induced rat liver lesions and hyperplastic foci occurring in the livers of humans with a history of drug exposure and/or other liver pathology.

The modal DNA values of cell nuclei in eosinophilic, clear cell, and simple basophilic rat liver foci showed a wider deviation than those of normal hepatocytes or hepatocytes outside the foci. Some of the increase could be due to higher rates of cell proliferation, but the results also support the concept that such liver foci are truly an "altered" hepatocellular population. The DNA patterns of the altered foci are in some respects comparable to those of metaplastic or dysplastic tissues and are regarded as "precancerous changes" in uterine cervix (*28, 35*), skin (*26*), or bronchus (*36*). Of particular significance was the finding that the DNA histograms of cells in hyperbasophilic foci showed an aneuploid pattern. This pattern distinguished these foci from the other types and established a possible relationship to hepatocellular carcinomas which were also aneuploid. In tumor development in the human uterine cervix, Böhm and

Sandritter (*23*) reported that alterations in DNA content preceded the invasive stage of carcinoma and suggested that "the first important step in the direction of malignancy is the transformation of the euploid-polyploid DNA distribution of dysplasia into a heterogenous aneuploid cell population of carcinoma in situ." Several investigators (*4, 11, 37, 38*) have considered basophilic liver lesions to be a transformed or transitional population between hyperplasia and neoplasia. Grundman and Sieburg (*13*) suggested that these lesions might even be microcarcinomas. A similarity of enzymatic or biologic properties between hyperbasophilic foci and hepatocellular carcinomas is also known (*11, 12*). Over 20 years ago, Maini and Stich (*39*) and Stich (*29*) described the presence of a genetically heterogenous population with abnormal chromosomes and different aneuploid amounts of DNA in precancerous livers of rats fed 4-(dimethylamino)azobenzene. The hepatocellular population they observed could correspond to the hepatocytes of the altered hyperbasophilic foci in the current study. The present finding of abnormally increased nuclear DNA content in hyperbasophilic foci thus suggests that hyperbasophilic foci are probably a population comparable to carcinoma in situ or a direct precursor lesion of hepatocellular carcinomas. Furthermore, these results support the hypothesis (*9*) that genetic alteration in hepatocytes renders them capable of forming altered foci and that altered foci may progress to hepatocellular neoplasms.

The DNA mode of neoplastic nodules showed a wider distribution than that of altered foci of the eosinophilic or clear cell type. Evidence indicates that neoplastic nodules arise by progressive growth of altered foci (*3, 10*). In the present study the development of neoplastic nodules after cessation of carcinogen exposure confirms a previous report (*40*) that these lesions are a progressively growing population. Their more deviant DNA content compared to the content of foci supports the concept that these lesions represent a further progression in neoplastic development (*9*). The cumulative evidence on the nature of nodules therefore continues to conform with their original designation by Sasaki and Yoshida (*41*) as adenomas. The present findings of a narrower distribution of modal DNA pattern of the nodules than that of hyperbasophilic foci or hepatocellular carcinomas is further evidence for the benign nature of the nodule.

In this study, compared to the DNA mode of hyperbasophilic foci, the DNA mode of some hepatocellular carcinomas also showed narrower distributions. Well-differentiated carcinomas are known to exhibit a narrower distribution of modal DNA values than do poorly differentiated carcinomas (*23, 31, 32*). Ploidy reduction in carcinomas may relate to the selection during proliferation of a near-diploid stem line (*23, 25*).

Human hyperplastic liver foci observed in this study also showed a wider distribution of their DNA mode than did the surrounding hepatocytes, and the pattern resembled that of some altered foci in rats. In the literature, such focal lesions in the human liver only have been reported infrequently (*42*). In the present study, the livers of 3 patients did not display major pathologic changes such as cirrhosis, and abnormalities in liver function tests were not detected. Therefore, such small liver lesions could be overlooked in many human livers. In these 3 cases, the patients all used some drugs such as clofibrate or antihypertensive agents. Both clofibrate and an analogue, nafenopin, are carcinogenic in experimental animals (*43*). Tumorigenicity or genotoxicity of some antihypertensive drugs has recently been described (*44, 45*). The promoting effect in experimental hepatocarcinogenesis of long-acting barbiturates (*46, 47*) is well known. Thus the ocurrence of multiple small hyperplastic foci in this study may be related to long-term use of some drugs. In one case, the patient had a positive HBsAg. Hir[illegible]a et al. (*42*) have reported a possible role of hepatitis B virus in producing such lesions. Thus advanced age or viral hepatitis could be other possible etiologic factors in the development of these lesions. The occurrence of hepatocellular adenomatous lesions (*34*) or of hepatocellular carcinomas in the livers of 2 patients suggests that these hyperplastic foci may be one of the precursor lesions of hepatocellular adenomas or carcinomas, as in experimental animals.

No Seasonality in the Diagnosis of Acute Leukemia in the United States[1,2]

Alexander M. Walker, *M.D., D.P.H,*[3,4] *and* **Paulus A. H. van Noord**, *M.D., M.Sc.*[3,5]

ABSTRACT—Dates of diagnosis of 7,000 cases of acute leukemia occurring in the United States between 1969 and 1981 were reviewed for detection of seasonal patterns. No strong evidence was found for seasonality in the diagnosis of acute leukemias as a whole or for subgroups based on cell type, age, or geography. Previous indications of seasonal fluctuation may represent the selective reporting of chance events.—JNCI 1982; 69:1283–1287.

Reports of seasonal fluctuations in the occurence of acute leukemia have appeared in the past (*1–10*), but their utility has been limited by lack of standard terminology and frequently by the absence of data on the source populations giving rise to the cases. Ages and seasons of peak occurrence have varied from one series to another, and the literature is, as a whole, a hodgepodge of individually impressive communications, which seem to represent the selective reporting of random quirks of disease incidence.

Seasonal fluctuations in disease occurrence can provide insight into possible pathogenic mechanisms and deserve to be documented, if they exist. To this end we have reviewed data from the TNCS, the SEER Program, and the CCPDS to ascertain the seasonality of the incidence of the acute leukemias.

DATA AND METHODS

The purposes and methods of the TNCS and SEER Program have been described elsewhere (*11, 12*). From the TNCS and the SEER data through 1977 we abstracted the following information on all cases of acute leukemia [codes 204.0, 205.0, 206.0, and 207.0 in International Classification of Disease, Eighth Revision (*13*)]: histology, age in years at diagnosis, date of diagnosis, race or ethnic background, sex, and place of residence at the time of diagnosis (TNCS or SEER reporting area). Although different areas reported for different periods within the total time intervals covered by these data (1969–71, 1973–77), each reporting center did provide data for some series of complete calendar years, so no month was overrepresented or underrepresented in the data by virtue of representing more or fewer reporting center-years.

Patterns of occurrence of cases were examined by visual inspection of cross-tabulations of age by month of diagnosis stratified by place of residence, ethnic background, year of diagnosis, and histologic type. Stratified data were extensively explored through Edwards's technique for seasonal analysis (*14*), through examination of partial autocorrelation functions (*15*), and through graphical techniques. We further evaluated major aggregations of cases by fitting a sine curve to the monthly pattern; we used the technique of Nelson et al. (*16*), with case counts assigned in a block to the middle of each month. This method involves mathematically transforming seasonal data in such a way that ordinary least-squares regression techniques can be utilized to estimate seasonal coefficients, test their statistical significance, and construct confidence intervals. No correction was made for the different lengths of months, but as will be evident from the results, such small corrections could not affect the final interpretation of the data in any important way. The term "amplitude" will be used here to describe the peak-to-trough differences for fitted sine curves. "Relative amplitude" will be used to describe the amplitude divided by the average monthly count.

Hypotheses raised on the basis of the TNCS–SEER data were tested with the use of comparable information from the files of the CCPDS. CCPDS is an association of 21 comprehensive cancer centers in the United States and has been collecting a standardized "minimal patient dataset" on all patients seen for diagnosis and therapy in the cancer centers since July 1, 1977. Items available on all patients give information on demographic characteristics, diagnoses, prior and newly initiated therapies, survival, and (when applicable) cause of death. This information is obtained by local data managers through chart review, hospital-based tumor registries, and direct contact with physicians. Data managers are given extensive initial training, are subjected to periodic quality control checks, and are supported by a central data management staff. Details of the organizational structure and operating procedures for CCPDS have been presented in (*17*). The data required for the present study were, as it turned out, age and month of diagnosis for subjects with acute monocytic leukemia [code 9891/3 in International Classification of Diseases for Oncology (*18*)], admitted to CCPDS centers in the 4-year period beginning July 1, 1977.

ABBREVIATIONS USED: CCPDS=Centralized Cancer Patient Data System; SEER=Surveillance, Epidemiology, and End Results; TNCS=Third National Cancer Survey.

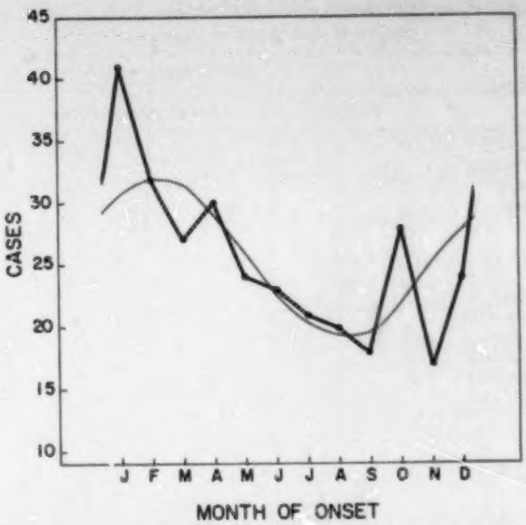
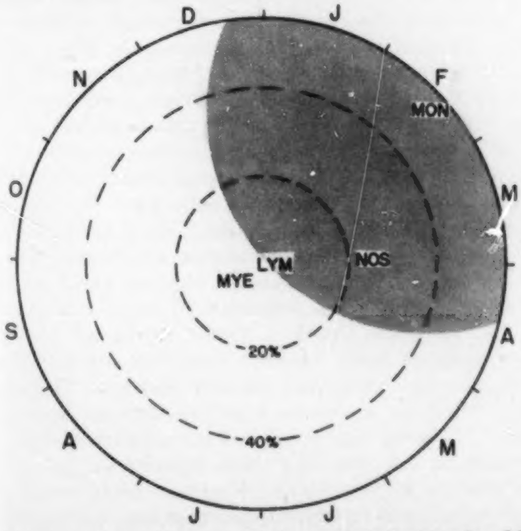
RESULTS

Table 1 presents the monthly distribution of cases cross-tabulated by age and histology. In text-figure 1, the relative amplitude and timing of the peak incidence of cases are plotted on polar coordinates for each of the four histologic types: acute lymphocytic, acute myelocytic, acute monocytic, and acute with histology not otherwise specified. The distance of each point from the center of the circle corresponds to the relative amplitude of fluctuation, and the direction from the center to each point indicates the timing of the peak. Of the four histologic types, only acute monocytic leukemia shows any important seasonal variation, with a relative amplitude of fluctuation of 55% and a seasonal peak in February. The 95% confidence region for acute monocytic leukemia (shown speckled) indicates that while the data were (barely) inconsistent with the null hypothesis of zero amplitude, they were quite consistent with underlying patterns of fluctuation of widely varying intensity and timing. In text-figure 2, the counts listed in table 1 for monocytic leukemia are plotted against the fitted sine curve. From table 1, it appears that any seasonality in monocytic leukemia incidence could be common to all age groups; in every group over the age of 9 years, January was the month of peak occurrence. The numbers of cases are too small to permit a statistical test of acceptable power comparing the different age groups with one another.

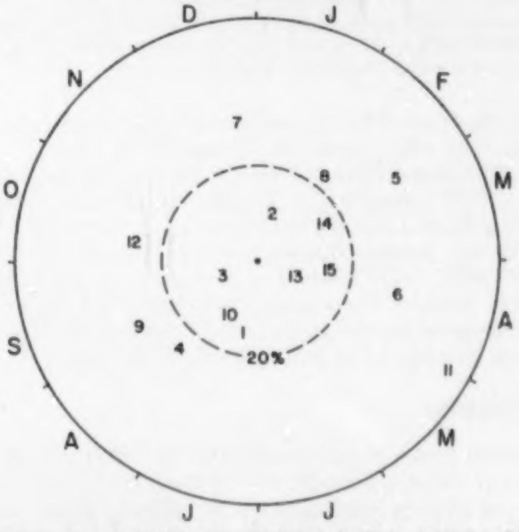
Further sifting through the data failed to reveal any other consistent seasonal patterns. Text-figure 3 shows the relative amplitude and timing of fitted sine curves for each reporting area. For none of the areas did the 95% confidence region exclude zero amplitude, and taken together, the data were not suggestive of any important overall fluctuation or any geographic correlates. Examination of age, race, and histology-specific patterns within each of the regions brought to light no relations that were obscured in the aggregate data. Further categorization of TNCS-SEER reporting areas according to climate, latitude, coastal versus central location, urbanization, and duration of continuously reported surveillance was similarly not helpful, as were analyses based



Text-figure 2.—Observed number of cases of acute monocytic leukemia in TNCS-SEER Program by month (J-D=January-December) of diagnosis (*solid line*) and the best-fitting sinusoidal curve (*dotted line*).



Text-figure 1.—Acute leukemia: Timing and relative intensity of fitted sine curves by histologic type in TNCS-SEER Program. Only acute monocytic leukemia (MON) shows a strong seasonality. *Distance from the center* indicates the relative amplitude of seasonal variation. *Direction from the center* indicates the month (J-D=January-December) of peak amplitude. LYM=acute lymphocytic leukemia, MYE=acute myelocytic leukemia, NOS=acute leukemia, histology not otherwise specified. *Shaded area* is a 95% confidence region for MON leukemia.



Text-figure 3.—Acute leukemia: Timing and relative intensity of fitted sine curves by U.S. region. SEER-TNCS reporting regions show no pattern of seasonality that has any ready geographic interpretation. *Distance from the center* indicates the relative amplitude of seasonal variation. *Direction from the center* indicates the month (J-D=January-December) of peak amplitude. 1) San Francisco, 2) Detroit, 3) Iowa, 4) Atlanta, 5) Connecticut, 6) Hawaii, 7) New Mexico, 8) New Orleans, 9) Seattle, 10) Utah, 11) Birmingham, 12) Colorado, 13) Dallas, 14) Minneapolis, and 15) Pittsburgh. None of the points has a confidence region that excludes zero relative amplitude.

on methods for detecting seasonality other than those of Nelson et al. (*16*) summarized in text-figures 1 and 2.

CCPDS data on acute monocytic leukemia for the period July 1, 1977, through June 30, 1981, are shown in table 2 and text-figure 4. Counts refer to new patients entering the CCPDS, i.e., patients diagnosed within a month of coming to a CCPDS center where they received their first cancer-directed therapy. There were 104 eligible patients, whose distribution of months of diagnosis showed no trace of the seasonal patterns noted in the TNCS–SEER data.

DISCUSSION

Common acute leukemias noted in the TNCS and SEER reporting systems through 1977 showed no consistent or even suggestive seasonal patterns of incidence. Acute monocytic leukemia, which accounts for about 5% of all acute leukemias, did show a distinct late winter peak of marginal statistical significance. Data from an independent source (CCPDS) failed, however, to corroborate the latter finding.

The availability of independent reporting systems with patient accruals as large as those of the SEER Program and CCPDS provides an important opportunity for cross-checking new and potentially significant findings. CCPDS does not, like the SEER Program, provide population-based data; so disease incidence rates are not calculable. However, CCPDS can generally provide relative frequencies of disease subtypes or, as in the present case, certain details of relative incidence that are unlikely to be distorted by cancer center referral patterns. Four of the 22 CCPDS centers are in SEER reporting regions; therefore, some cases are reported through both systems. In areas in which cases are reported in common, concordance is not complete, however, since catchment areas of the CCPDS centers generally extend far beyond the SEER regions within which the centers are located, and the SEER centers register all regional cases, only some of which come through the local CCPDS center. Because in the present case the overlap in calendar time between cases reported from the SEER Program and CCPDS was only 6 months and because the CCPDS data did not support the hypothesis of seasonality raised in the TNCS–SEER Program, elimination of the overlapping center-months could not substantially affect conclusions based on tables 1 and 2.

Previous reports of seasonal variation in leukemia incidence have emphasized the possibility of an infectious origin of the disease. Observations cited to support this theory have been individually very impressive, but in the aggregate contradictory. Lambin and Gerard (*1*) reported a relative amplitude of variation of more than 100%, with a winter peak in their Belgian clinic. Engelbreth-Holm (*2*) found a similar pattern (but in adults only) in Copenhagen. Several Italian investigators (*3–6*) have addressed the question of seasonality, with findings that seemed to confirm the earlier work, at least in adults. Storti and Brotto (*3*), considering all ages, found acute leukemia to peak in November and December, with a relative amplitude of variation of about 60%. Scanu (*4*) in Naples found an adult winter peak as striking as many other winter peaks previously reported and noted a summer peak in children under 12 years of age. Fantuzzi (*5*) reported the opposite of Scanu's latter finding, i.e., a pediatric winter peak, to which Gerola (*6*) added data supporting a pronounced late spring peak in children. All of these reports were based on the experience of single clinics or small geographic areas and covered periods of less than a decade. Lee (*7, 8*) employed data from the National Cancer Registration Scheme of the United Kingdom covering a period of 15 years to discover a previously unseen pattern—a more shallow summer increase found in both children and adults but restricted to acute lymphocytic leukemia. In North Carolina, Hayes (*9*) found a modest winter excess in acute leukemia cases but was unable to demonstrate any association between leukemia occurrence and the incidence of common infectious diseases. Spiers and Quade (*10*) found that childhood lymphoblastic leukemia occurrence as inferred from three separate surveys in the United States and the United Kingdom could be successfully fit to a model in which occurrence was tied to seasonality through entry into schools.

For seasonality of leukemia onsets to appear in data such as those presented here, there would have to be an agent, itself seasonally distributed, which would lead either to the onset or the diagnosis of cancer. That agent would have to be widespread geographically (covering at least large parts of SEER regions or CCPDS catchment areas), and it would have to lead to a diagnosis within a fairly short time (months rather than years) after exposure; the variability of a long preclinical period would be likely to smear out the effect even of strong seasonality in exposure times. Moreover, if the effect were to be restricted to a few age groups, it would have to result in a large relative amplitude to be detectable with any reliability. The negative results presented here then do not completely rule out an infectious role, for example, in the genesis of leukemia. However, the TNCS-SEER and CCPDS data on acute leukemia onsets are more extensive than any reported so far and probably at least as reliable; so the lack of consistent findings of seasonal fluctuation strengthens the supposition that earlier reports of annual variations in leukemia incidence were specious. These earlier reports may reflect only part of the sociology of science: Positive findings gain prominence from the natural interest of investigators, their colleagues, and the editors of journals; negative results excite less attention.

Probable Clonal Origin of Neurofibrosarcoma in a Patient With Hereditary Neurofibromatosis[1,2,3]

Jan M. Friedman, *M.D., Ph.D.,*[4] **Philip J. Fialkow,** *M.D.,*[5,6] **Claudia L. Greene,** *M.D.,*[7] *and* **Michael N. Weinberg,** *M.D.*[8,9]

ABSTRACT—A neurofibroma, a fibroma, a primary neurofibrosarcoma, and four neurofibrosarcoma metastases from a woman with hereditary neurofibromatosis who was heterozygous (Gd^{B}/Gd^{A-}) for the X-linked enzyme glucose-6-phosphate dehydrogenase were studied to determine the number of cells from which the tumors developed. Both enzyme types were observed in the benign tumors in proportions similar to those present in seven different normal tissues studied. These findings indicated that the benign tumors arose from many cells. In marked contrast, only type A activity was detected in the primary neurofibrosarcoma and in all of the metastases. Two or more steps probably were involved in the development of neurofibrosarcoma in this patient: the inherited genetic mutation producing neurofibromatosis and a rare event or combination of events that permitted a single cell to undergo malignant proliferation.—JNCI 1982; 69:1289–1292.

Hereditary neurofibromatosis (von Recklinghausen's disease) is one of the most common human autosomal dominant diseases. Patients with this disorder characteristically have many benign soft tissue tumors containing excessive disorganized overgrowths of Schwann's cells associated with perineural and endoneural elements. These neurofibromas, which may be hamartomas rather than true neoplasms, have been shown to arise from many cells in patients with hereditary neurofibromatosis (*1*). This finding contrasts with the apparent clonal development of most studied neoplasms (*2, 3*).

Neurofibrosarcomas arise in at least 2–3% of all patients with hereditary neurofibromatosis (*4, 5*) and may be even more common in older patients (*6*). To investigate carcinogenesis in hereditary neurofibromatosis, we studied benign and malignant tumors from a woman with this disease who was heterozygous at the X-linked G-6-PD locus. Because one X-chromosome in each somatic cell in a female is inactive, a given cell expresses the products of only one of the two X-chromosomes. In women heterozygous for electrophoretic variants of G-6-PD, normal tissues consist of a mixture of cells expressing type A enzyme and cells expressing type B enzyme. With this cell marker system, it is possible to determine if a neoplasm in a heterozygous woman is clonal, i.e., exhibits only type A *or* type B enzyme, or has multicellular origin, in which case it may exhibit *both* enzyme types. Single-cell origin implies that a neoplasm developed as a result of a rare event (e.g., somatic mutation) or a rare series of events. In contrast, multiple-cell origin suggests that a tumor arose by a process involving many cells, e.g., overstimulation by a circulating substance such as nerve growth factor (*7*).

METHODS

Patient report.—A 28-year-old black woman was diagnosed as having hereditary neurofibromatosis after rectal nodules were found on pelvic examination. She had mild scoliosis, many cafe au lait spots, axillary freckling, and several subcutaneous nodules. The patient's mother and brother were known to have the same disorder, and one of her children had several cafe au lait spots noted at birth.

In December 1978, the patient developed paresthesia and hyperesthesia in association with a right forearm mass, which had been enlarging for about a year. On January 22, 1979, the mass was removed along with a small muscular branch of the median nerve from which it apparently arose. The tumor measured 8×5.5 cm and was found on histologic examination to be a neurofibrosarcoma. The contiguous nerve was thickened along several branches into a plexiform neurofibroma.

During the next few months, a large, painful tumor reappeared at the site of previous surgery. On June 13, 1979, amputation of the right arm above the elbow was performed. The tumor, which was 13 cm in diameter, involved all of the flexor muscles of the forearm but not the median nerve. Microscopically, the tumor was a high-grade neurofibrosarcoma (fig. 1) with evidence of invasion of muscle. Portions of this tumor were tested for G-6-PD phenotype.

The patient recovered from surgery uneventfully. About 2 months later she noted that a mass that had been present on her left chest for some time was enlarging rapidly. On August 16, 1979, this mass was removed. The well-encapsulated, 10-cm tumor was a typical neurofibroma with

[b] Typing of red blood cells indicates that this patient is Gd^B/Gd^{A-}.

myxoid degeneration. This tumor was also tested for G-6-PD phenotype.

The patient was subsequently noted to have another rapidly enlarging mass, this time involving the left thigh. Biopsy on February 15, 1980, revealed neurofibrosarcoma. This tumor, which is believed to have been a second primary cancer, was resected on March 27, 1980. The tumor was 6.4 cm in diameter and was found to be a neurofibrosarcoma with patchy lymphocytic infiltration throughout. The neoplasm was associated with several plexiform neurofibromas.

The patient died of metastatic disease involving the lungs, liver, pancreas, intestines, and bones on October 14, 1980. Post mortem, metastatic nodules of typical neurofibrosarcoma removed from the liver and lung were tested for G-6-PD phenotype. A rectal fibroma was also removed and tested.

Specimens.—Tumor specimens were prepared and analyzed for G-6-PD phenotype by starch gel and cellulose acetate electrophoresis as previously described (*8–11*). We estimated the ratio of A:B G-6-PD activity by visually using prepared standards as controls (*11*). Because there was excellent agreement between the methods, only the data from the starch gels were reported. All specimens included in table 1 were free from appreciable gross contamination with blood or microscopic vascular invasion or lymphocytic infiltration. Red cell and buffy coat preparations from peripheral blood, samples of uninvolved muscle and skin from the right forearm and left chest, respectively, and samples of normal lung, liver, rectum, and pancreas were also studied.

RESULTS

The results of the electrophoretic G-6-PD assays are shown in table 1. Both types A and B enzymes were found in all normal tissues studied, indicating that the patient is heterozygous for G-6-PD. Approximately equal amounts of both enzyme types were also observed in the benign tumors. In contrast, only A-type G-6-PD was detected in the primary neurofibrosarcoma from the right forearm and in all the neurofibrosarcoma metastases.

DISCUSSION

The finding of a double-enzyme phenotype in the benign neurofibroma and fibroma from this patient with hereditary neurofibromatosis is consistent with the conclusion that such growths develop from many cells. Other possible explanations for a double-enzyme phenotype are very unlikely (*1*).

In marked contrast to the double-enzyme phenotype found for this hereditary neurofibroma and for all 14 similar tumors previously reported (*1*), the primary neurofibrosarcoma from this patient's right forearm and all four neurofibrosarcoma metastases studied exhibited single-enzyme phenotypes. The finding of a single-enzyme phenotype in these malignant tumors is consistent with clonal origin of neurofibrosarcoma in this patient. However, a single-enzyme phenotype could also occur in a neoplasm of multicellular origin if cells containing one or the other active X-chromosome had a marked selective advantage or if the normal cells from which the tumor arose were arranged in large patches of contiguous cells of a single-enzyme type. Neither of these last two possibilities seems likely because the large, rapidly growing but benign neurofibroma in this same patient exhibited a double-enzyme phenotype similar to that of adjacent normal tissues (capsule and skin; table 1). Thus the malignant neoplasm probably developed from a single transformed cell.

Our demonstration that benign hereditary neurofibroma arises from many cells whereas neurofibrosarcoma is clonal is consistent with the hypothesis that malignant transformation is a multistep process. One possibility, suggested by Knudson and Meadows (*12*), is that hereditary neurofibromas are collections of neural crest-derived cells that form benign tumors because their normal development is altered by the inherited mutation. One or more further events within such premalignant cells might result in transformation into neurofibrosarcoma. The intimate association of the neurofibrosarcomas with neurofibromas in this patient suggests that malignant transformation did indeed occur within preexisting neurofibroma cells.

Several possible mechanisms exist that, acting alone or in combination, might produce a clonal cancer within a neurofibroma. First, one cell might have become transformed because of a rare alteration, e.g., a "spontaneous" somatic mutation or a specific chromosomal rearrangement. Second, malignant transformation might have resulted from a series of events, each of which involved several cells, but which occurred in such a manner that any single cell was very unlikely to undergo the entire requisite set. Finally, all cells of a neurofibroma might be potentially malignant, but escape of a cell from normal tumor surveillance or control mechanisms might be rare. Available data do not permit favoring any one of these pathogenic models over the others. However, the data clearly support the hypothesis that development of neurofibrosarcoma in this patient was a multistep process. The first step was genetic—the inherited autosomal mutation that causes neurofibromatosis. A rare event or combination of events then occurred in a cell, permitting it to undergo malignant neoplastic proliferation.

Accessory Cell Function in Tumor-Bearing Mice and Effects of *Corynebacterium parvum* [1,2,3]

Seiya Okuda,[4] **Kazuto Taniguchi,**[4] **Chiharu Kubo,**[5] *and* **Kikuo Nomoto**[4]

ABSTRACT—Primary in vivo production of antibody to sheep red blood cells (SRBC) was consistently suppressed in EL 4 tumor-bearing C57BL/6 mice, but the secondary response was not suppressed. This suppressed primary in vivo production of antibody was partially restored by systemic administration of *Corynebacterium parvum*. For investigation of the mechanism of the immunosuppression in tumor-bearing mice and the effects of *C. parvum*, the accessory cell function of adherent cells from tumor-bearing mice and *C. parvum*-treated tumor-bearing mice in in vitro cultures was studied. Peritoneal and splenic cells from tumor-bearing mice were less efficient in promoting in vitro production of antibody to SRBC by macrophage-depleted normal nonadherent cells than the adherent cells from normal mice. *C. parvum* treatment restored the accessory cell function of splenic adherent cells from tumor-bearing mice but not that of peritoneal cells. Furthermore, adherent cells from tumor-bearing mice did not show suppressive activity against the in vitro plaque-forming cell response.—JNCI 1982; 69:1293–1297.

Many reports are concerned with depressed immune responses in tumor-bearing mice, but the mechanism of immunosuppression in the tumor-bearing state is not completely understood since the immune response requires various types of cells.

Functional abnormalities of macrophages, including defective mobility and chemotaxis (*1–3*), impaired inflammatory response (*4, 5*), and increase and decrease in phagocytic activity (*6, 7*) have been found in tumor-bearing individuals. However, little information exists about the accessory cell function for the induction of immune responses in tumor-bearing mice.

We (*8*) previously reported that depressed immune responses in EL 4 tumor-bearing C57BL/6 mice are restored by treatment with *Corynebacterium parvum* or by in vivo transfer of splenic adherent cells of *C. parvum*-treated normal mice. *C. parvum* has been shown to exert a stimulatory effect on the function of accessory cells (*9, 10*). These results suggest that immunosuppression in tumor-bearing mice may be due to the suppression of the accessory cell function of adherent cells from EL 4 tumor-bearing mice in in vitro culture and from the effects of *C. parvum* treatment on these cells.

MATERIALS AND METHODS

Animals.—Male mice of an inbred C57BL/6 strain were obtained from the Breeding Unit of Kyushu University and used at 8 weeks of age. Each experimental group included 8–10 mice.

Tumor.—EL 4 tumor, a thymus-deprived benzo[*a*]pyrene-induced lymphoma of C57BL/6 origin, has been maintained in the ascites form through syngeneic C57BL/6 mice. After sc inoculation of 10^6 cells into the right flanks of C57BL/6 mice, palpable tumors appeared in a few days, grew progressively, and killed all the hosts within 2 weeks.

Antigen.—SRBC were obtained from the Laboratory of Biotest (Tokyo, Japan).

In vivo immunization.—Mice were inoculated ip with 10^8 SRBC in saline. For primary immunization in the tumor-bearing state, mice received injections of SRBC 4, 8, or 10 days after tumor inoculation. For secondary immunization in the tumor-bearing state, mice were inoculated with tumor cells 20 days after the primary immunization and with SRBC 4, 8, or 10 days later.

C. parvum *injections.*—A suspension of heat- and Formalin-killed *C. parvum* (IM1585; Institute Merieux 17, Lyon, France) containing 2 mg organisms/ml was obtained commercially. Mice were inoculated ip with various doses of this suspension 7 days before in vivo immunization or before cell harvest for in vitro culture. (In our preliminary experiments, *C. parvum* showed a maximal effect for 7–10 days after injection.)

Assay of PFC.—Spleen cells were obtained 5 days after primary immunization or 3 days after secondary immunization. The number of PFC against SRBC in individual mice was determined by the method of Cunningham and Szenberg (*11*). Indirect PFC were developed in rabbit anti-mouse immunoglobulin serum (Institute for Medical Biology, Nagoya, Japan) and enumerated according to the method of Dresser and Greaves (*12*).

Preparation of splenic and peritoneal adherent cells.—We exposed mice to 1,300 rad of whole-body radiation 24 hours before in vitro culture to eliminate lymphocytes and tumor cells. X-rays were delivered with a Shimazu 250-kVp machine operating at 200 kVp with 0.3-mm copper and 1-mm aluminum filters. Spleen cells were suspended at 2×10^7/ml in HBSS and incubated in a glass petri dish at 37°C for 1 hour in a 5% CO_2 atmosphere. Nonadherent cells were removed with a rubber policeman. Peritoneal exudate cells were harvested by irrigation of the peritoneal cavity with HBSS 2 days after an ip injection of 2 ml of 10% sterile

[c] Mice were inoculated with tumor cells 20 days after primary immunization. Spleen cells were obtained 3 days after secondary immunization. Values are means ± SD.

proteose peptone (Difco Laboratories, Detroit, Mich.). Peritoneal adherent cells were prepared in the same manner as splenic adherent cells.

Preparation of nonadherent cells.—Adherent cells were removed from normal or primed spleen cells by passage through an SG-10 column prepared according to the method of Ly and Mishell (*13*) with some modification. Swollen, washed, autoclaved SG-10 (3 g, dry wt; Pharmacia Chemicals AB, Uppsala, Sweden) was loaded into a sterile plastic 10-ml syringe packed with 2 ml of glass wool. The column was washed repeatedly with a total of 30 ml HBSS and loaded with spleen cells suspended in HBSS at $1\text{-}2\times10^7$/ml. The initial cell specimens usually contained 10–15% macrophages as estimated by latex particle injection assay. After one passage through the column, the cell suspensions contained less than 1% macrophages. Spleen cells were used as a nonadherent cell population after three passages.

In vitro culture.—The test for in vitro PFC response to SRBC was conducted according to the method of Mishell and Dutton (*14*). RPMI-1640 (GIBCO, Grand Island, N. Y.) supplemented with 10% heat-inactivated fetal calf serum, 20 m*M* HEPES[6] (Dojin Chemical Laboratory, Kumamoto, Japan), 100 U penicillin/ml, and 100 μg streptomycin/ml and adjusted to pH 7.2 with $NaHCO_3$ was used as culture medium. In some experiments, 2-ME was added to the cultures (5×10^{-5} *M*). The nonadherent cells obtained by SG-10 column separation were used as responder cells. The immunizing SRBC were washed three times and added to the culture. The adherent cells prepared as described above were added in various ratios. For in vitro culture, 1×10^6 nonadherent cells, 2×10^5 SRBC, and $1\text{-}10\times10^4$ adherent cells were suspended together in 0.3 ml of culture medium in a well of a culture plate (A/S Nunc, Roskilde, Denmark) and cultured in a humidified atmosphere containing 5% CO_2 in air for 5 days. We used 40 wells for each experimental group. At the time of harvest, the cells were resuspended by gentle agitation. The cell suspensions from eight wells were pooled, centrifuged at 1,000 rpm for 10 minutes, at 4°C, and incubated with SRBC and complement for 1 hour in a Cunningham chamber. The mean numbers of PFC were calculated from the numbers of PFC in five Cunningham chambers.

Statistical analyses.—The standard Student's *t*-test was used for the determination of statistical significance.

RESULTS

Primary and secondary production of antibody to SRBC in tumor-bearing mice.—Mice were primarily or secondarily immunized as described in "Materials and Methods." Spleens were obtained 5 days after primary immunization or 3 days after secondary immunization (table 1). The primary response assayed by production of direct PFC was consistently depressed in the tumor-bearing mice compared with that in normal control mice ($P<0.001$). The degree of the suppression was marked in the late stages of tumor bearing, 8 or 10 days after tumor inoculation. However, the secondary response, assayed by production of indirect PFC, in the tumor-bearing mice was at almost the same level as that in normal mice. These results were confirmed by two other experiments (data not shown).

Effect of C. parvum *on suppressed primary production of antibody in tumor-bearing mice.*—Mice received various injected doses of *C. parvum* and SRBC 1 and 8 days after tumor inoculation, respectively. The suppressed direct PFC response in tumor-bearing mice was restored to some extent by the injection of 0.5 mg or by more of *C. parvum* ($P<0.005$) (table 2). The results showed that the optimal doses of *C. parvum* were 0.5 or 1.0 mg.

Accessory cell function of tumor-bearing mice in in vitro antibody production.—Accessory cell functions of peritoneal and splenic adherent cells from normal and tumor-bearing mice were investigated in an in vitro culture system. Macrophage-depleted normal spleen cells were cultured, and various numbers of peritoneal or splenic adherent cells from normal and tumor-bearing mice were added to this culture (text-fig. 1). When the ratio of responding nonadherent cells to added adherent cells was 10:1, the direct PFC response was very weak irrespective of the origin of the adherent cells. The effect of peritoneal adherent cells on the restoration of

TABLE 2.—*Restorative effect of* C. parvum *on suppressed in vivo production of antibody to SRBC in tumor-bearing mice*

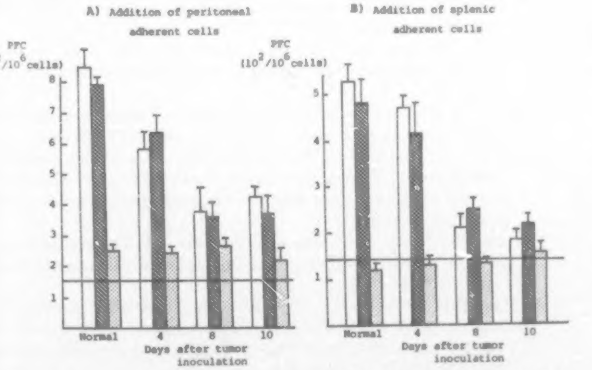
the PFC response was stronger than that of splenic adherent cells, when these cells were obtained from normal mice. The ability to restore the PFC response was slightly depressed in peritoneal and splenic adherent cells obtained 4 days after tumor inoculation and markedly depressed in those obtained 8 or 10 days after tumor inoculation ($P<0.005$). The numbers of PFC in the cultures to which 2-ME was added were similar to those in the cultures without 2-ME.

Lack of suppressive effect of adherent cells from tumor-bearing mice on in vitro culture.—To determine whether adherent cells of tumor-bearing mice include suppressor macrophages that actively depress in vitro antibody production, adherent cells were obtained 8 days after tumor inoculation and added to the cultures with the same number of adherent cells from normal mice (table 3). The number of direct PFC in the culture to which both cells were added was similar to that in the culture to which only normal adherent cells were added, suggesting that adherent cells from tumor-bearing mice do not possess suppressive activity in in vitro cultures.

Restorative effect of C. parvum *on depressed accessory cell function.*—To determine the effect of *C. parvum* on the depressed accessory cell function in tumor-bearing mice, peritoneal or splenic adherent cells from *C. parvum*-treated tumor-bearing mice were added to nonadherent responding cells (table 4). The donors of adherent cells were inculated with tumor cells 8 days and with *C. parvum* 7 days before cell harvest. The ability of the peritoneal and splenic adherent cells to restore the in vitro PFC response was partially suppressed in tumor-bearing mice. *C. parvum* treatment of the donors restored the ability of splenic adherent cells of tumor-bearing mice to respond ($P<0.005$) but had no effect on their peritoneal adherent cells. The level of response of splenic adherent cells in *C. parvum*-treated tumor-bearing mice did not reach that of splenic adherent cells in the normal control mice. Other experiments showed that the adherent cells from *C. parvum*-treated normal mice produced a similar number of PFC to that of normal mice when they were added to the cultures (data not shown). These results suggested that *C. parvum* may have restored the accessory cell function of spleen adherent cells from tumor-bearing mice.



TEXT-FIGURE 1.—Depressed accessory cell function of peritoneal and spleen cells from tumor-bearing mice in in vitro production of antibody to SRBC by macrophage-depleted normal spleen cells. The 1×10^6 nonadherent cells and 2×10^5 SRBC were suspended together in 0.3 ml culture medium in a well and cultured for 5 days. Adherent cells were obtained 4, 8, or 10 days after tumor inoculation and added to the wells at concentrations of 1×10^4 (□), 2×10^4 (▩), and 10×10^4 (▨). *Horizontal line* represents the mean PFC of the culture without adherent cells. *Vertical lines* represent standard deviations.

[d] *C. parvum* was injected ip 7 days before in vitro culture.

DISCUSSION

Primary in vivo production of antibody to SRBC was suppressed in tumor-bearing mice (table 1). The immunosuppresssion was restored to some extent by systemic administration of *C. parvum*. In in vitro culture, adherent cells from the peritoneal cavity and spleen of tumor-bearing mice did not restore the ability of nonadherent cells to produce antibody against SRBC (text-fig. 1).

Administration of *C. parvum* restored the accessory cell function of such splenic adherent cells but not of peritoneal adherent cells (table 4). These results suggest that immunosuppression in tumor-bearing mice may be related to the depression of the function of macrophages as accessory cells and that the restoration of the depressed immune reaction by *C. parvum* treatment may be due to an adjuvant effect of *C. parvum* on the accessory cell function of splenic adherent cells.

The results in our previous (*8*) and present studies and those of Joshua et al. (*15*) suggest that depression of immune responses in tumor-bearing mice may be due at least in part to the depressed function of accessory cells. However, the mechanisms of such a depression are not clearly understood. There are several possible explanations for the phenomenon. Macrophages capable of functioning as accessory cells may accumulate primarily around the tumor and become scarce in the splenic or peritoneal cavity. Alternatively, binding of the complex of antibodies against tumors and tumor antigens on the surface of accessory cells may block antigen-binding sites of the cells. We have no evidence to support any explanation strongly; many other mechanisms can be suggested.

Multiply passed tumors such as EL 4 are reported to be contaminated with LDV (*16*). Some investigators (*17, 18*) have shown that macrophage function is severely depressed in LDV-infected mice. To examine mice bearing EL 4 tumors for the presence of LDV, we measured lactate dehydrogenase activity in their sera and found that it was less than twice that in normal mice. Therefore, we do not think that the EL 4 tumor was contaminated with LDV.

Some investigators emphasize the role of suppressor macrophages in immunosuppression in tumor-bearing mice (*19, 20*). To determine whether adherent cells from tumor-bearing mice included suppressor macrophages in our in vitro experiments, we studied the effects of adherent cells from tumor-bearing mice on in vitro antibody production by nonadherent spleen cells supplemented with normal adherent cells. The number of PFC in this culture was similar to that in the culture to which only normal adherent cells were added. These results suggest that suppressor macrophages are not involved in the depressed PFC response, at least in our system.

In the secondary response, the PFC response was not affected by the tumor-bearing state. This finding is in agreement with reports by Zolla (*21*) and Kamo and Friedman (*22*). Pierce (*23*) reported that macrophage dependency is lower in the secondary response than in the primary response. The difference in the suppressive effect between the primary and secondary response in our study may be explained by a difference in the requirement for macrophages to process and present antigen.

C. parvum is able to stimulate phagocytosis, increase resistance to infection, stimulate antibody response, and augment antitumor activity. Many of these phenomena have been shown to be due to macrophage functions activated by *C. parvum*. Wiener (*9*) showed that macrophages of *C. parvum*-treated mice are more effective than normal macrophages in promoting in vitro response to SRBC by macrophage-depleted spleen cells. Furthermore, Wiener and Bandieri (*10*) reported that *C. parvum*-activated macrophages retained much antigen on their surfaces, which intensified the presentation of antigen to lymphocytes. Such a mechanism may contribute to the restorative effect of *C. parvum* in our study. Although *C. parvum* restored the accessory function of splenic adherent cells of tumor-bearing mice in vitro, it did not restore that of peritoneal adherent cells, which may show a difference in susceptibility to *C. parvum* of splenic and peritoneal adherent cells in tumor-bearing mice. In further experiments, we are studying surface markers and morphologic changes in peritoneal and splenic adherent cells in tumor-bearing mice and *C. parvum*-treated tumor-bearing mice.

Induction of γ-Glutamyltransferase-Positive and Nonspecific Esterase-Positive Foci in Rat Liver by Partial Hepatectomy Following Single Injection of *N*-Nitrosodiethylamine[1]

Norio Hirota,[2] Shinichi Moriyama,[2] *and* Takeshi Yokoyama[2,3]

ABSTRACT—The effect of partial hepatectomy (PH) on alteration of liver foci induced by *N*-nitrosodiethylamine (DENA) was studied in inbred F344 male rats. As early as 2 weeks after PH was performed 6 hours after an injection of 100 mg DENA/kg, γ-glutamyltransferase-positive hepatocellular foci were induced, whereas DENA alone induced no foci until 12 weeks after PH. The focus counts of the group with PH performed 6 hours after an injection of 100 mg DENA/kg were consistently greater than those of a group with PH performed at 24 hours following DENA injection. At 3 and 6 weeks after PH was done at 12 weeks following treatment with 100 or 200 mg DENA/kg, the focus count was significantly increased compared with that in nonhepatectomized groups. The results indicate that increased liver cell proliferation resulting from PH enhances the conversion of persisting DNA damage to a permanent alteration in DNA. The effect at 12 weeks after exposure supports the concept that DNA damage in hepatocytes is highly persistent.—JNCI 1982; 69:1299–1304.

In experimental hepatocarcinogenesis, initiated cells or focally altered islands of hepatocytes are recognized by varied histochemical phenotypes including *a*) positivity for GGT, deficiency for ATP or glucose-6-phosphatase and *b*) resistance to iron accumulation (*1–10*). Hirota and Williams (*11*) recently reported that most of the iron-resistant hepatocellular altered foci were persistent in nature even to the point that nodules or carcinomas developed multicentrically, and Hirota et al. (*12*) observed similar foci in hemochromatotic human livers in association with hepatocellular carcinomas. Thus such persistently altered foci might be the precursors of neoplastic nodules or carcinomas (*4, 7, 11, 13–15*).

Scherer et al. (*16*) reported that the number of altered foci detected by ATP deficiency was significantly increased by PH performed before the administration of carcinogen. Liver cancer has rarely been reported to be produced by a single administration of carcinogen to rats. This phenomenon seems to be related to the possibility that DNA damage of hepatocytes induced by a single exposure to a hepatocarcinogen is generally repaired in time. Craddock (*17, 18*), however, documented a high incidence of liver cell cancers in rats after a single treatment with a hepatocarcinogen given during the period of semisynchronized increased DNA synthesis following PH. Recently, Ishikawa et al. (*19*) reported a correlation between the time of PH after treatment with DENA followed by phenobarbital and the appearance of ATP-deficient islands in rat livers. The functionally altered foci identified by histochemical abnormalities may be composed of phenotypic hepatocytes with defective DNA or with an inappropriate form of DNA repair (misrepair) following initial DNA damage by carcinogen exposure to the liver. We hypothesize that DNA damage initiated by a limited injection of DENA may persist indefinitely to some extent and that increased DNA synthesis induced by PH may contribute to the effect of induced proliferation in converting persisting DNA damage to a permanent alteration in DNA leading to the formation of histochemically altered foci.

In the present study, we investigate the effect of PH on the formation of histochemically altered foci following the exposure to hepatocarcinogen. PH without any other subsequent treatment such as administration of phenobarbital was done at various times after DENA treatment of rats. For histochemical analysis not only GGT but also NSE was used. The data indicate that the focus formation in terms of the number and size of foci is closely related to the interval between DENA injection and PH.

MATERIALS AND METHODS

Animals and chemicals.—Inbred F344 male rats (Charles River Japan Inc., Kanagawa, Japan), weighing 180–200 g, were maintained on a high-protein (23.0%) basal diet (CRF-1; Oriental Yeast Co., Ltd., Tokyo, Japan) for at least 1 week before the experiments were begun. The animals were housed in metal cages in an air-conditioned room at 24°C with food and water available ad libitum. DENA was obtained from Tokyo Chemical Industry Co., Ltd., Tokyo. It was dissolved in a 0.9% NaCl solution and injected ip.

Experimental design.—The experimental design is shown in text-figure 1. Experiment 1 (groups 1–4) was designed to investigate the effect of PH on the evolution of initiated cells recognized by the formation of GGT-positive or NSE-positive foci. Groups 1 and 2 were given an injection of 100 mg DENA/kg body weight followed by PH with the use of the technique of Higgins and Anderson (*20*). PH was performed in group 1 at 6 hours after DENA injection and in group 2 at 24 hours after DENA injection. Group 3 received 100 mg DENA/kg but was not subjected to PH. Animals in group 4 were subjected to PH at approximately 10 weeks, the same age as that of groups 1–3, but were not treated with DENA.

ABBREVIATIONS USED: DENA=*N*-nitrosodiethylamine; 2-FAA=*N*-2-fluorenylacetamide; GGT=γ-glutamyltransferase; NSE=nonspecific esterase; PH=partial hepatectomy.

[3] We thank Ms. Keiko Ohtomo for excellent assistance with the animal handling and histochemical procedures; the technical staffs of the Department of Pathology for the preparation of histological slides; and Dr. Gary M. Williams, Associate Director of Naylor Dana Institute for Disease Prevention, for reviewing the manuscript.

Five animals in group 1 were killed at weeks 2, 6, 12, and 18 after the commencement of the experiment. The same number of animals in group 2 were killed at weeks 2, 6, and 12 and in group 3 at weeks 2, 6, 12, 15, and 18. In group 4, 3 animals were killed at the same times as in group 2.

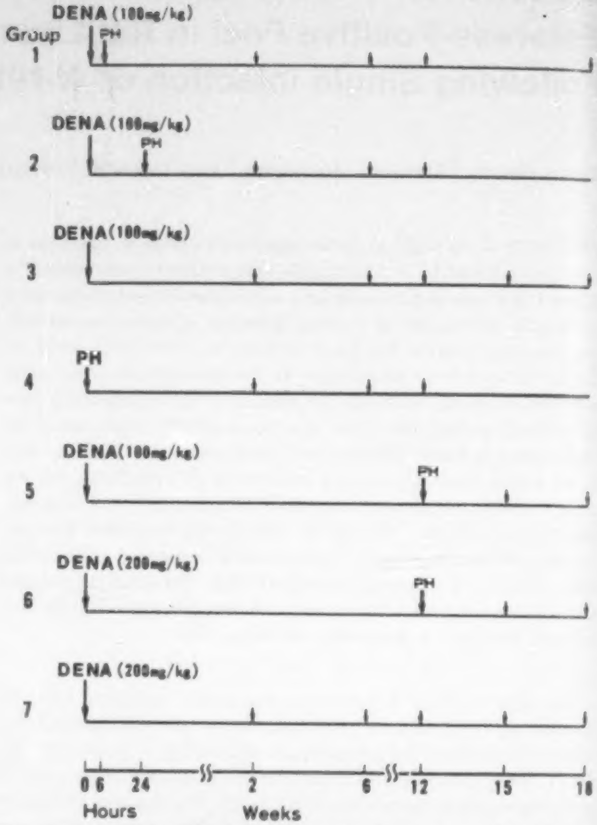
On the basis of our preliminary results that the earliest GGT-positive foci were induced at 12 weeks after a single injection of 100 mg DENA/kg (Hirota N, Moriyama S, Yokoyama T: Unpublished data), PH in experiment 2 (groups 5-7) was done 12 weeks following an injection of DENA at a dose of 100 mg/kg for group 5 and at a dose of 200 mg/kg for group 6 to test the effect of PH when some altered foci were already present. PH was not performed on group 7, which received a single injection of 200 mg DENA/kg. Animals in experiments 1 and 2 were fed a basal diet during the experiments. Five animals in groups 5 and 6 were killed at weeks 15 and 18 and 5 animals in group 7 were killed at weeks 2, 6, 12, 15, and 18 after DENA treatments.

Histochemistry of and quantitative analysis for induced altered foci.—Liver sections (3–5 mm thick) were obtained from the right anterior, right posterior, and caudate lobes of both hepatectomized and nonhepatectomized animals. They were fixed in cold acetone (4°C). The NSE reaction was used as an additional histochemical marker for altered foci because we have found that neoplastic nodules induced by 2-FAA in rat liver showed, on occasion, more evenly strong positivity for NSE than for GGT (Hirota N, Moriyama S, Yokoyama T: Unpublished data). Staining for both GGT and NSE was done on paraffin-embedded serial sections (4–5 μm). For GGT staining, the sections were incubated in a freshly prepared medium containing 6-glutamyl-4-methoxy-2-naphthylamine as substrate and fast blue BBN as the coupling agent (*21*). Following the method of Burstone (*22*) for NSE staining, we used naphthol AS-D (3-hydroxy-2-naphthol-*o*-toluidide) acetate as substrate and garnet GBC as the coupling agent. Counterstaining for GGT was done with hematoxylin, but no counterstaining for NSE was done. We quantitatively analyzed induced altered foci by calculating their numbers and measuring the area—by use of the method previously employed (*11, 23*)—of the foci identified by histochemically positive reactions for GGT and NSE.

RESULTS

Effects of PH Before Appearance of Altered Foci in Liver Exposed to a Single Injection of DENA (Expt 1)

A small number of GGT-positive hepatocytes occasionally scattered loosely in the periportal area was not counted as foci, but the foci were limited to discrete hepatocellular lesions forming GGT-positive islands (fig. 1). A strong positive reaction for NSE was frequently evident in the foci in contrast to a weak positive reaction for NSE found primarily in the central zone of the hepatic lobule from any liver examined (fig. 2). The results, summarized in table 1 and in text-figure 2, show that PH after a single injection of DENA induced hepatocellular altered foci much earlier than did DENA alone and that the number of foci was closely related to the interval between DENA treatment and PH.



TEXT-FIGURE 1.—Diagramatic representation of experimental designs for the study of the effect of PH on the formation of histochemically altered foci after DENA injection. *Small arrows*=time periods when animals were killed.

In the group of animals subjected to PH at 6 hours after an injection of 100 mg DENA/kg (group 1), GGT-positive foci were observed as early as 2 weeks after PH (average number of foci, ≈11/cm^2), whereas no foci were found in group 3 until 12 weeks after DENA (100 mg/kg) treatment without PH. The number of foci decreased slightly by the 6th week but was maintained at almost the same level until the 18th week. As compared with the number of foci in the group that received DENA alone, the number of foci in group 1 was about four times greater at the 18th week. In some instances, large areas of foci almost exceeding those of the hepatic lobule were observed at the 12th or 18th week.

In the group of animals subjected to PH 24 hours after the DENA treatment (group 2), the number of foci also increased but the number at each time point after PH was less than half that in group 1. The number of foci at any time point, however, was still greater than that in group 3. No foci were found in the group treated with PH alone (group 4) for the duration of the experiment.

Effect of PH After Appearance of Altered Foci in Liver Exposed to a Single Injection of DENA (Expt 2)

A small number of GGT-positive foci (0.6/cm^2) and of NSE-positive foci (0.2/cm^2) was present at 12 weeks after

TABLE 1.—*Number[a] of histochemically altered foci, with a comparison of positivity for GGT and NSE*

TEXT-FIGURE 2.—Effect of PH after DENA injection on the induction of GGT-positive foci as measured by the number of foci/cm^2. Graphs for group 4 (PH alone). which gave no foci at any point examined, is eliminated in this text-fig. □----□, group 1; △-----△, group 2; ○——○, group 3; ○----○, group 5; ●----●; group 6; ●——● group 7; *bars*, SEM.

an injection of 100 mg DENA/kg (group 3). At the same number of weeks after treatment with 200 mg DENA/kg (group 7), the number of both foci was about five times as high as that in group 3. As shown in table 1 and text-figure 2, at 3 or 6 weeks after PH, the number of foci in both groups 5 and 6 significantly increased in contrast to the focus counts in groups 3 and 7, which slightly increased or remained almost constant. The number of GGT-positive foci in both groups 5 and 6 reached approximately three times greater levels at 6 weeks following PH as compared to the levels seen in the nonhepatectomized groups 3 and 7, respectively.

GGT-positive foci were more frequently detected than NSE-positive foci at any point in experiment 2 as well as experiment 1 (table 1). The former foci on occasion did not necessarily correspond to the latter foci (figs. 3, 4) but not vice versa.

DISCUSSION

The present studies document that PH performed even up to 12 weeks after a single exposure to DENA enhances the formation of altered foci. Foci are believed to be the progeny of liver cells in which the carcinogen damage to genetic material has been converted into a permanently altered genome (*24–27*). Since DENA alkylates DNA (*28–*

30), the effect of PH is interpreted to represent the enhanced conversion of DNA damage to permanent mutations during the cell replication induced by PH. This interpretation is consistent with the finding that increased replication of liver cells in culture enhances the mutagenic effects of alkylating agents (*31, 32*).

With time, damage to DNA will be repaired (*28, 30, 33, 34*). The difference between groups 1 and 2 in the increasing number of foci following PH further supports the concept that DNA damage will be repaired over time, if not to the point of absolute elimination. The present data agree with a recent hypothesis of Ishikawa et al. (*19*) that the extent of repair of carcinogen-induced DNA damage is proportionally related to the length of the resting phase of the cell cycle. Although DNA repair in the target cells appears to occur with time following DNA damage by carcinogen exposure, the significant increase in foci effected by PH, which was observed in groups 5 and 6, conceivably indicates that some minor fraction of liver cells continues to have DNA damage even as long as 12 weeks after a single treatment with DENA.

The present approach in which PH is used to enhance the appearance of foci provides a means in vivo to distinguish genotoxic carcinogens from epigenetic carcinogens, since the former induce DNA damage but the latter do not, according to the concepts proposed by Williams (*35, 36*). A single injection of DENA into rats provided an excellent system for in vivo study of the mechanism of DNA damage and repair because there was no need to resort to techniques for acceleration, such as repeated exposure to carcinogen or other chemicals. PH has been applied extensively by Ito et al. (*37*) and Tsuda et al. (*38*) to the short-term in vivo assay in rat liver for the assessment of the carcinogenicity of various chemical compounds. However, Ito et al. and Tsuda et al. used some complex modalities. The former group (*37*) used 2-FAA or DENA as initiator followed by PH performed in the middle of administration of test chemicals; the latter group (*38*) performed PH prior to or after the treatment with the test compounds followed by an injection of carbon tetrachloride in the midst of 2-FAA feeding (*38*). The possibility exists that the length of time required for the assessment of the genotoxic carcinogenicity of other chemicals to various target organs other than the liver could also be shortened in vivo by use of techniques that stimulate cell proliferation.

In regard to histoenzymic markers employed, we found that phenotypic heterogeneity occurred between foci for the two markers GGT and NSE and that NSE was relatively less sensitive for the detection of foci than GGT and yet an increase of GGT-positive and NSE-positive foci was induced by PH. Considerable phenotypic heterogeneity among foci, possibly reflecting multiple genotypic changes in the cells of foci, was also described previously by Hirota and Williams (*9*) who studied the sensitivity and heterogeneity of various histochemical markers for 2-FAA-induced altered foci; these authors found that, compared to any of the other histochemical properties in the siderotic liver, which was sufficiently loaded with iron, resistance to iron accumulation was the property that identified the greatest number of foci, with GGT positivity being the next most sensitive property.

Evidence for Involvement of Mast Cells in Tumor Suppression in Mice[1,2,3]

Hiroshi Tanooka,[4] Yukihiko Kitamura,[5] Toshihiko Sado,[6] Kazuhiko Tanaka,[4] Mizue Nagase,[4] *and* Sohei Kondo[5,7]

ABSTRACT—Mast cell-deficient W/W^v mice had an increased tumor incidence after subcutaneous treatment with 3-methylcholanthrene, compared with that in normal congenic mice treated in the same way. This increased tumor incidence was suppressed to the normal level when the carcinogen was given after the mast cell deficiency had been overcome by transplantation of bone marrow cells from normal congenic mice. The W/W^v mice, however, were not defective in natural killer and T-cell-mediated cytotoxic activities. These results support the hypothesis that mast cells are involved in tumor suppression.—JNCI 1982; 69:1305–1309.

A role of immunosurveillance for tumor suppression has been suggested (*1*). However, no clear evidence exists that the candidates for this role, such as T-cells or NK cells, have this function, inasmuch as mutant mice deficient in these cells, i.e., beige and nude mice, do not show a higher incidence of autochthonous tumors after treatment with carcinogen than their normal counterparts (*2, 3*). Nevertheless, earlier studies (*4–6*) have suggested involvement of mast cells in tumor suppression, and a recent review (*7*) indicated the possible importance of an allergic type reaction in host resistance to solid tumors and hence the possible involvement of mast cells. More directly, isolated mast cells were shown to inactivate tumor cells selectively in vitro (*8, 9*).

To test the hypothesis that mast cells are involved in tumor suppression, we used mice with a mutant genotype, W/W^v (*10*); these mice lack hair pigmentation and are anemic and sterile. W/W^v mice were recently found to be deficient in mast cells, and this characteristic has been extensively studied (*11, 12*). Spontaneous development of leukemia (*13, 14*) and forestomach papillomas (*15*) have been reported in the W/W^v mice. In the experiments reported herein, we observed an increased tumor incidence in the W/W^v mice, over that in normal congenic +/+ mice, after sc injection of MCA.

Furthermore, mast cell deficiency in these mice can be overcome by transplantation of bone marrow cells from normal congenic mice (*11*). We, therefore, tested tumor induction in W/W^v mice after bone marrow transplantation to demonstrate more directly the effect of mast cells. The results were consistent with the hypothesis that mast cells are involved in tumor suppression.

MATERIALS AND METHODS

Mice.—Mice with a W or W^v mutation (*10*) were originally obtained from The Jackson Laboratory, Bar Harbor, Maine. A cross between WB-$W/+$ ($H\text{-}2^w$) and C57BL/6-$W^v/+$ ($H\text{-}2^b$) mice yielded WBB6F$_1$ offspring of the genotypes W/W^v, $W/+$, $W^v/+$, and $+/+$. W/W^v and $+/+$ mice, which were easily distinguishable by their hair color, were used in this experiment. The mice were given free access to a mouse diet (CE-1; Clea Japan Inc., Tokyo, Japan) and water and kept in cages in an isolation rack supplied with filtered air. Both males and females were 2–3 months old when used in the experiments.

Bone marrow transplantation.—Bone marrow was obtained from the femurs of +/+ mice, and a homogeneous suspension of cells in Eagle's minimum essential medium was prepared. About 3×10^7 bone marrow cells of +/+ mice were transplanted intravenously into W/W^v mice 2 months before the experiments commenced (*11*).

Tumor induction and analysis of data.—MCA (Fluka AG, Buchs, Switzerland) was dissolved in olive oil at 5 or 0.5 mg/ml, and 0.1 ml of the mixture was injected sc into the right groin of the mice, as described in (*16*). Tumor formation was examined by palpation at intervals after the carcinogen injection, and the day of tumor appearance and the day of death of animals without tumors were recorded. Data from two independent experiments were combined, and cumulative tumor incidence rates were calculated by the Kaplan-Meier method (*17*). Statistical significances of differences in tumor incidences between the two groups were evaluated by the log-rank test (*18*). Tumor size was measured with a caliper, and the volume-doubling time was determined from the slope of the initial portion of the tumor growth curve, as described previously (*16*). The tumors produced were examined histologically after being stained with H & E and with toluidine blue (pH 3.0) to confirm the presence of mast cells (*11*).

ABBREVIATIONS USED: Con A=concanavalin A; H & E=hematoxylin and eosin; LPS=lipopolysaccharide; MCA=3-methylcholanthrene; NK=natural killer; PHA=phytohemagglutinin.

NK activity.—NK activity was assessed by a direct ^{51}Cr release assay in vitro (*19*). A fixed number of spleen cells from a single test mouse was incubated for 6 hours with 2×10^4 YAC-1 target cells labeled with ^{51}Cr ($Na_2{}^{51}CrO_4$; sp act, 568 mCi/mg; New England Nuclear Corp., Boston, Mass.) at two effector-to-target cell ratios, 50:1 and 100:1. Cytotoxicity was expressed as the percentage release of ^{51}Cr.

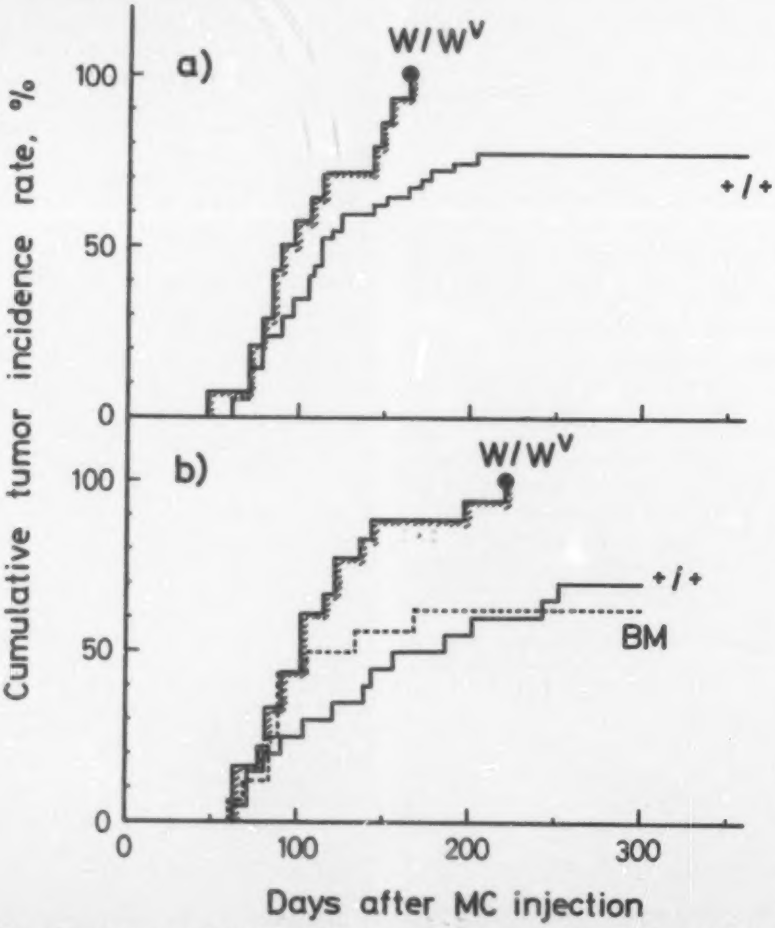
Cytotoxic T-cells.—Cytotoxic T-cell activity was assayed, as described previously (*20*), with a 6-day mixed lymphocyte culture of test spleen cells and 1,500-rad-irradiated allogeneic (B10.D2, *H-2^d*) spleen cells; ^{51}Cr release was assayed with DBA/2 (*h-2^d*)-derived L5178Y target cells. Results, expressed as lytic units per culture and per spleen, were calculated by the method of Cerottini et al. (*21*). One lytic unit is defined as the number of effector cells that kills 50% of 4×10^4 target cells.

Mitogen responsiveness.—The method for assessing the proliferative response of spleen lymphocytes to mitogens has been described in detail elsewhere (*22*). The mitogens used were PHA (Wellcome Reagents Limited, London, U.K.), LPS (Difco Laboratories, Detroit, Mich.), and Con A (Sigma Chemical Co., St. Louis, Mo.).

RESULTS

Tumor induction.—Text-figure 1A shows the cumulative tumor incidences in *W/W^v* mice and congenic +/+ mice after injection of 0.5 mg MCA/animal. The tumor incidence in *W/W^v* mice was significantly higher than that in +/+ mice. Incidence reached 100% in *W/W^v* mice on day 163, when it was still 65% in +/+ mice. The higher tumor incidence in *W/W^v* mice was more significant with a lower MCA dose of 0.05 mg/animal (text-fig. 1B). No significant difference was apparent in each group between the incidence in males and the incidence in females.

To demonstrate the effect of mast cells on tumor induction



TEXT-FIGURE 1.—Tumor incidence after sc injection of MCA into *W/W^v* and +/+ mice, and effect of transplantation of bone marrow from +/+ mice into *W/W^v* mice on the incidence. a) Tumor induction with 0.5 mg MCA. Final tumor incidence: *W/W^v*, 14/14; +/+, 30/39. Death without tumors: 1 +/+ mouse. Significance of difference in tumor incidence between *W/W^v* and +/+ mice evaluated by the log-rank test (*18*): $P<0.05$. b) Tumor induction with 0.05 mg MCA. Final tumor incidence: *W/W^v*, 18/18; +/+, 14/20; and bone-marrow-transplanted *W/W^v* mice (BM), 10/16. Death without tumors: 0. Significance of difference between tumor incidence in *W/W^v* and +/+, and in *W/W^v* and bone marrow-transplanted mice: $P<0.005$ and $P<0.05$, respectively.

more directly, we gave iv injections of bone marrow cells from normal +/+ mice to *W/W^v* mice. The shift in size of the red blood cells in the peripheral blood of *W/W^v* mice (62 μm^3) to normal size (47 μm^3)—an indicator of the effectiveness of bone marrow transplantation that is substantiated by the appearance of mast cells in various organs (*11*)—was monitored with a Coulter counter. Two months after this transplantation, normal blood cells proliferated fully in all the *W/W^v* mice. The mice were then given sc injections of 0.05 mg MCA. The time course of tumor formation is shown in text-figure 1B. Data show that bone marrow transplantation suppressed the higher tumor incidence in *W/W^v* mice to the level in normal +/+ mice.

Except for 1 squamous cell carcinoma and 1 adenocarcinoma in +/+ mice treated with 0.5 mg MCA, all the tumors produced in the present experiments were sarcomas [fibrosarcomas, 77%; malignant fibrous histiocytomas, 16%; other sarcomas (pleiomorphic, myogenic, and liposarcomas, 7%)]. No mast cells were detectable around the tumors that developed in the *W/W^v* mice. In contrast, many mast cells were observed surrounding the tumors that developed either in the +/+ mice or in the *W/W^v* mice that had been given injections of bone marrow cells from the +/+ donors (fig. 1). Even in such cases, mast cells were scarcely detected within the tumors.

Tumor volume-doubling times were determined from the sarcoma growth curves. The average values after treatment with 0.5 mg MCA were 2.8±1.0 days for *W/W^v* mice and 3.1±1.1 days for +/+ mice; after treatment with 0.05 mg MCA the values were 2.9±0.7 days for *W/W^v* mice and 2.9±0.5 days for +/+ mice. The volume-doubling time was independent of the time of tumor appearance, and the results show that tumors grew at the same speed in *W/W^v* and +/+ mice.

Immunologic parameters of splenic lymphocytes of W/W^v *and +/+ mice.*—Several immunologic parameters of spleen lymphocytes from *W/W^v* and +/+ mice were assessed, including NK and cytotoxic T-cell activity and the proliferative response to mitogens. The results summarized in table 1 indicate the following: 1) The total number of viable cells per spleen was higher in *W/W^v* than in +/+ mice. The difference was highly significant. 2) NK activity, assessed with a fixed number of spleen cells, was slightly lower in *W/W^v* mice, but the difference was not significant. Correction of NK activity for total spleen cells resulted in much closer values for the 2 groups (data not shown). 3) Cytotoxic T-cell activity in total spleen was higher in *W/W^v* than in +/+ mice. However, this difference was not significant when the activity was normalized for the cell number. 4) The proliferative responses to PHA and Con A were significantly lower, and the response to LPS was considerably lower, in *W/W^v* than in +/+ spleens when compared on the basis of ^{3}H-labeled thymidine uptake by 5×10^5 cells.

TABLE 1.—*Immunologic parameters of splenic lymphocytes of +/+ and* W/W^v *mice*[a]

Parameter	+/+	*W/W^v*	Statistical significance[b]
Total No. of viable cells per spleen ($\times10^6$)	127.7±13.1	248.6±24.4	$P<0.001$
NK cell[c]	24.3±2.3	18.3±7.6	$0.5>P>0.4$
Cytotoxic T-cell[d]	62.4±16.8	235.5±39.1	$0.01>P>0.001$
Mitogen response[e]			
PHA	4.385±0.017	4.121±0.085	$0.02>P>0.01$
LPS	4.124±0.054	3.56±0.29	$0.1>P>0.05$
Con A	4.330±0.054	3.82±0.11	$0.01>P>0.001$

[d] Lytic units per spleen.
[e] Log Δ cpm/5×10^5 cells.

DISCUSSION

The present work shows that tumor incidence after MCA treatment is higher in *W/W^v* mice than in normal congenic mice. In addition to being deficient in mast cells, *W/W^v* mice also differ from +/+ mice in showing marked symptoms of anemia. However, we know of no report of an increased incidence of solid tumors in anemic mice after treatment with a carcinogen. Moreover, our results indicate that *W/W^v* mice show no significant defects in NK, T-cell-mediated cytotoxic activity or in the proliferative responses of their spleen lymphocytes to mitogens. Mekori and Phillips (*23*) reported that the antibody-forming ability of B-cells and the helper function of T-cells were normal in the *W/W^v* mice, and Bennett (*24*) stated that alloantigen-sensitive cells of the *W/W^v* mice had normal function. The conclusions of these authors are consistent with the results we obtained. Thus we regard the findings of our study as evidence for the hypothesis that mast cells are involved in tumor suppression.

The growth rates of tumors in *W/W^v* and +/+ mice, however, were equal, which suggests that the tumor-suppressing action of mast cells becomes inefficient after the tumors have grown to a certain size. Mast cells were found around the periphery of tumor masses in histologic sections, but not many were seen inside the masses. Such histologic features are similar to those described by Cramer and Simpson (*6*) who investigated the reaction of mast cells to epithelial tumors induced by skin painting with MCA. Furthermore, increased ornithine decarboxylase activity, an indicator of tumor promotion, did not differ in *W/W^v* and +/+ mice after treatment of the skin with 12-*O*-tetradecanoyl phorbol 13-acetate (Fujiki H, Tanooka H: Unpublished observation). The action of mast cells, therefore, seems to be exerted at an early stage of tumorigenesis.

H-2 Expression on a Teratocarcinoma-Derived Cell Line, TerC[1,2,3]

David B. Searls[4,5] *and* **Michael Edidin**[4]

ABSTRACT—The murine teratocarcinoma-derived cell line TerC, previously thought to lack products of the major histocompatibility locus *H-2*, was shown to express low levels of *K*- and *D*-end H-2 specificities with the use of a sensitive cytotoxic assay. The assay, based on the ability of antibody and complement to inhibit uptake of the thymidine analogue $[^{125}\text{I}]$5-iodo-2′-deoxyuridine, detected appropriate public and private specificities, as demonstrated with the use of oligospecific antisera and by absorption analyses. A series of clones of TerC varied only slightly in *H-2* expression, and there was no tendency for expression to increase with time in culture; thus the low levels of H-2 were not the result of a differentiating subpopulation.—JNCI 1982; 69: 1311–1315.

Because of their embryonic character, teratocarcinoma-derived cell lines have been used as immunogens in the study of embryonic and oncofetal antigens [*see* (*1*) for review]. The primary stem cell lines of these tumors, termed "embryonal carcinomas," have proved particularly useful for the production and characterization of antisera and monoclonal antibodies that cross-react with various stages and cell types of the early mouse embryo (*2, 3*). Embryonal carcinomas appear to be devoid of products of the mouse major histocompatibility complex *H-2* (*4*), a unique trait that not only makes these cells intrinsically interesting but also has proved useful in the study of H-2 restriction phenomena (*5*). Using cell hybridization techniques (*6*) and by following differentiation in vitro (*7*), other investigators have used teratocarcinoma-derived cell lines to study the regulation of *H-2* expression.

One of the first cell lines to be used in the study of oncofetal antigens was the 402AX teratocarcinoma-derived cell line TerC. Gooding and Edidin (*8*) characterized a xenoantiserum against this cell. This xenoantiserum contained multiple specificities defining embryonic and tumor antigens. Subsequent work has elucidated the chemical nature of some TerC-defined antigens (*9, 10*), and cellular immune reactions against these antigens have been investigated (*11*). Early studies reported that a small percentage of TerC was H-2-positive as judged by immunofluorescence and that large inocula of TerC slightly accelerated *H-2*^{b} skin graft rejection on congenic *H-2*^{k} mice (*12*). However, the cells are resistant to lysis by anti-H-2 antibody and complement and TerC can produce tumors in various allogeneic mice (*13*).

Further study of *H-2* expression on TerC cells would seem to be warranted to resolve the discrepancies in the published data. Also, TerC appears to resemble primitive endoderm, rather than embryonal carcinoma (*14*). Differentiation to endoderm is among the first events seen in embryogenesis (where endoderm arises from the inner cell mass) (*15*), as well as in the differentiation of embryonal carcinoma cells, both in vivo (in the formation of endoderm-coated embryoid bodies in ascites) (*16*) and in vitro (*17*). Thus the low levels of *H-2* expression on TerC might effectively model the earliest appearance of H-2 in both these systems, an unresolved aspect of early mouse development (*18*) that bears on the suggestion that H-2 antigens may be important in cell associations during early development (*19, 20*) and on the problem of maternal tolerance of the fetal allograft. Though another group did not detect H-2 antigens on endodermal derivatives of a pluripotent embryonal carcinoma (*7*), we find that low levels of H-2K and H-2D molecules are indeed present on teratocarcinoma-derived primitive endodermal cell lines.

MATERIALS AND METHODS

Cells.—TerC and cl1D (LM-TK^{-}) have been described previously (*16*). LM cells were donated by Dr. Richard Pagano, Carnegie Institution of Washington, Department of Embryology, Baltimore, Md., and EL 4 G-cells were donated by Dr. R. B. Herberman, National Cancer Institute, Bethesda, Md., (*21*). Embryonal carcinoma F9 (*22*) and the parietal endoderm cells PYS-2 (*23*) derived from teratocarcinoma OTT6050 were the gifts of Dr. Karen Artz, Memorial Sloan-Kettering Cancer Center, New York, N.Y. All cells were grown in Eagle's minimum essential medium (GIBCO, Grand Island, N.Y.) supplemented with 5% (vol/vol) fetal bovine serum (Reheis Chemical Co., Phoenix, Ariz.) and 1% antibiotic–antimycotic (GIBCO). Adherent cell lines were harvested with a mixture of 0.2% (wt/vol) trypsin, 0.002% (wt/vol) collagenase, and 2.5% (vol/vol) chick serum in Ca–Mg-free Hanks' balanced salt solution. They were then passaged every 3 days.

Cell cloning.—Cells were diluted to approximately 2×10^{2} cells/ml in growth medium, and 10-μl droplets of this suspension were placed in the center of each well of a 24-well plate (Linbro, subsidiary of Flow Laboratories, Inc., McLean, Va.). Each droplet was examined visually with an inverted phase-contrast microscope, and wells containing a single cell were filled with growth medium consisting of approximately 10^{3} irradiated primary embryonic fibroblasts. Cloning efficiency for the TerC cell line was about 90%.

ABBREVIATION USED: $[^{125}\text{I}]$IdUrd=$[^{125}\text{I}]$5-iodo-2′-deoxyuridine.

Antisera.—High-titered anti-H-2 antisera were raised in mice in the congenic combination C3H anti-C3H.SW (anti-$H\text{-}2^b$) and its reciprocal, C3H.SW anti-C3H (anti-$H\text{-}2^k$) by use of the following protocol: day 0, inject ip spleen and mesenteric lymph node cells in a donor:recipient ratio of 1:4; day 14, follow the same procedure as used on day 0; day 35, inject sc spleen and lymph node, sonicated with complete Freund's adjuvant, at 1:4; day 45, bleed from the retro-orbital sinus; day 50, inject ip spleen and lymph node at 1:5; days 52 and 59, bleed; day 63, inject ip spleen and lymph node at 1:5 with 10^6 Ehrlich ascites tumor cells; day 72, bleed and remove ascites; day 78, bleed terminally and remove ascites. High titers of polyspecific antibodies were found in both serum and ascitic fluid. For this study, only serum from the final bleed was used; reactions with lymphocytes of different *H-2* haplotypes are shown in table 1. Low levels of reactivity against L-cells were found in the anti-$H\text{-}2^b$ serum but were removed by absorption without affecting reactivity against TerC or EL 4. Age-matched and sex-matched C3H normal mouse serum was used as a control. All sera were heated for 30 minutes at 56°C, a procedure that removed some nonspecific reactions without affecting titers.

Putatively monospecific anti-H-2 sera were obtained from the Genetics and Transplantation Biology Branch, National Institute of Allergy and Infectious Diseases, Bethesda, Md.

Sera were titered against mouse lymphocytes by a two-step microcytoxicity assay (*24*).

Assay for cell damage by [^{125}I]IdUrd uptake.—This assay is an adaptation of the [^{14}C]uridine method of Garrido et al. (*25*). Freshly harvested cells were brought to a concentration of 5×10^6 cells/ml growth medium, and 30 µl of this suspension was dispensed into each well of a 96-well microtiter plate (Costar, Data Packaging Corp., Cambridge, Mass.). Between steps of the procedure, plates were returned to a humidified, 5% CO_2, 37°C incubator; 10 µl of appropriately diluted antiserum (or, in control wells, growth medium) was added, for a final dilution of 1:4 of the initial dilution. After 10 minutes, 10 µl of diluted rabbit serum used as a source of complement (Pel-Freez Bio-Animals, Inc., Rogers, Ariz.) was added, for a final dilution 1:5 of the initial dilution. Growth medium was added to some wells instead of complement to gauge the nonspecific effects of complement alone. After 10 minutes, 100 µl of growth medium with a total of 2% antibiotic–antimycotic was added, and the plates were incubated for 2–4 hours. At the end of this time, 10 µl of [^{125}I]IdUrd (New England Nuclear Corp., Boston, Mass.) at 0.1 µCi/ml in growth medium was added to each well for a final dilution of 1 µCi/well. (Addition of the label immediately after the other steps resulted in an appreciable reduction in uptake.) Cells were allowed to take up label overnight (16–18 hr) and were then collected in a cell harvester (Otto Hiller Co., Madison, Wis.) with the use of 934 AH glass fiber filter paper (Whatman Inc., Clifton, N.J.). Filters were counted in a Beckman gamma counter.

Percent inhibition of [^{125}I]IdUrd uptake was calculated as follows, where *C* is the mean uptake (in cpm) in control wells, *E* is the uptake in those containing antiserum, and *B* is the counter background:

$$\text{Percent inhibition} = \frac{C-E}{C-B} \times 100.$$

The standard deviation of the percent inhibition is given as

$$\frac{E}{C} \times \sqrt{\frac{e^2}{E^2} + \frac{c^2}{C^2}},$$

where lowercase letters represent the standard deviations of their respective (uppercase letters) means.

A large number of lots of rabbit serum were tested in this assay, and about one lot in seven was selected and pooled on the basis of relatively high specific and low nonspecific activities. Complement was generally used at a final dilution of 1:20, a concentration that nonspecifically inhibited [^{125}I]IdUrd uptake by approximately 20% while maintaining maximal specific reactions.

All additions to the wells were sterile except for antisera and complement. The concentration of antibiotic–antimycotic was raised to 2% as a precaution; visual inspection revealed no evidence of contamination attributable to the nonsterilized additions, and test wells containing label but no cells gave no counts above background.

Absorption assay.—Varying numbers of cells were used to absorb 50 µl of anti-H-2 sera for 2 hours on ice. Antisera were diluted to give approximately 90% lysis of target cells (mesenteric node lymphocytes), as judged by nigrosin dye exclusion. Cell diameters were determined with a Zeiss micrometer eyepiece.

RESULTS

Characterization of *H-2* Expression on TerC

The titers of our antisera in a conventional complement-dependent cytoxicity assay on lymphocytes are given in

TABLE 1.—*Titers of anti-*H-2 *sera by conventional microcytotoxicity against a standard panel of lymphocytes*

Strain	Haplotype	Anti-$H\text{-}2^b$	Anti-$H\text{-}2^k$	D-2	D-5AF	D-28(2)	D-29	D-33	D-35

table 1. These antisera are described fully in table 2, which also indicates their activity in the [^{125}I]dUrd-uptake inhibition assay against TerC and two control cell lines, EL 4 (*H-2^b*) and LM (*H-2^k*). Antisera detecting both *K*- and *D*-end private specificities (after absorptions that rendered them monospecific) reacted with TerC to some degree, as did at least two antisera against public specificities. Two other antisera with weak titers against *H-2^b* public antigens did not show appreciable reactions with TerC. High-titered oligospecific antisera against *H-2^k* public and private specificities were also tested (data not shown) and did not react with TerC. The polyspecific anti-*H-2^b* antiserum also reacted at high concentrations, whereas the reciprocal anti-*H-2^k* did not. All antisera reacted as expected with the H-2-positive control cell lines.

The anti-*H-2^b* antiserum was absorbed with the control cell lines and with a series of B10-congenic lymphocytes as shown in table 3. EL 4 cells were able to completely absorb the activity of this antiserum with TerC, whereas LM cells failed to do so. An appropriate number of *H-2^b* lymphocytes also ablated the reactivity; *H-2^k* lymphocytes were ineffective. Recombinant haplotypes absorbed only part of the serum's activity, which confirmed that products at both ends of the *H-2* complex were being detected by the polyspecific anti-*H-2^b* serum.

Clonal Variation in *H-2* Expression

Even at high concentrations of anti-*H-2^b*, specific inhibition of TerC seldom exceeded 50%. This observation raised the possibility that a subpopulation of cells was expressing relatively higher levels of the antigen. To test this possibility, we cloned the line and tested several of the resulting clonal lines along with a series of control cell lines as shown in table 4. Some variation was found; two clones, TerCb and TerCe, consistently demonstrated the highest and lowest reactivities, respectively. Nevertheless, growth even of TerCb was never completely inhibited, and all of the clones reacted to some degree. The F9 embryonal carcinoma cells, though derived from the same mouse strain as TerC, were not damaged by anti-*H-2^b*. The PYS-2 parietal endoderm cells from the same strain were somewhat more sensitive to the antiserum than were any of the TerC clones. Like the parent cell line, these clones were completely negative by immunofluorescence when the same antisera were used at a 1:2 dilution (data not shown).

Reactivity of the TerC clones tended to level off at the higher antiserum concentrations (table 4). Inasmuch as antibody is probably in excess at this point, it may be that antigens are saturated with antibody but that they are too few in number to effect efficient complement-mediated killing by IgG antibodies; it is also possible that TerC is intrinsically resistant to complement-dependent lysis. However, since teratocarcinoma-derived cell lines tend to differ-

[a] These absorptions remove undesired reactions observed in the panel test above and also noted in the National Institutes of Health Catalog of Mouse Alloantisera. Generally, 2–3 volumes of appropriately diluted antisera were absorbed for 2 hr on ice with 1 volume of packed lymphocytes teased from spleens and lymph nodes of mice noted below.

[b] Absorption with DBA/1 removes a weak reaction against *H-2.56*.

[c] Precautionary absorption with B10.D2 removes a potential reaction against *H-2.29* (not present, according to the National Institutes of Health catalog).

[d] Precautionary absorption with DBA/1 removes a potential reaction against *H-2.54* (weak, according to the National Institutes of Health catalog, and not detected in the panel test above).

[e] Absorption with B10.PL removes a weak reaction against *H-2.53*.

[f] Absorption with B10.SM removes a nonspecific reaction, also noted in the National Institutes of Health catalog. All antisera were tested against control cell lines EL 4 and LM at dilutions of 1:500 and against TerC at a dilution of 1:20.

	TerCe	8	85

[a] Antisera were diluted and absorbed as described in "Materials and Methods." Anti-$H\text{-}2^b$ was tested against 129/SvSl lymphocytes, and anti-$H\text{-}2^k$ was tested against C3H/He lymphocytes by standard microcytotoxicity.

entiate spontaneously, even their clones may produce heterogeneous cell populations despite clonal origins.

If TerC were exhibiting a tendency to differentiate to an H-2-positive cell type, it might be expected that the proportion of such cells would increase with time in culture or [by analogy with the differentiation of pluripotent embryonal carcinoma cells in culture (*7*)] with time after subculturing. As can be seen in table 5, this is not the case; the reactivity of TerC clones with anti-H-2^b, in fact, decreased somewhat under both circumstances.

Quantitation of H-2 Antigens

To quantitate relative levels of *H-2* expression on these lines, we used TerCb and TerCe to absorb anti-*H-2* sera, which were then retested on the appropriate target lymphocytes by standard microcytotoxicity. Table 6 shows the results of these absorptions in comparison with absorptions by the target lymphocytes. The TerC clones were five to ten times less effective than lymphocytes in absorbing anti-$H\text{-}2^b$ reactivity. Inasmuch as the cell diameters of the TerC lines are about three times greater than those of lymphocytes, the ratio of their surface areas is approximately 9:1 [neglecting microvilli, which are found on both cell types (Ostrand-Rosenberg S: Personal communication)]. Thus the density of H-2 antigens on the TerC lines appears to be fiftyfold to a hundredfold less than that on lymphocytes.

DISCUSSION

An assay for antibody plus complement-mediated cell damage, measured by inhibition of [^{125}I]IdUrd uptake, has been used to detect low levels of *K*- and *D*-end gene products of the *H-2* complex on the teratocarcinoma-derived cell line TerC. This conclusion is supported by the cell line's reaction with a wide variety of anti-$H\text{-}2^b$ sera, including operationally monospecific reagents detecting both private specificities, and by the absorption of the activity against TerC with lymphocytes of the appropriate haplotypes. The partial absorptions observed with recombinant haplotypes also suggest that the reactions are not due solely to closely linked loci on one side or the other of the *H-2* complex, such as the *Qa*, the *Tla*, or the *T*-locus. It is also unlikely that the reactions with TerC are attributable to Ia antigens, since absorption with the Ia-negative, $H\text{-}2^b$-positive cell line EL 4 (*26*) completely removed the activity. Although it is possible that the assay is detecting fetal or tumor antigens with determinants cross-reactive with H-2 specificities, this alternative explanation is highly unlikely since many specificities of the $H\text{-}2^b$ haplotype are expressed while no specificities of the $H\text{-}2^k$ haplotype appear to be present.

Using a highly sensitive [^{14}C]uridine-uptake inhibition assay (from which the present assay was adapted), Garrido et al. (*25*) detected numerous "inappropriate" H-2 specificities in virally transformed cell lines. The failure of a high-titered, polyspecific anti-*H-2*^{k} serum (in which only H-2^{b} specificities are "covered") to react with TerC suggests that no such unexpected specificities are being detected. Using cell lines derived from mouse blastocysts in quantitative absorption studies, Ostrand-Rosenberg et al. (*24*) found that individual H-2 specificities were present in widely varying proportions relative to each other on embryo-derived cell lines when compared to adult lymphocytes. In the absence of such quantitative absorptions with monospecific sera, such a phenomenon cannot be ruled out with the TerC line, but the reactivities of the antisera employed in this study against lymphocytes, the EL 4 cell line, and TerC were of roughly the same degree relative to each other; i.e., relative to those antisera with weak titers, antisera with high titers against *H-2*^{b} lymphocytes in standard microcytotoxicity reacted strongly in [^{125}I]IdUrd uptake inhibition with EL 4 and TerC. Thus neither unexpected specificities nor unusual proportions of appropriate specificities relative to each other have been detected in the data presented.

The nullipotent embryonal carcinoma line F9 showed no specific anti-*H-2*^{b} reactivity when our [^{125}I]IdUrd assay was used (table 4). However PYS-2, a parietal yolk-sac carcinoma derived from the same tumor, reacted somewhat more strongly than did TerC. Thus endodermal derivatives of the teratocarcinoma model system appear to demonstrate *H-2* expression quantitatively lower than but qualitatively similar to adult patterns of *H-2* expression.

Inhibitory Effect of Fumaric Acid on Forestomach and Lung Carcinogenesis by a 5-Nitrofuran Naphthyridine Derivative in Mice[1]

Keiko Kuroda,[2] Masayoshi Kanisawa,[3] *and* Mitsutaro Akao[2]

ABSTRACT—The inhibitory effect of fumaric acid (FA) on carcinogenesis by potassium 1-methyl-7-[2-(5-nitro-2-furyl)vinyl]-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylate (*trans*, NFN) was examined histologically with male ICR/JCL mice. NFN was fed to mice at a dose level of 0.012% in the diet for 14 weeks. These mice were then divided into 2 groups. One group was given a basal diet, and the other group was given a diet containing 1% FA in the subsequent 39 weeks. In the group of 30 mice fed NFN alone, squamous cell carcinomas were found in the stomachs of 7 mice, multiple papillomas in the stomachs of 13 mice, and multiple and large papillary adenocarcinomas in the lungs of 27 animals. The administration of FA suppressed the NFN-induced stomach and lung carcinogenesis. In the group of 32 mice fed NFN and FA, no stomach tumors developed except 1 early-stage of squamous cell carcinoma. In the lungs, only a small focus of mild atypical hyperplasia and a few early-stage adenocarcinomas were noted in 7 and 11 animals, respectively.—JNCI 1982; 69:1317–1320.

Previously, we indicated that the extract of *Capsella bursa-pastoris* (Cruciferae) herb has various kinds of pharmacologic activities such as diuretic, oxytocic, anti-inflammatory, antiulcerative, and anticarcinogenic (*1–4*). Later we isolated and identified FA as the component of the herb responsible for inhibiting the growth of subcutaneously transplanted Ehrlich tumors in mice (*5*) or gastric ulcers in rats (*6*).

NFN (*trans*) was synthesized by Nishigaki et al. (*7*) as a therapeutic agent for *Pseudomonas* infection but later was found by Kanisawa et al. (*8*) to be carcinogenic to the stomach and lung in mice fed the 5-nitrofuran with their diets and to the oral mucosa, esophagus, forestomach, lung, and mammary gland in animals given NFN with their drinking water (Kanisawa M: Unpublished data).

Recently, we (*9, 10*) found that FA reduced toxicity in mice exposed to mitomycin C and aided in the recovery of cultured cells that had been exposed to mitomycin C, NFN, and other carcinogens. In the present study, we examined the effect of FA on the carcinogenic processes in the stomach and lung tissues of mice fed the 5-nitrofuran carcinogen.

MATERIALS AND METHODS

Chemicals.—NFN (*trans*) was prepared by Daiichi Pharmaceutical Co., Tokyo, Japan, and FA was purchased from Nakarai Chemicals Ltd., Kyoto, Japan.

Animals and feed.—A total of 81 male ICR/JCL mice (CLEA Japan Inc., Tokyo), 5 weeks old, were used. Commercial diet CE-2 (CLEA Japan Inc.) was used as the basal diet, and an experimental diet containing either 0.012% of NFN or 1% of FA was also prepared by the same manufacturer. The animals were housed in an air-conditioned room kept at 23°C and 60% relative humidity with 12-hour light and 12-hour dark cycles.

Experimental procedure.—The feeding schedule is shown in text-figure 1. The animals were divided into 3 groups. Sixty-six mice weighing about 25 g were given the diet containing 0.012% of NFN for 14 weeks, and then the mice were divided into groups 1 and 2. Thirty-three mice of group 1 were given the basal diet for 39 weeks, while the same number of mice of group 2 were given the diet containing 1% FA for the same period. Fifteen mice of the control group were given the basal diet for 53 weeks. All animals were killed at the end of 53 weeks, and all organs except brain and bone marrow were fixed in a 10% Formalin solution. The stomach and lung were particularly fixed with instillation of 10% Formalin solution into the gastric or bronchial lumen. Animals that died during the feeding experiment were also necropsied. Five animals of group 1 and 1 animal of group 2, all of whom died after 7 months of the experiment, were counted as effective animals, inasmuch as the 5 animals of group 1 were found to have developed lung carcinomas. After macroscopic observation, all the tissues and tumors found in the gastric mucosa and the pleural surface of the lung were sliced, embedded in paraffin, sectioned, stained with hematoxylin and eosin, and examined histologically.

RESULTS

Untreated control mice showed no neoplastic changes in the stomach and lung. The administration of NFN to mice resulted in widespread growth of 7 squamous cell carcinomas (23% in incidence with regard to the effective number of animals; figs. 1–3), 3 keratinized and 4 nonkeratinized, and 13 multiple squamous cell papillomas (43%), which sometimes showed focal atypia (figs. 4, 5) in the stomachs. Leiomyosarcoma was found in the forestomach wall of 1 animal. NFN administration also produced large and multiple papillotubular adenocarcinomas (figs. 7–9) in the lungs of most animals (90%). In the mice given FA after the administration of NFN, the development of neoplastic changes was almost completely inhibited (fig. 6). Squamous epithelium of the forestomach as well as the glandular stomach mucosa showed no pathologic alterations, except

TABLE 1.—*Inhibitory effect of FA on induction of tumors and associated lesions in mice fed NFN*

Site of tumor	Tumor type	Group[a]		
		Control (15)	NFN (30)	NFN+FA (32)
Forestomach	Keratinized squamous cell carcinomas	0	3	0[b]
	Nonkeratinized squamous cell carcinomas	0	4	0[b]
	Early stage of squamous cell carcinoma	0	0	1
	Multiple papillomas	0	13	0
	Leiomyosarcoma	0	1	0
Lung	Papillotubular adenocarcinomas	0	27	0[c]
	Early stage of adenocarcinomas	0	2	11
	Mild atypical hyperplasia	0	1	7

[a] *Numbers in parentheses* are the effective No. of animals.

[b] Significant at $P<0.05$ by Fisher's exact probability test as compared with the induction of squamous cell carcinomas in NFN group.

[c] Significant at $P<0.01$ as compared with NFN group.

for the presence of an early-stage squamous cell carcinoma that showed minimal invasive growth of atypical squamous cells into the submucosa. Macroscopic observation of the lungs failed to indicate obvious tumor development, but histologic examination revealed early stages of adenocarcinoma in 11 mice (34%; fig. 10) and a small focus of hyperplasia of atypical bronchiolar cells in 7 mice (22%; fig. 11). Results obtained are summarized in table 1. In other organs no tumor development was observed except leukemia; 1 leukemia was seen in the group fed NFN alone and 2 leukemias were found in the group fed NFN and FA. Microscopic examination also indicated that no pathologic change was induced by NFN or FA at the dose levels used in this experiment.

DISCUSSION

In our previous experiment (*4*) we used the extract of *C. bursa-pastoris*, which completely inhibited hepatocarcinogenesis in the rats fed the 0.06% 3-methyl-4′-(dimethylamino)azobenzene-containing diet for 50 days and then given drinking water containing the herb extract at a concentration of 0.2% for 285 days. In the present study, a possible inhibitory effect of FA (an active component of the herb extract) on the carcinogenic process by a different carcinogen, NFN, was examined histologically. As a result, induction of forestomach cancer as well as neoplastic papillomatous growth in the mice fed a carcinogenic amount of NFN was almost completely inhibited by the subsequent administration of FA. This anticarcinogenic activity was also noted in the lung, although it was not as complete as in the stomach. The reason for this difference in the anticarcinogenic activity of FA is so far unknown. There may be certain differences in the susceptibility or affinity of the target cells of the gastric and respiratory epithelia to NFN. This hypothesis is supported by the fact that the feeding of a higher dose (0.1% in the diet) of NFN for 1 week produced multiple pulmonary tumors (7.6 nodules/mouse) in more than 90% of ICR mice, whereas in the stomach only benign papillomas (60% in incidence) developed. Also, the induction time of pulmonary tumors was earlier (*8*). These results indicating the vulnerability of respiratory epithelium to NFN might be related to the fact that NFN produces its carcinogenic effect quite selectively and quickly on the bronchiolar nonciliated Clara cells without causing any obvious morphologic changes in the forestomach epithelium (*11*). Another possible explanation for the above-mentioned results is that FA affects nonspecifically tissues of the whole body. FA has various kinds of activities supposedly related to the present finding; i.e., FA inhibits gastric ulceration in rats (*6*), inhibits the solid growth of Ehrlich tumors in mice (*5*), and reduces the toxicity of mitomycin C and some carcinogens including NFN (*9*, *10*). Either of these activities or a combination of these activities of FA might be associated with the inhibitory effect on carcinogenesis. The increase of the concentration of FA in the diet or the simultaneous administration of FA with NFN would be expected to bring about a complete inhibition of cancerous changes in the lung.

Characterization of Anti-Inflammatory Factors Produced by Murine Tumor Cells in Culture[1,2,3]

S. J. Normann[4,5,6] *and* J. Cornelius[4]

ABSTRACT—P-815 mastocytoma cells from DBA/2 mice and a 3-methylcholanthrene-induced fibrosarcoma from C57BL/6 mice produced in culture at least two soluble anti-inflammatory factors that inhibited macrophage accumulation in vivo when the factors were injected sc into syngeneic recipients. One factor was a low-molecular-weight peptide (<1,000), as judged by ultrafiltration, failure of extraction by lipid solvents, nonsusceptibility to DNase or RNase, partial inactivation by trypsin, and complete inactivation by carboxypeptidase B. The second anti-inflammatory factor had a molecular weight between 30,000 and 100,000 and was also not extractable with lipid solvents. Production of anti-inflammatory factors by P-815 mastocytoma cells was inhibited by cycloheximide and cell irradiation but not by colchicine pretreatment of the cells, suggesting a relationship to protein synthesis rather than cell growth. Soluble anti-inflammatory factors depressed granulocyte as well as macrophage responses. Anti-inflammatory factors were not found in supernatants from cultures of splenocytes, peritoneal exudate cells, or murine lung fibroblasts.—JNCI 1982; 69:1321–1327.

Tumor bearing in experimental animals usually inhibits macrophage accumulation at inflammatory sites (*1–5*), and this phenomenon may be related to soluble anti-inflammatory factors (*6–10*). Such anti-inflammation has been observed during growth of both spontaneously arising (*11–13*) and transplanted tumors (*1–4*). Cell-free homogenates of transplanted tumors (*6, 7, 9*) and tumor ascitic fluid (*14*) contain factors that inhibit macrophage inflammatory responses when the factors are injected into normal animals. These factors are dialyzable (*6, 7*), unrelated to LDH viral infection (*15*), stimulatory to macrophage phagocytosis, but inhibitory to adherence and chemotaxis (*9, 10*), and have been associated with tumor virulence in a mouse lymphoma cell line (*8*).

Appropriately activated macrophages can alter the growth kinetics of tumor cells both in vitro (*16, 17*) and in vivo (*18–20*). Therefore, what inhibits macrophage accumulation at inflammatory sites in the tumor-bearing host is a critical issue. We previously reported that culture supernatants from rapidly proliferating cells inhibit macrophage chemotaxis in vitro and diminish macrophage accumulation in vivo in response to peritoneal stimuli (*21*). We now extend these studies using cell culture techniques to examine the types of cells that produce anti-inflammatory factors, the requirements for cell growth or protein synthesis in their production, and the nature of the factors themselves. We obtained evidence that multiple factors may be involved and that one of these is a very low-molecular-weight peptide.

MATERIALS AND METHODS

Mouse tumors.—Cryopreserved P-815 mastocytoma cells were obtained from the Mason Research Institute, Worchester, Mass., and passaged in syngeneic DBA/2 mice. These tumor cells had been tested and found to be free of mycoplasma as well as a variety of viruses including LDH virus. A 3-methylcholanthrene-induced fibrosarcoma designated PC-8 was obtained from the Tumor Biology Unit, University of Florida, and passaged in syngeneic C57BL/6 mice. Tumor cells were periodically tested and remained free of LDH virus as measured by normal serum LDH levels after tumor transplantation into syngeneic mice (*22*). All DBA/2 and C57BL/6 mice (20–25 g) were obtained from The Jackson Laboratory, Bar Harbor, Maine.

Cell culture.—First-generation cultures of tumor cells were used throughout. P-815 cells were obtained 6–7 days after the ip transplantation of 1×10^6 tumor cells into syngeneic DBA/2 mice. Cells were obtained by ip injection of 1.0 ml sterile RPMI-1640 medium containing 10 U heparin, by gentle massage of the belly, and by aspiration of 2 ml fluid by syringe containing about 10^8 cells, of which more than 95% were mastocytoma cells. The cell suspension was washed twice and adjusted to 5×10^6 cells/ml. For culturing, 0.5×10^6 cells were added to 10 ml medium in a 25-cm T-flask (Falcon Plastics, Oxnard, Calif.). PC-8 tumors were obtained 17 days after sc transplantation of 2×10^6 tumor cells into syngeneic C57BL/6 mice. The tumors were finely minced, digested with trypsin (0.25%) and DNase for 60 minutes at room temperature with stirring, passed through a sterile gauze, and collected by centrifugation. After being washed three times, 2.5×10^6 viable tumor cells were seeded into 25-cm^2 tissue culture flasks containing 10 ml culture medium. Culture medium for both tumors consisted of bicarbonate-buffered RPMI-1640 medium supplemented with L-glutamine, 10% fetal bovine serum, and 1% antibiotic–antimycotic solution (GIBCO, Grand Island, N.Y.). The cells were cultured at 37°C in a 95% humidified atmosphere containing 5% CO_2. Culture supernatants were harvested (usually, after 2 or 4 days) by decantation into a 50-ml conical centrifuge tube and centrifugation at 750×*g* for 10 minutes to remove cells and then at 25,000×*g* for 30

ABBREVIATIONS USED: FCS=fetal calf serum; LDH=lactate dehydrogenase; PHA=phytohemagglutinin; PMN=polymorphonuclear leukocyte(s); V_0=void volume.

minutes to remove cellular debris. The clear supernatant was stored at −20°C in sterile plastic tubes. No decay of anti-inflammatory activity was noted up to 2 months of storage, but longer storage appeared detrimental.

Control cultures consisted of splenocytes and peritoneal exudate cells from non-tumor-bearing DBA/2 mice and of splenocytes and lung fibroblasts from normal C57BL/6 mice. We obtained splenocytes by cutting the spleen into fine fragments and passing the fragments first through a 40-mesh screen and then in succession through 19-, 21-, and 23-gauge needles to ensure a single cell suspension. The cells were washed twice and seeded as 1.5×10^6 cells/2.0 ml culture medium in 12×75-mm Falcon polypropylene tubes. Peritoneal exudate cells were obtained 3 days after ip injection of proteose peptone and contained 30% lymphocytes, 48% macrophages, and 19% polymorphonuclear leukocytes. The cells were washed twice and seeded as 5×10^5 cells/10 ml culture medium in 25-cm Falcon T-flasks. We obtained fibroblasts from the lungs of normal adult C57BL/6 mice by removing the lung, mincing the tissue, and digesting the tissue for 90 minutes in a solution containing trypsin, EDTA, and collagenase. The fibroblasts were passaged for 19 generations and then seeded as 5×10^5 fibroblasts/10 ml culture medium in a 25-cm^2 tissue culture flask.

Assay for anti-inflammatory activity.—Biologic testing was performed with the use of syngeneic male mice of at least 16 weeks of age. For each test, a control test was performed simultaneously consisting of culture medium processed identically. Each mouse received sc 0.5 ml test solution in each hind leg. Twenty-four hours later the mouse was given an ip injection of 1.3 ml 8% proteose peptone, and 3 days later the peritoneal cells were harvested with 10 ml RPMI-1640 medium containing 10 U heparin/ml in a total of five washings. The cells were pooled, collected by centrifugation, washed once, and enumerated by means of a Coulter counter. Differential cell counts were made on cytocentrifuge-prepared slides stained with Wright's Giemsa. In addition to being recognized by their morphology, macrophages were recognized by their capacity for carbon phagocytosis (*14*) and/or their content of nonspecific esterase (*23*). We have observed seasonal variation in macrophage responses with higher responses in winter than in summer. Accordingly, each reported experiment includes its own control.

Anti-inflammatory activity directed against PMN was evaluated by ip injection of 1.3 ml sterile sodium caseinate in place of proteose peptone. The exudates were harvested 18 hours later and evaluated for total and differential cell counts.

Irradiation.—Mastocytoma cells were added to 25-cm^2 T-flasks (8×10^6 cells/10 ml culture medium) and irradiated with 6,000 rad from a cesium source (model M gammator; Radiation Machinery Corp., Parsippany, N.J.).

Ultrafiltrations.—Culture medium or 2-day cell culture supernatants were ultrafiltered in an Amicon (Lexington, Mass.) microultrafiltration unit 8MC with the use of nitrogen gas (5 atm/cm^2) as a pressure source. A UM-2 membrane (mol wt cutoff, 1,000) was used to prepare the low-molecular-weight anti-inflammatory factor. Ultrafiltrates were collected and stored frozen (−20°C) until used. In some instances, ultrafiltrates were prepared with the use of a PM-30 membrane (mol wt cutoff, 30,000) or an XM-100 membrane (mol wt cutoff, 100,000).

Molecular sieving.—G-25 Sephadex (Pharmacia Fine Chemicals, Piscataway, N.J.) was swollen overnight in 0.02 *M* phosphate buffer (pH 7.4) without stirring. A 2.5×24-cm column of G-25 Sephadex was used in downward flow. Since the sample fraction that appeared in the V_0 was diluted about fourfold, it was lyophilized and reconstituted with the use of water in a volume equivalent to that of the sample applied.

Lipid extraction.—Culture medium and supernatants were extracted with ethyl acetate (1:2 vol/vol) after being acidified to pH 4.0 with 0.1 *N* HCl as described by Hensby (*24*) for extraction of prostaglandins. They were extracted also with chloroform only (2:1 vol/vol) as described by Cheung et al. (*9*) after acidification to pH 1.6 with 0.5 *N* HCl. Chloroform–methanol solution (2:1 vol/vol) was used as 3.5:1 volumes of aqueous culture medium or supernatant. All extractions were repeated three times, and the fractions were pooled, evaporated to near dryness, and redissolved in phosphate-buffered saline.

Enzymatic degradation.—Insoluble trypsin, DNase I (DN-25), and RNase A (type III) were obtained from Sigma Chemical Co., St. Louis, Mo., and carboxypeptidase B was obtained from Worthington Biochemical Co., Freehold, N.J. Insoluble trypsin was used at a concentration of 1 mg/ml (pH 7.6), DNase at 1 mg/ml in the presence of 0.1 *M* magnesium sulfate (pH 7.0), RNase at 1 mg/ml (pH 7.3), and carboxypeptidase B at 100 µg/ml (pH 7.6). All enzymatic reactions were performed at room temperature for 1 hour with stirring. Biologic testing was performed both before and after removal of the enzyme by centrifugation or refiltration through a UM-2 membrane. Since results were essentially identical, they have been combined in reporting biologic activity.

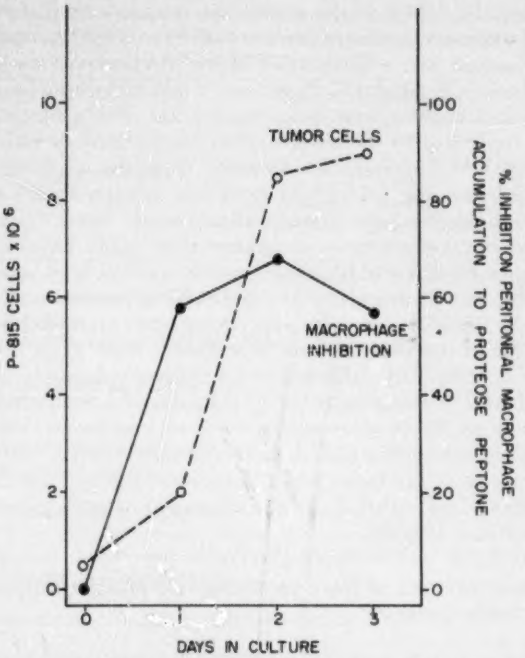
Statistics.—Differences between two means were analyzed by Student's *t*-test. Data are reported as means ± 1 standard error.

RESULTS

Anti-Inflammatory Factors From Cultured Cells

Growth of P-815 mastocytoma cells in vitro was associated with the rapid appearance in the culture supernatant of a factor or factors inhibitory to macrophage inflammatory responses (text-fig. 1). Anti-inflammatory activity preceded and rose concurrently with cell growth. Maximum anti-inflammatory activity was consistently observed in 2-day culture supernatants at 100% concentration, which decreased in proportion to dilution. Accordingly, such supernatants were used in all subsequent work with this tumor. Similar to the growth of the P-815 mastocytoma, growth of the PC-8 fibrosarcoma was associated with rapid appearance of anti-inflammatory activity in the culture supernatant (text-fig. 2). The fibrosarcoma grew more slowly than the mastocytoma, and maximum activity did not appear until day 4.

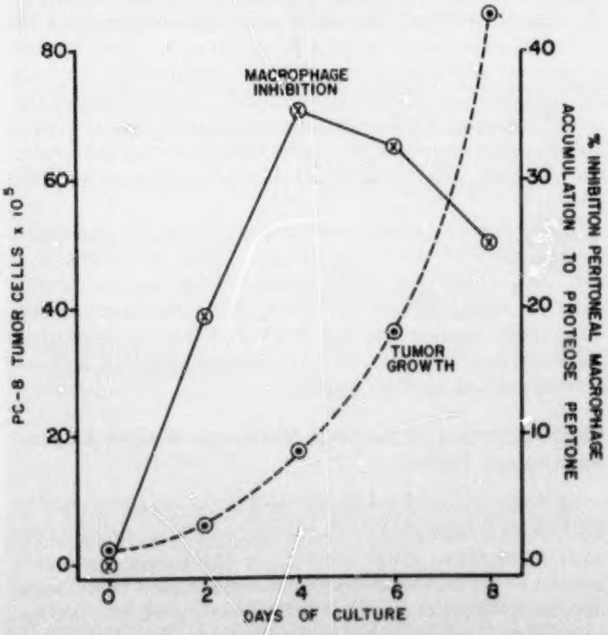
Not all cells in culture elaborated anti-inflammatory factors (table 1). Spleen cells from normal mice or peritoneal



TEXT-FIGURE 1.—Appearance of anti-inflammatory activity in culture supernatants of P-815 mastocytoma cells.

exudate cells from mice given injections of proteose peptone produced no detectable anti-inflammatory activity in culture. Cultures of splenocytes were examined unstimulated or after stimulation with PHA either for 48 hours (DBA/2) or for 96 hours (C57BL/6). Normal lung fibroblasts grew rapidly in culture, and supernatants were examined either during rapid cell growth (2 days in culture) or after the cells had reached confluence and were in a stationary growth phase (days 3 and 4). No significant anti-inflammatory activity was observed in any of these supernatants obtained from splenocytes, peritoneal exudate cells, or murine lung fibroblasts.

We next examined certain requirements for producing anti-inflammatory activity by P-815 mastocytoma cells. One objective was to explore further the relationship between production of anti-inflammatory activity and tumor cell growth. In the first experiment, cell growth was arrested by irradiation with 6,000 rad. Supernatants from irradiated cells grown 2 days in culture were compared to those from nonirradiated cells (table 2). In contrast to nonirradiated cells, irradiated cells elaborated no detectable anti-inflammatory activity. In a second experiment, 0.2 mg colchicine/ml was used to inhibit mitotic division. When supernatants from such colchicine-pretreated cells were examined, they were found to contain anti-inflammatory activity. In a third experiment, tumor cells were cultured in the presence of 100 μg cycloheximide/ml, which interferes with protein synthesis. Cycloheximide markedly decreased anti-inflammatory activity such that the marginal residual activity in supernatants from treated cells was not statistically different from that in supernatants from nontreated cells. These data suggested that production of anti-inflammatory activity was related more to protein synthesis than to actual cell proliferation. A second objective was to examine the requirement for serum proteins in the culture medium. For this experiment, 1×10^6 P-815 cells were seeded into 10 ml medium without FCS, and after 2 days in culture 3×10^6 cells were recovered. While the cells grew in the absence of FCS, they did not do so as readily as in the presence of FCS. Nonethe-



TEXT-FIGURE 2.—Appearance of anti-inflammatory activity in culture supernatants of PC-8 fibrosarcoma cells.

TABLE 1.—*Presence of anti-inflammatory activity in culture supernatants from tumor but not normal cells*

Materials tested	No. of trials	Yield of macrophages, $\times10^{5a}$	Degree of inhibition, %[b]
DBA/2 mice			
Culture medium only	8	52±6	
Culture supernatants[c]			
P-815 mastocytoma	6	22±3	58
Peritoneal exudate from normal mice	6	50±4	NS
Splenocytes from normal mice	7	46±5	NS
Splenocytes + PHA	5	47±4	NS

less, P-815 cells in the absence of FCS produced anti-inflammatory activity.

The molecular size of the anti-inflammatory factor(s) was examined in a series of experiments summarized in table 3. During these experiments, it emerged that more than one anti-inflammatory factor existed. Using 2-day P-815 mastocytoma culture supernatants, we demonstrated that one factor was a low-molecular-weight entity capable of crossing a dialysis membrane (Union Carbide Corp., Chicago, Ill.). However, exhaustive dialysis did not eliminate anti-inflammatory activity from the retained fraction. The impression of at least two anti-inflammatory factors was confirmed by the following experiment. An ultrafiltrate was obtained by means of a UM-2 Diaflo membrane (mol wt cutoff, 1,000) that contained anti-inflammatory activity. This low-molecular-weight anti-inflammatory factor was removed by passage over a Sephadex G-25 column, which retards molecules with molecular weights of less than 5,000. This assumption was confirmed by the absence of anti-inflammatory activity in the UM-2 ultrafiltrate obtained from the V_0 fraction. Nonetheless, the V_0 fraction itself was strongly inhibitory. Accordingly, a second anti-inflammatory factor existed whose molecular weight was greater than 5,000. This factor did not cross a PM-30 Diaflo membrane (mol wt cutoff, 30,000) but did cross an XM-100 Diaflo membrane (mol wt cutoff, 100,000). A similar experiment was conducted with the use of the 4-day culture supernatant from PC-8 fibrosarcoma cells. Anti-inflammatory activity was found in both the UM-2 filtrate and in the V_0 fractions of a Sephadex G-25 column. From these experiments, we concluded that at least two anti-inflammatory factors existed in tumor culture supernatants, one factor having a molecular weight less than 1,000 and the other having a molecular weight between 30,000 and 100,000.

[c] The UM-2 Diaflow membrane has a mol wt cutoff of 1,000.

Characteristics of the Low-Molecular-Weight Anti-Inflammatory Factor

Our attempts to extract the anti-inflammatory factor by use of organic solvents were unsuccessful (table 4). First, we tried to extract the factor with chloroform at pH 1.6 as recommended by Cheung et al. (*9*) for extracting factors from tumor homogenates with antimacrophage activities. However, such extracts of UM-2 filtrates did not contain anti-inflammatory activity. Next we attempted to extract the UM-2 filtrate with ethyl acetate at pH 4.0 following the procedure described by Hensby (*24*) for extraction of prostaglandins. This extraction also failed to contain anti-inflammatory activity. The addition of methanol to the UM-2 filtrate either at 22 or at 4°C resulted in a fine, whitish precipitate and inactivation of the anti-inflammatory factor. As expected, a chloroform–methanol (2:1) extraction resulted in no anti-inflammatory activity. In each instance, an oily substance could be extracted into the organic phase, but this substance actually enhanced macrophage accumulation.

Table 5 summarizes results obtained on the enzymatic susceptibility of the low-molecular-weight anti-inflammatory factor. The anti-inflammatory factor was not inactivated by either RNase or DNase, although these enzymes were active against purified RNA or DNA. In contrast, it was completely inactivated by carboxypeptidase B and was partially inactivated by trypsin.

Characteristics of the High-Molecular-Weight Anti-Inflammatory Factor

The high-molecular-weight factor contained in the V_0 fraction of a Sephadex G-25 column could not be extracted with chloroform, ethyl acetate, or chloroform–methanol. Similar to the findings with the low-molecular-weight factor, methanol addition (50% vol/vol) formed a whitish precipitate upon addition to the G-25 V_0 fraction. After removal of the precipitate, the remaining fluid possessed no inhibitory

TABLE 4.—*Failure to extract the low-molecular-weight anti-inflammatory factor with lipid solvents from culture supernatants of P-815 mastocytoma cells*[a]

Materials tested	Yield of macrophages, ×10⁵: Mice given injections of:[b]		Change, %

activity. The high-molecular-weight factor was not inactivated by DNase or RNase.

Inhibition of PMN by Tumor Culture Supernatants

Anti-inflammatory activity associated with tumor bearing has been reported by some to be specific for macrophages (*1*, *2*), whereas others describe activity against PMN (*25*, *26*). Therefore, we tested culture supernatants of P-815 tumor cells for their effect on PMN (table 6). Whole supernatants strongly inhibited peritoneal PMN accumulation to sodium caseinate as an irritant and this activity was present as both a low- and a high-molecular-weight inhibitor. In contrast to macrophages, however, the low-molecular-weight inhibitor was less potent than the high one.

TABLE 5.—*Inactivation of low-molecular-weight anti-inflammatory factor in culture supernatants of P-815 tumor cells by trypsin and carboxypeptidase B but not by RNase or DNase*[a]

DISCUSSION

Tumor bearing alters macrophage function as indicated in experimental animals by decreased accumulation at inflammatory foci in vivo and in humans by decreased chemotactic migration in vitro. It has been reported that the mechanism of inhibition may involve soluble anti-inflammatory factors (*6–10*). Our studies support this hypothesis but indicate that more than one factor may be involved.

The following evidence suggests that one factor affecting macrophage is an anti-inflammatory peptide. *a*) An anti-inflammatory factor was identified in culture supernatants of P-815 mastocytoma cells; this factor was dialyzable, retarded on a Sephadex G-25 column, and had a molecular weight of less than 1,000 by ultrafiltration. *b*) This anti-inflammatory factor could not be extracted by organic solvents used to extract lipids and prostaglandins. However, the failure to extract activity with organic solvents does not necessarily preclude some lipid content in the active factor. *c*) This factor was resistant to both DNase and RNase but was completely inactivated by carboxypeptidase and partially inactivated by trypsin. A second anti-inflammatory factor was identified that was not dialyzable, not extractable with lipid solvents, appeared in the V_0 of a Sephadex G-25 column, and by ultrafiltration had a molecular weight between 30,000 and 100,000. It is not clear whether this second factor is a distinct entity or is due to aggregation or adsorption of the low-molecular-weight factor to some substance in the culture medium.

Anti-inflammatory factors have been obtained from tumor homogenates, from urine, plasma, and ascitic fluid of tumor-bearing animals, and from supernatants of cultured tumor cells. The nature and specificity of these factors are under investigation. Pike and Snyderman (*7*) first described a dialyzable anti-inflammatory factor in homogenates prepared by sonication of cancerous tissues that had a molecular weight of less than 25,000 by ultrafiltration but eluted from a Sephadex G-50 column in the region of 6,000–10,000

(*10*). The chemical nature of this factor was not defined, although it occurred in spontaneously arising cancers (*13*). Cheung et al. (*9*) described a lipid-like inhibitor of less than 3,500 in tumor homogenates that altered macrophage spreading and migration. While we concur that one anti-inflammatory factor has a molecular weight less than that reported by Snyderman's group, we believe this factor to be a peptide rather than a lipid since it is inactivated by carboxypeptidase and not extractable by methanol, chloroform, or ethyl acetate. Factors obtained from homogenized tissue may differ from those obtained from culture supernatants, and different functions may be affected by different factors. We tested macrophage inflammatory responses in vivo, whereas Cheung et al. (*9*) used an in vitro assay of macrophage spreading. Nelson and Nelson (*27*) reported isolating a low-molecular-weight factor from tumor culture supernatants; this factor inhibited the early phase of a prolonged delayed-type hypersensitivity reaction in vivo as well as macrophage migration and motility in vitro. While most workers describe antimacrophage activity, Stahl et al. (*26*) reported a carboxypeptidase B- and trypsin-sensitive factor that affected granulocytes in 48-hour tumor culture supernatants whose molecular weight was 500–2,000. This factor has many similarities to our low-molecular-weight factor. Since the factor described by Stahl et al. (*26*) was considered to be toxic to macrophages, it may be identical to the low-molecular-weight anti-inflammatory factor described here.

P-815 cells growing intraperitoneally produce tumorous ascitic fluid that contains anti-inflammatory activity (*14*). The use of culture supernatants rather than whole tumors allowed us to examine certain conditions essential for the production of these factors. Appearance of the factors in the culture supernatant preceded rapid cell proliferation and suggested a relationship between factor production and tumor growth. This hypothesis seemed to be supported by the observation that cell irradiation sufficient to inhibit proliferation blocked production of the anti-inflammatory factor. However, prior treatment of the cells with colchicine did not inhibit factor production, although it arrested mitotic division. Such data suggest that factor production did not depend on actual cell division but required intact DNA and probably DNA transcription which was inhibited by cell irradiation. Cycloheximide inhibits protein synthesis by blocking transfer of activated amino acids from tRNA to growing polypeptide chains without inhibiting DNA synthesis. Thus the fact that cycloheximide prevented appearance of anti-inflammatory activity supports the contention that factor production was related to protein synthesis. Further, anti-inflammatory activity did not require serum proteins in the culture medium, and this observation supports the contention that the factors were produced by the cells.

In conclusion, multiple anti-inflammatory factors appear to be produced by primary tumor cells in culture but not by normal fibroblasts, splenocytes, or peritoneal exudate cells. Additional work is necessary to determine if the various factors are related or are distinct entities. We have identified one factor as a very low-molecular-weight peptide. The capacity to produce such factors in vitro may help clarify their nature, source, and mode of action in the tumor-bearing host.

Collagenolytic Activity of Rabbit V_2 Carcinoma Implanted in the Nude Mouse[1,2,3,4]

Chitra Biswas,[5,6] **Kurt J. Bloch,**[5] *and* **Jerome Gross**[5,7]

ABSTRACT—The relative contribution of host cells and tumor cells to the production of collagenase and its regulation during tumorigenesis were studied with the use of a heterologous rabbit tumor–nude mouse host system. The V_2 carcinoma, a malignant neoplasm of the New Zealand White rabbit, behaved as a nonmetastasizing, noninvasive tumor when implanted and grown in the inbred Swiss albino nude mouse. The extracts from both tumors contained similar levels of collagenase. Tumor explants also released enzyme into culture medium in both cases, but the rabbit tumor produced approximately 10 times more collagenase than the nude mouse. Freeze-thawing of the explants or treatment with cycloheximide markedly inhibited the appearance of enzyme in the medium from the rabbit tumor but not from the nude mouse tumor. The relative proportions of mouse- and rabbit-derived collagenase in the nude mouse tumor extracts and culture medium were determined with the use of antibodies specific for rabbit V_2 tumor and mouse bone collagenases. Approximately 70% of the nude mouse tumor enzyme was derived from the rabbit tumor, and approximately 30% was derived from the mouse host. These findings indicate that the former might represent stored enzyme carried over during tumor transplantation into the nude mouse, whereas the latter might have originated from stimulation of host cells during tumorigenesis.—JNCI 1982; 69:1329–1336.

Increased collagenase activity and degradation of connective tissue matrix in the host have been found to be associated with several neoplasms (*1–8*). However, the cellular source and the regulation of collagenase activity during tumorigenesis are still not well understood. We have approached this problem by implanting rabbit V_2 carcinoma in the nude mouse. This heterologous host–tumor model system has permitted us to identify the source of tumor enzyme on the basis of differences in immunologic characteristics of the collagenase from the two species. In addition, we have been able to compare the levels of collagenase present in invasive and noninvasive tumors derived from the same tumor cell origin since the V_2 carcinoma is invasive in the rabbit but noninvasive in the nude mouse.

The V_2 carcinoma is an epithelially derived tumor originally obtained from Shope virus-induced papillocarcinoma (*9*). The tumor grows rapidly in muscle and in subcutaneous tissue of the rabbit and is lethal to the host. McCroskery et al. (*5*) extracted relatively large amounts of active collagenase from this tumor implanted in muscle. We observed that the subcutaneously implanted V_2 carcinoma contained extractable collagenase in latent form requiring activation by trypsin, whereas muscle tumor extracts rarely contained significant amounts of active or latent collagenase (*8*). Upon implantation of tumor in intramuscular and subcutaneous sites in the same rabbit, extractable latent enzyme was obtained from both sites (*8*).

In this paper, we have compared some biochemical properties of the collagenase obtained by extraction and culture of V_2 carcinoma implanted subcutaneously in both the rabbit and nude mouse hosts and determined the contribution of host and tumor cells to the collagenase present in the nude mouse tumor with the use of antibodies raised against rabbit tumor enzyme and normal mouse bone enzyme.

MATERIALS AND METHODS

Reagents and their sources included: TPCK-trypsin and SBTI from Worthington Biochemical Corp., Freehold, N.J.; pancreatic trypsin (type I) from Sigma Chemical Co., St. Louis, Mo; [^{14}C]acetic anhydride and ^{14}C-labeled amino acid mixture from New England Nuclear Corp., Boston, Mass.; DMEM from Grand Island Biological Co., Grand Island, N.Y.; Diaflo PM-10 membranes from Amicon Corp., Lexington, Mass.; and Sephacryl S-200 and DEAE-Sephadex A-50 from Pharmacia Chemicals AB, Uppsala, Sweden. Ultrogel ACA-54 was obtained from LKB Producter AB, Stockholm, Sweden; *Staphylococcus aureus*-Cowan I strain (IgG-Sorb) from The Enzyme Center, Boston, Mass.; and Whatman DEAE-cellulose (DE-52) from Metropolitan Supply Corp., Cambridge, Mass.

Maintenance and implantation of V_2 carcinoma.—Rabbit V_2 carcinoma was maintained by serial im passage in New Zealand White rabbits as described previously (*8*). The tumor was provided by Dr. Judah Folkman, Children's Hospital, Boston, Mass. Six-week-old male and female Swiss albino nude mice of *nu/nu* genotype were obtained from Life Sciences, Inc., St. Petersburg, Fla. Suspensions of rabbit

tumor prepared as described previously (*8*) were centrifuged at 240×*g*, and the cell pellet was washed twice with sterile mammalian Ringer solution and suspended in the same medium. About 1 g tumor in 0.5 ml Ringer solution was injected sc in the scapular region of both the rabbit and the mouse. After 3–4 weeks, the animals were killed and the tumors were removed for histologic examination, tissue culture, and extraction of enzyme. The yield of tumor was approximately 10–20 g from each rabbit and 1–1.5 g from each nude mouse.

Preparation of enzymes.—Rabbit tumor collagenase: Approximately 30 g of tumor tissue was homogenized in a buffer containing 50 m*M* Tris-HCl, 1 *M* NaCl, and 5 m*M* $CaCl_2$ (pH 7.4). The homogenate was clarified by centrifugation, and the enzyme precipitated with $(NH_4)_2SO_4$ between 20 and 50% saturation as described previously (*8*). The resulting fraction was dialyzed against 50 m*M* Tris-HCl, 0.2 *M* NaCl, and 1 m*M* $CaCl_2$ (pH 7.4) (buffer A) and activated with trypsin as described below. The active enzyme was fractionated on a Sephacryl S-200 column (4×100 cm) equilibrated with buffer A. The fractions containing collagenase activity were combined, and the pooled fractions were concentrated to one-third of the starting volume by ultrafiltration on a Diaflo PM-10 membrane. The concentrated fraction was dialyzed against buffer A free of NaCl and applied to a column of DEAE-Sephadex (2×10 cm) equilibrated with this buffer. Collagenase activity was eluted with the same buffer. Eluted fractions were adjusted to 0.2 *M* NaCl, the enzyme activity was determined, and the active fractions were pooled, concentrated, and used as antigen for injection into goats. The specific activity of the preparation was 10 U collagenase/mg protein (*see* below for definition of units); the purification achieved was fiftyfold to seventyfold.

Mouse collagenase: Calvarias from 150- to 200-g Swiss-Webster mice 4–5 days old were cultured in serum-free Tyrode's solution in the presence of heparin as described by Shimizu et al. (*10*). The media were harvested after 4 days, replaced with fresh media, and collected again after a 4-day period. The media were pooled, buffered with 1 *M* Tris-HCl (pH 7.5) to a final molarity of 50 m*M*, and concentrated five times on a PM-10 membrane. The concentrated culture media were fractionated by $(NH_4)_2SO_4$ at 70% saturation, and the precipitate was suspended in buffer A and dialyzed against the same buffer. The dialyzed enzyme preparation containing latent collagenase activity was fractionated on an Ultrogel ACA 54 (1.8×90 cm) column equilibrated with the same buffer. The column fractions were assayed for both active and latent collagenase. The eluted column fractions showed only active collagenase, suggesting that the latent enzyme was autoactivated during the column fractionation. The enzymatically active fractions were pooled, concentrated five times on a PM-10 membrane, and used as antigen for injection into rabbits. The specific activity of the final preparation was 10 U/mg protein; the purification achieved was fiftyfold.

Nude mouse tumor collagenase: Tumor tissue was homogenized and fractionated by $(NH_4)_2SO_4$ as described for the rabbit tumor enzyme. Since only 1–1.5 g of tumor tissue was obtained from each nude mouse, tumors from several animals were pooled. The latent collagenase present in the $(NH_4)_2SO_4$ fractionated (20–50%) preparation was further fractionated on a Sephacryl S-200 column, and the fractionated concentrated enzyme was used for all experiments.

All buffers used for enzyme preparation contained 0.02% sodium azide, and the procedures were conducted at 4°C.

Preparation of anticollagenase antisera.—Goats were immunized with rabbit tumor collagenase. Two goats were each given an im injection of 1.5 mg partially purified enzyme preparation emulsified in CFA, followed by two additional injections of 0.7 mg enzyme emulsified in IFA, at 10-day intervals. The animals were bled on the 14th day after the second booster injection. The antisera were fractionated and tested as described below.

Rabbits were immunized with partially purified mouse bone enzyme. Two rabbits were each given an injection of 300 µg collagenase preparation emulsified in CFA, followed by two additional injections of 150 µg in IFA. The animals were bled on day 14 after the second injection.

The IgG fraction was obtained from the goat and rabbit antisera by precipitation with $(NH_4)_2SO_4$ brought to 50% saturation. The precipitate was suspended and dialyzed against 0.01 *M* phosphate buffer (pH 7.4) and applied to a DEAE-cellulose column equilibrated with the same buffer (*11*). The proteins eluted with this buffer were dialyzed against water and lyophilized. The lyophilized powders were reconstituted at a concentration of 15–20 mg/ml in buffer A, and the purity of the preparation was tested by agarose gel electrophoresis in sodium barbital buffer (pH 9.0) (*12*). Preparations containing a single protein band migrating in the "slow" IgG region were used in the assays (*see* below). Nonimmune goat and rabbit sera were similarly treated to obtain the IgG fractions.

Interaction of enzyme with antibodies.—Increasing amounts of immune or nonimmune IgG fractions were added to a fixed amount of enzyme solution in a total volume of 0.45 ml, and the mixtures were incubated for 16 hours at 4°C. Two procedures were then used to measure the reaction of enzyme samples with different IgG preparations. In the first case, 200 µl of each enzyme-IgG mixture was tested directly for enzyme activity. In the second case, 50-µl suspension of IgG-Sorb (an amount previously determined by titration to remove 100% of the IgG) was added to each mixture as an absorbent for antigen-antibody complexes (*13*), the mixture was further incubated at 25°C for 1 hour and centrifuged at 900×*g* in a Beckman microcentrifuge for 15 minutes at 4°C, and 200 µl of each supernatant was tested for collagenase activity. Addition of IgG-Sorb alone to enzyme samples did not affect collagenase activity. For both procedures the interaction of enzyme with IgG is expressed as percentage of inhibition of collagenase activity in the mixtures of enzyme and IgG. The term "inhibition" is used here to denote removal of the enzyme from solution by interaction with IgG only or by subsequent treatment with IgG-Sorb.

Enzyme assays.—Type I collagenase: Collagenase activity was determined by measurement of soluble radioactive peptides released from ^{14}C-labeled, reconstituted collagen fibrils. ^{14}C-acetylated rat tail tendon collagen was prepared according to the method of Gisslow and McBride (*14*) as modified by Johnson-Wint (*15*). Enzyme samples (100–200 µl) were added to the fibrillar substrate and incubated at 37°C in a total volume of 200 μl for 4 hours. Each assay included a trypsin blank (0.01%) and a buffer blank as controls. At the end of the incubation, the unreacted substrate was sedimented in a Beckman microcentrifuge, and the radioactivity present in 200 μl of the supernatant was measured. Collagenase activity was also determined by a fibril film lysis assay (*15*) in which the Microwells of 96-well plates (Linbro Scientific Inc., Hamden, Conn.) were coated with radioactive collagen solution and the collagen was polymerized to fibrils at 37°C for 1 hour. Enzyme samples were added and incubated as described above. The radioactivity released into the supernatant served as an indicator of enzyme activity. The amount of radioactive collagen used in either assay corresponded to approximately 5,000 cpm. One unit of collagenase activity is defined as the amount of enzyme required to degrade 1 μg collagen/minute.

Both active and trypsin-activable (latent) collagenolytic activities were assayed. Samples were incubated with TPCK-trypsin for 5 minutes at 37°C, followed by the addition of a fivefold excess of SBTI. The concentration of TPCK-trypsin required for maximal activation of latent collagenase was 90 μg/ml sample for rabbit and nude mouse tumor extracts and 18 μg/ml for mouse calvaria culture medium. The optimal concentrations of TPCK-trypsin required for activation of collagenase were determined in a separate experiment.

Collagen degradation products were identified by polyacrylamide disk gel electrophoresis at pH 4.0 as described by Nagai et al. (*16*).

Type IV collagenase: Radioactively labeled type IV collagen from two sources was used for the assay. A purified preparation of type IV collagen extracted with acetic acid from bovine anterior lens capsule was supplied by Dr. Carlo Mainardi, Veterans Administration Hospital, Memphis, Tenn. The other preparation was from murine EHS fibrosarcoma and was provided by Dr. Lance Liotta, National Cancer Institute, Bethesda, Md. Enzyme assays, with the use of either substrate, were performed according to the procedure described by Garbisa et al. (*17*). The total amount of radioactivity used in each assay was 3,000 cpm. The total volume of the incubation mixture was 270 μl, and incubation time was 4 hours at 37°C. Type IV collagenase was assayed before and after trypsin activation.

Type V collagenase: Radioactively labeled type V collagen from human placenta was obtained from Dr. Liotta. Enzyme assay was performed according to the procedure of Liotta et al. (*18*) before and after trypsin activation. The total volume of the incubation mixture was 270 μl, and the incubation period was 4 hours at 37°C. The total amount of radioactivity used in the assays was 1,600 cpm.

Culture of tumor tissue.—Fragments of tumor approximately 1–2 mm^3 were washed three to four times in serum-free DMEM containing 100 U penicillin/ml and 100 μg streptomycin/ml. The fragments were distributed in plastic tissue culture dishes (0.6 g tissue/6-cm dish) with 2 ml DMEM and incubated at 37°C in a moist atmosphere with 5% CO_2 and 95% air. Portions of the subcutaneous tumor from rabbits were dissected free of the surrounding normal tissue and necrotic tumor tissue and placed in culture. The entire tumor from the nude mouse, free of normal tissue, was sliced and used for culture. The culture medium was harvested and replaced daily. The media from three to four dishes were pooled and centrifuged at 20,000×*g* for 30 minutes; the unconcentrated supernatants were assayed for collagenase activity before and after trypsin activation.

To investigate whether protein synthesis is required for the presence of collagenase in culture media of tumor explants, we cultured the explants in the presence of cycloheximide. Furthermore, to ensure that the cycloheximide was effectively inhibiting protein synthesis, we determined incorporation of ^3H-labeled amino acid into TCA-precipitable proteins of cultured explants. The tumor fragments were preincubated at 37°C for 30 minutes in DMEM. The medium was then replaced with 1 ml fresh medium with or without cycloheximide (10 or 50 μg/ml) containing 10 μCi of a mixture of ^3H-labeled amino acids (sp act, 1 mCi/ml; New England Nuclear Corp.). After 24 or 48 hours of incubation at 37°C, the tumor explants were removed, washed extensively with Hanks' balanced salt solution, suspended in 5 volumes of 10% TCA, and homogenized. The TCA precipitate was collected by centrifugation, washed two times with absolute ethanol, and dissolved in NCS tissue solubilizer (Amersham Corp., Arlington Height's, Ill.); the radioactivity in 0.25-ml samples was measured in a scintillation spectrometer.

RESULTS

Morphologic Characteristics of V_2 Carcinoma in Rabbits and Nude Mice

Two weeks after subcutaneous implantation of V_2 carcinoma in rabbits or in nude mice, large palpable tumors developed at the site of injection. In rabbits, the neoplasm was firmly attached to the subcutaneous and surrounding tissue, whereas in the mouse it was loosely attached to the subcutaneous tissue and was readily removable. The central, pink tumor mass was surrounded by a thicker and more diffuse connective tissue layer in the rabbit than in the mouse. During later stages of growth (usually, 5 wk), central necrosis was observed in both hosts. In rabbits, tumor metastases were observed in lymph nodes and, occasionally, in liver and lung, but none was found in nude mice.

Histologic examination of the tumor from both species revealed certain characteristic features. In the 10 rabbits studied, fibrosis was extensive, and clusters of tumor cells extended from the central mass deep into the surrounding connective tissue in all cases. In contrast, tumor implants in nude mice were well circumscribed, and the interface of the thin fibrous layer with the tumor mass was sharply defined. Infiltration of this connective tissue layer by tumor cells was observed in only 1 of 10 animals.

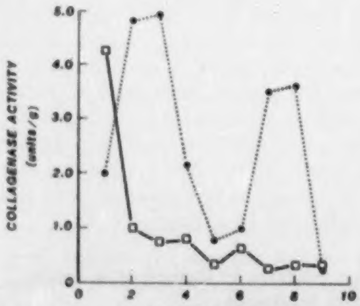
Collagenase Activity in Rabbit and Nude Mouse Tumor Extracts

Extracts prepared from subcutaneously implanted V_2 carcinoma in rabbits or in nude mice were assayed for both latent and active forms of collagenase (*19*). Only trypsin-activable enzyme activity was detected in extracts, and approximately the same amount of enzyme per gram of tumor tissue was obtained from the two hosts, viz., 2.68±0.40 U/g for 56 of 70 rabbits and 2.76±0.93 U/g for 100 nude mice. Extracts prepared from tumors for the other 14 rabbits were inactive before or after treatment with trypsin.

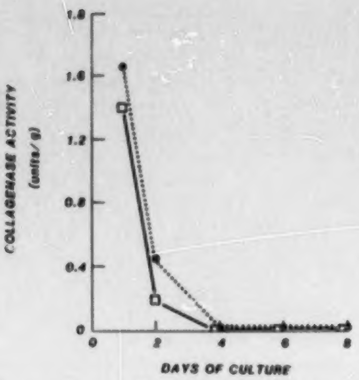
Collagenase Activity in Rabbit and Nude Mouse Tumor Explant Cultures

Tumor explants from both hosts released collagenase into the culture medium. In the rabbit, enzyme activity appeared in the medium of three of seven cultures (each from an individual animal) after an initial lag period of 1–2 days. Two cycles of collagenase production were observed: The first occurred during days 2 and 3, and the second occurred during days 7 and 8 (text-fig. 1); no activity was detected thereafter. In the other four cultures, enzyme activity appeared on the 1st day; then after a quiescent period of 1–4 days, a peak of enzyme release occurred lasting 1–3 days. Thus trypsin-activable collagenase was obtained from all seven cultures. Furthermore, explants of tumor from 2 rabbits also released spontaneously active enzyme in addition to trypsin-activable enzyme. The total amount of latent enzyme released into the culture medium from day 1 to day 9 ranged from 15 to 23 U/g of tumor tissue. Cultures of necrotic tumor tissue released lesser amounts of enzyme. Repeated freeze-thawing of the tumor tissue before culture prevented the appearance of enzyme in the medium. Addition of cycloheximide (10 or 50 μg/ml) to the rabbit tumor explants in culture blocked the appearance of 90% of collagenase activity in the medium after day 1 (text-fig. 1). Cycloheximide, in concentrations of 10 and 50 μg/ml, inhibited incorporation of ^{3}H-labeled amino acids into total protein 37 and 75%, respectively.

The pattern of appearance of enzyme activity in the culture medium of the nude mouse tumor differed significantly from that of the rabbit. In all cultures from 6 groups of animals, the maximum amount of enzyme activity appeared on the 1st day of culture (text-fig. 2). The enzyme activity decreased sharply by the 2d day and was not detectable subsequently. All cultures released trypsin-activable enzyme, although three of the six cultures also had spontaneously active enzyme. The amount of enzyme activity obtained in different experiments during the culture period of day 1–day 9 ranged from 0.7 to 2 U/g. In the presence of cycloheximide (10 or 50 μg/ml), the level of collagenase activity decreased by 20–50% of that of controls in four experiments; there was no change in the pattern of release (text-fig. 2). Cycloheximide at the same concentrations blocked 75% of the incorporation of ^{3}H-labeled amino acids into total protein. Although repeated freeze-thawing of the rabbit tumor explants inhibited the appearance of enzyme in the media, it did not have any effect on the nude mouse tumor explants.



TEXT-FIGURE 1.—Release of collagenase into serum-free medium from explants of V_2 carcinoma obtained from rabbits. Explants were cultured in the absence (●) and presence (□) of cycloheximide (10 μg/ml culture medium). Results shown represent levels of trypsin-activable collagenase activity.



TEXT-FIGURE 2.—Release of collagenase into serum-free medium by explants of V_2 carcinoma obtained from nude mouse. Explants were cultured in the absence (●) and presence (□) of cycloheximide. Results shown represent levels of trypsin-activable collagenase activity.

These results indicate that explants from the invasive V_2 carcinoma have the capacity to produce relatively large amounts of collagenase over a considerable period of culture, whereas explants from the noninvasive nude mouse tumor mainly release stored enzyme into the medium and have a low capacity for continued collagenase production.

Activity of Collagenase Preparations Toward Type IV and V Collagen

Enzyme preparations from rabbit V_2 carcinoma, nude mouse tumor, and mouse calvaria were tested for their ability to cleave type IV and type V collagen. With all three enzymes, the activity against type I collagen was greater than that toward type IV and type V. In each case, with the use of the same assay conditions, 90% of the type I substrate was cleaved, whereas with type IV or V only 20–30% was degraded.

Some Properties of Collagenase Preparations

The collagenase activity of extracts of V_2 carcinoma from the rabbit and the nude mouse was completely inhibited by 10 m*M* EDTA or 3 m*M* dithiothreitol. Acid gel electrophoresis of collagenase cleavage products produced by enzyme from extracts or culture media of both hosts showed the TC^A and TC^B fragments, characteristic of animal collagenase reaction products (*16*). The enzyme from mouse calvaria had similar properties.

Gel filtration on Sephacryl S-200 of extracts prepared from rabbit tumor revealed a single major peak of latent collagenase with an apparent molecular weight of approximately 40,000, which was reduced to 20,000 after trypsin activation. A major peak of collagenase activity with a similar molecular weight was obtained upon fractionation of the nude mouse tumor extract. However, the chromatographic profile of the nude mouse tumor extract was somewhat heterogeneous, suggesting the presence of large molecular weight forms of enzyme. Trypsin activation of the nude mouse enzyme gave rise to increased heterogeneity with peaks of activity ranging from 12,000 to 20,000 and from 34,000 to 50,000. About 20% of the amount of trypsin required for activation of unfractionated samples was optimal for activation of the eluted column fractions in each case; higher concentrations of trypsin diminished the collagenase activity.

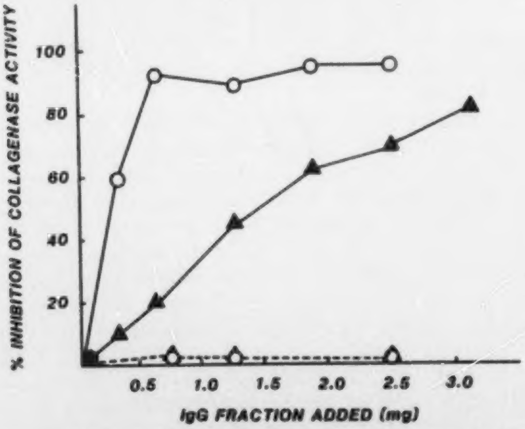
Concentrated culture medium containing mouse bone enzyme was applied to a Sephacryl S-200 column; a single peak of active collagenase with an apparent molecular weight of 90,000 was eluted.

In each of the above experiments, approximately 70% of applied enzyme activity was recovered.

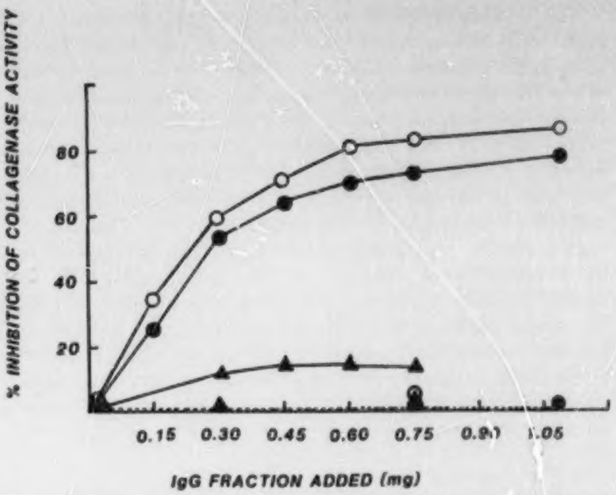
Effect of Antibodies on Rabbit Tumor Collagenase and Normal Mouse Bone Collagenase

The specificity of the antibodies directed against rabbit tumor and normal mouse bone collagenases was tested prior to reaction with the enzyme from the nude mouse tumor.

Inhibition of rabbit tumor collagenase by the isologous antibody was concentration-dependent, reaching a maximum of 92% of control values (text-fig. 3). Goat anti-rabbit tumor collagenase IgG also inhibited the enzyme prepared from normal rabbit synovial cells and skin fibroblasts (not shown). This antibody was ineffective against mouse bone collagenase. Addition of the IgG fraction of normal goat serum to rabbit tumor collagenase did not affect enzyme activity. Similarly, rabbit anti-mouse bone collagenase IgG selectively blocked the mouse enzyme to a maximum level of 80% (text-fig. 3) and had no blocking action on rabbit tumor collagenase. The IgG fraction from nonimmune rabbit serum did not affect the mouse enzyme. Similar results were obtained by the two procedures for measurement of interaction of enzyme with antibodies (*see* "Materials and Methods").



TEXT-FIGURE 3.—Specificity of antibodies against rabbit tumor and normal mouse bone collagenases. Amounts of 0.05 U normal mouse bone enzyme (▲——▲) and 0.08 U rabbit tumor enzyme (○——○) were incubated for 16 hr at 4°C with their corresponding IgG fractionated from rabbit antisera and goat antisera, respectively, and the supernatants were assayed for collagenase activity. Control incubations were performed with collagenase from mouse and rabbit mixed with the γ-globulin fractions from nonimmune rabbit (▲- - -▲) and goat serum (○- - -○), respectively.



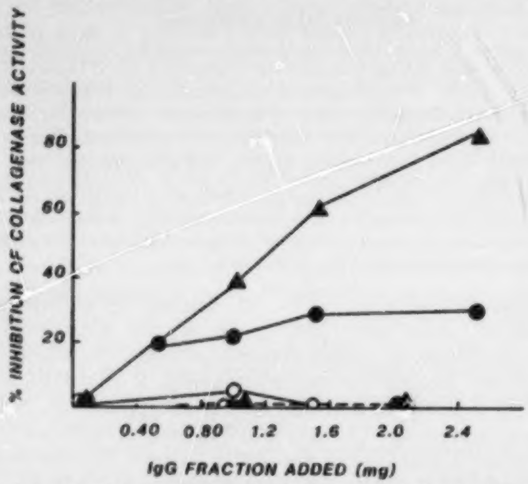
TEXT-FIGURE 4.—Interaction of antibody against rabbit tumor collagenase with different enzyme preparations. Amounts of 0.1 U enzyme from rabbit tumor (○——○) and nude mouse tumor (●——●) and 0.07 U enzyme from mouse bone (▲——▲) were each incubated for 16 hr at 4°C with the indicated amounts of IgG. After incubation, 50 µl reconstituted IgG-Sorb was added to each incubation mixture, and these mixtures were incubated further for 45 min at 25°C. Mixtures were centrifuged to remove the precipitated immune complexes, and the supernatants were assayed for collagenase activity. Control incubations were performed with each enzyme with the γ-globulin fraction from nonimmune goat serum (○- - -○, ●- - -●, ▲- - -▲).

Effect of Antibodies on Nude Mouse Tumor Collagenase

Antibodies to rabbit V_2 carcinoma collagenase resulted in 67–80% inhibition of nude mouse tumor enzyme in six experiments (text-fig. 4). The IgG fraction of nonimmune goat serum had no effect on nude mouse tumor enzyme.

Antibodies to normal mouse bone collagenase also partially inhibited nude mouse tumor enzyme; the degree of inhibition varied from 30 to 40% in six experiments, and no further inhibition was observed with additional increments of γ-globulin (text-fig. 5). Nonimmune rabbit γ-globulin had no effect on nude mouse tumor collagenase (text-fig 5). Similar results were obtained by the two procedures used to measure interaction of enzyme with antibodies (*see* "Materials and Methods"). The inhibitory effect of the antibodies against rabbit tumor and mouse bone collagenase on the enzyme activity present in nude mouse tumor culture medium was also examined. The antibody against rabbit collagenase inhibited this activity by approximately 65% and that against mouse enzyme by 34% (data not shown).

The combined effect of antibodies against rabbit and mouse enzymes on nude mouse tumor collagenase was found to be approximately additive (table 1). The combined effect of the two antibodies on artificial mixtures of rabbit tumor enzyme and normal mouse bone collagenase was also measured (table 2). For these experiments the enzymes were mixed in a ratio of 70:30 to mimic the proportions of rabbit and mouse enzyme detected in the nude mouse tumor collagenase as shown in text-figures 4 and 5. The dose of each antibody was chosen so as to inhibit the corresponding individual enzyme to an extent of approximately 50% (as shown in table 2–52% for the rabbit enzyme and 55% for the mouse enzyme). Thus the anti-rabbit tumor collagenase antibody would be expected to inhibit the mixture of enzyme preparations by 35% and the anti-mouse bone collagenase antibody by 16%. The actual results obtained were 48 and 20%, respectively. When both IgG fractions were added together to the enzyme mixture, 67% inhibition of the enzyme activity was observed, a value that closely corresponds to the sum of the inhibitory effects of the inidividual antibodies.



TEXT-FIGURE 5.—Interaction of antibody against mouse bone collagenase with different enzyme preparations. A total of 0.04 U enzyme from normal mouse bone (▲——▲), nude mouse tumor (●——●), and rabbit tumor (○——○) was incubated for 16 hr at 4°C with the indicated amounts of IgG. After incubation, 50 µl IgG-Sorb was added to each incubation mixture, and the mixtures were further incubated for 45 min at 25°C and assayed for collagenase activity. Control incubations were performed with the γ-globulin fraction from nonimmune rabbit serum (●- - -●, ○- - -○, ▲- - -▲).

TABLE 1.—*Effect of simultaneous addition of antibodies to nude mouse tumor collagenase*[a]

Expt No.[b]	Percent inhibition of collagenase activity		
	Goat anti-rabbit collagenase IgG	Rabbit anti-mouse bone collagenase IgG	Combined goat and rabbit IgG
1	49	18	57
2	71	26	87

[a] A total of 0.06 U of nude mouse tumor enzyme was incubated with the IgG fraction of the antisera added either separately or in combination. Residual enzyme activity in the supernatant was measured after removal of immune complexes (*see* "Materials and Methods").

[b] Expt 1—0.12 mg anti-rabbit IgG and 0.7 mg anti-mouse IgG; expt 2—0.62 mg anti-rabbit IgG and 2.0 mg anti-mouse IgG.

TABLE 2.—*Effect of addition of antibodies to a mixture of rabbit tumor and normal mouse bone collagenase*[a]

Source of enzyme	Percent inhibition of collagenase activity		
	Goat anti-rabbit collagenase IgG	Rabbit anti-mouse bone collagenase IgG	Combined goat and rabbit IgG[b]
Rabbit V_2 carcinoma	52	0	ND
Mouse calvaria	0	55	ND
Rabbit V_2 carcinoma and mouse calvaria mixture, 70 and 30%	48	20	67

[a] A total of 0.07 U rabbit V_2 carcinoma enzyme and 0.03 U normal mouse bone enzyme was mixed and incubated with the IgG fraction of the antisera either alone or in combination. The residual enzyme activity in the supernatant was measured after removal of immune complexes (*see* "Materials and Methods"), and 0.12 mg of goat IgG and 0.17 mg rabbit IgG were used in the experiment.

[b] ND=not determined.

DISCUSSION

Two major conclusions can be drawn from these studies. First, extracts of invasive and noninvasive V_2 carcinomas, grown in the rabbit and nude mouse, respectively, contain similar amounts of collagenase, whereas cultured explants of invasive tumors from the rabbit produce approximately 10 times more collagenase than explants of noninvasive tumors from the nude mouse. Second, it was shown, with the use of antibodies directed against rabbit and mouse collagenases, that both the nude mouse tumor extracts and culture medium contain a mixture of host mouse and rabbit tumor enzymes.

Implantation of the rabbit V_2 carcinoma into the nude mouse gave rise to a noninvasive tumor in which no infiltration of tumor cells into neighboring host tissue and no metastases were noted. Most other malignant tumors are known to behave similarly in the nude mouse (*20, 21*). The ability of the nude mouse to retard the malignant behavior of tumors has been attributed to an active natural killer cell system present in these hosts (*22*). Despite the difference in malignancy of the V_2 carcinoma implanted in the rabbit and the nude mouse, no significant difference in level of collagenase activity was observed in extracts from the two types of tumor. The major difference between the two neoplasms with respect to collagenase was in the pattern of release of enzyme from the cultured explants. In the rabbit, maximum activity often appeared after an initial lag period, and collagenase was produced by the explants over several days, resulting in accumulation of approximately tenfold more enzyme than that obtained in extracts of the tumor. Similar patterns of enzyme production have been observed in nearly all tissue culture systems producing collagenase

(*23, 24*). In the nude mouse, in contrast, the maximum amount of enzyme was obtained on the 1st day of culture followed by a rapid decrease to a base-line level within 2–3 days. The total amount of enzyme released per gram of tissue was very similar to that present in tumor extracts. Further, there was a marked difference in susceptibility of the explants to inhibition of collagenase production by cycloheximide and freeze-thawing. These procedures had much less effect on the appearance of enzyme in culture media of nude mouse tumor explants than in rabbit tumor explant cultures. These results suggest that in the nude mouse tumor explants, much of the enzyme was released from storage and was not newly synthesized, whereas in the rabbit explants de novo synthesis continued for a considerable period. Thus it appears that regulation of collagenase production in the invasive V_2 tumor is clearly different from that in the noninvasive V_2 tumor. Both types of tumor differ from normal tissue where little or no extractable enzyme accumulates but de novo synthesis in explant culture usually occurs (*25*).

Collagenase has been detected in several neoplasms (*1–7*), and the enzyme has been localized in the connective tissue stroma surrounding some tumors by immunofluorescence (*26*), leading to suggestions that collagen degradation is involved in tumor infiltration. Our recent morphologic studies on V_2 carcinoma implanted in rabbit cornea revealed disruption of the compact laminated collagenous structure associated with collagenase production (*27*). Both collagenolysis and tumor growth were inhibited by the presence of medroxyprogesterone or dexamethasone (*27*). However, the presence of detectable collagenase in tumors, for example, in the noninvasive V_2 carcinoma of the nude mouse, is not sufficient for the migration or penetration of tumor cells through connective tissue barriers; additional conditions are obviously necessary. Among other factors, the production of hyaluronate may be involved, since the invasive rabbit V_2 carcinoma growing in the rabbit contains larger amounts of this polysaccharide, which is often associated with cell migration (*28*), than does the tumor grown in the nude mouse (*29*). Failure of the V_2 carcinoma to metastasize in the nude mouse cannot be attributed to a lack of type IV or type V collagenase because both enzyme activities were detected at similar low levels in extracts of both the nude mouse and the rabbit V_2 carcinomas. It is not known whether the type I, IV, and V collagen-degrading activities of the V_2 carcinoma represent a single enzyme or a mixture of enzymes.

In the present studies, we sought to determine whether or not host–tumor cell interactions lead to production of collagenase by host cells associated with the tumor. Antibodies were induced to the rabbit tumor and mouse bone enzyme. Mouse bone was selected as a source of mouse collagenase because this tissue has been reported to yield larger amounts of enzyme in culture than do other mouse tissues (*30, 31*). These antibodies reacted only with autologous antigen and thus could be used to determine whether the collagenase present in nude mouse tumor originated in host or tumor cells. The results indicated that, in the V_2 carcinoma implanted into nude mice, the major portion of collagenase activity (≈70%) is contributed by rabbit cells, but a significant amount (≈30%) is produced by mouse cells. The source of rabbit enzyme in the nude mouse tumor is probably tumor cells, rather than fibroblasts, since implantation of normal rabbit muscle or synovial cells into the nude mouse did not result in any growth. However, the possibility that normal rabbit fibroblasts do survive and multiply in nude mice in the presence of tumor cells and that these cells might be a source of rabbit collagenase cannot be excluded. In support of our observation that host–tumor cell interaction might lead to production of collagenase by host cells are the studies reported by Harris et al. (*32*). They showed that the central tumor tissue from rabbit V_2 carcinoma does not synthesize enzyme in culture, whereas the surrounding connective tissue does. Possibly, in their tumor system, collagenase production occurred in the connective tissue layer because of the presence of both host and tumor cells in that region, whereas in the central tumor mass only tumor cells predominate.

Since macrophage infiltration of tumors (*33*) and collagenase production by stimulated macrophages in culture are known to occur (*34, 35*), these may be the host cell source of enzyme. Werb and Gordon (*34*) reported that these cells secrete small amounts of collagenase for prolonged periods in culture and that secretion is inhibited by cycloheximide, thus suggesting de novo synthesis of the enzyme in culture. However, our data on the profile of enzyme production by nude mouse tumor explants in culture and enzyme production's relative insensitivity to the presence of cycloheximide suggest that most of the measurable enzyme is stored within cells or bound to collagen fibrils rather than being newly synthesized.

Although, immunologically, the nude mouse tumor extracts were shown to contain a mixture of rabbit and mouse collagenases, it was difficult to ascertain biochemically whether both enzymes were present. The rabbit tumor enzyme was shown to have a molecular weight of 40,000, whereas the mouse bone enzyme was of molecular weight 90,000. In the case of the nude mouse, the enzyme was somewhat heterogeneous, with the major component of molecular weight 40,000 and a minor component of higher molecular weight. However, it cannot be concluded with certainty that the minor component was of molecular weight 90,000, which would be expected if the mixture contained mouse enzyme.

Cell–cell interactions regulating collagenase production have been documented in normal systems in which factors secreted by blood-derived mononuclear cells (*36, 37*), epithelial cells (*38, 39*), or macrophages (*40*) enhance production of this enzyme by connective tissue cells. Preliminary in vitro experiments have shown that co-culture of mouse B-16 melanoma or A-10 adenocarcinoma cells with normal rabbit fibroblasts results in stimulation of collagenase production (*41*). The tumor cells have been found to secrete factor(s) that stimulate the fibroblasts to produce elevated levels of the enzyme. Thus it is possible that in vivo tumor cells may interact with host cells to stimulate collagenase production.

Immunoadjuvant Effects of *Blastomyces dermatitidis* Against EL 4 Lymphoma in C57BL/6J Mice [1,2,3]

L. Scott McDaniel [4,5] *and* George C. Cozad [4,6]

ABSTRACT—The ability of thimerosal-killed *Blastomyces dermatitidis* yeast cells, which greatly enhance the cell-mediated immune response in C57BL/6J mice, to act as an immunopotentiator against EL 4 lymphoma was investigated. Mice treated with yeast cells were protected from as many as 10^4 tumor cells. Complete suppression of tumor growth was observed in treated animals that received ip injections of 10^2 or 10^3 tumor cells. The mice, however, were not immune to further EL 4 lymphoma cell challenge. The lack of tumor-specific immunity indicated nonspecific suppression of tumor growth probably by macrophages. Ten days after treatment, the peritoneal macrophages from mice that showed complete tumor suppression were tested for their ability to prevent in vitro tumor cell proliferation. These macrophages demonstrated 90% inhibition of [^{3}H]thymidine incorporation by EL 4 tumor cells at a 100:1 effector-to-target cell ratio. Macrophages from *B. dermatitidis*-treated animals exhibited a twofold increase in specific lysis of EL 4 at 10 and 15 days compared to resident macrophages. Spleen and lymph node cells from protected animals showed no cytotoxic activity against EL 4 in a ^{51}Cr release assay. Treatment of tumor-bearing mice with a single dose of *B. dermatitidis* was effective only if administered within 24 hours of tumor establishment. These results demonstrated that nonviable *B. dermatitidis* prohibits the growth of EL 4 under conditions where *Corynebacterium parvum* fails to do so.—JNCI 1982; 69;1337–1342.

It is a generally accepted theory that macrophages play a major role in resistance against growth of tumor cells within the host tissue. The in vitro cytolytic capacity of activated macrophages is well substantiated (*1, 2*). Also, macrophages activated by bacterial or protozoal infections are able to inhibit the growth of tumor cells in vivo (*3, 4*). Microorganisms such as BCG (*2*), *Toxoplasma gondii* (*3*), or *Corynebacterium parvum* (*4*) are capable of inducing macrophages that have the capacity to distinguish tumor cells from normal cells. There is a great interest in agents that enhance the ability of macrophages to nonspecifically kill tumor cells. Various agents are also able to activate cultured resident macrophages to a tumoricidal state. These include lymphokines (*2*), LPS (*5*), and poly I:C (*6*). Evidence continues to mount for the importance of macrophages as primary targets of such immunomodulating agents.

Past studies in our laboratory with yeast cells of the dimorphic fungus *Blastomyces dermatitidis* indicated that this organism elicits a strong cell-mediated immune response (*7, 8*). We report here results of experiments on the protective effects of *B. dermatitidis*-induced resistance in C57BL/6J mice against the syngeneic lymphoma EL 4.

MATERIALS AND METHODS

Culture.—The thimerosal-killed whole yeast cell Ag was prepared by the method of Restrepo-Moreno and Schneidau (*9*) as modified by Spencer and Cozad (*7*). In all experiments the *B. dermatitidis* was washed three times in 10 volumes of a sterile PSS to remove the thimerosal. The yeast phase culture of *B. dermatitidis* 242 was originally isolated from a fatal human case of blastomycosis. The culture was maintained on BHI agar slants at 37°C.

Test animals.—Inbred C57BL/6J mice of both sexes, 2–3 months old were used in this study. The strain was originally obtained from The Jackson Laboratory, Bar Harbor, Maine, and bred in our animal facilities. The mice were separated by sex and given water and Purina Mouse Chow (Ralston Purina Co., St. Louis, Mo.) ad libitum.

Cell line.—The thymus-derived benzo[*a*]pyrene-induced lymphoma EL 4 of C57BL mice was used in this study. The cells were maintained as ascites tumors in 8–12-week-old C57BL/6J mice. Transfers were made at 10–12 days by ip injection of 10^6 cells in 0.2 ml HBSS (GIBCO, Grand Island, N.Y.). In vitro cultures of the EL 4 lymphoma were maintained as suspensions in RPMI-1640 medium (GIBCO) supplemented with 10% heat-inactivated FCS (M.A. Bioproducts, Walkersville, Md.). The medium also included 2 m*M* L-glutamine, 100 U penicillin/ml, and 100 µg streptomycin/ml (GIBCO). Cells were carried in logarithmic growth (12- to 14-hr doubling time) within a cell density of 1×10^5–2×10^6 cells/ml. EL 4 tumor cell viability under these growth conditions was between 97 and 100% as determined by the trypan blue exclusion test.

Preparation of immunizing inoculum and assessment of delayed hypersensitivity.—An Ag emulsion of thimerosal-killed *B. der-*

matitidis yeast cells was prepared by the mixing of equal volumes of the yeast suspension and Freund's incomplete adjuvant (Difco Laboratories, Detroit, Mich.). A control suspension was prepared by substitution of PSS for the yeast suspension.

The mice were sensitized according to the method of Cozad and Chang (*8*). On days 0 and 7, mice were inoculated sc in the inguinal area with 0.1 ml Ag emulsion (containing 2 mg dry wt equivalent of killed *B. dematitidis* yeast cells). A control group was inoculated in the same manner with the PSS emulsion. Some animals were given ip 0.1 or 1.0 mg killed *B. dermatitidis* in 0.2 ml PBS 5 days before tumor challenge.

To determine the delayed hypersensitivity pattern, we gave 3 mice from each group footpad tests on days 3, 15, and 30 after the initial injection with a killed whole yeast cell suspension. We performed the footpad tests by the procedure of Youmans and Youmans (*10*), as described by Cozad and Chang (*8*).

Tumor inoculations.—We conducted preliminary experiments to determine the median survival time of mice that received 10^2–10^7 tumor cells without treatment. To test the effect of preimmunization with the Ag emulsion, we challenged groups of 10 mice with a range of 10^2–10^6 ip tumor cell injections on days 0, 3, and 15 after the initial Ag emulsion injection. We performed all experiments at least twice.

We also evaluated the protective effects by mixing the yeast cells with tumor cells prior to injection. The mice were given 0.2 ml ip injections of 10^2–10^6 EL 4 cells mixed with 0.1 or 1.0 mg killed *B. dermatitidis* yeast cells. Survival of the animals was checked daily for 2 months.

To test the therapeutic potential of *B. dermatitidis*, we gave mice ip inoculations of 10^2–10^6 EL 4 cells and treated them with ip injections of 1.0 mg *B. dermatitidis* in 0.2 ml PBS at various times after tumor challenge. A control group of tumor-bearing mice received ip injections of PBS alone. Treatment times were at 2 hours and at 1, 2, 3, 5, 8, and 11 days.

Collection of peritoneal cells.—We collected peritoneal cells without the use of an exudate-inducing agent by a modification of the method described by Tolnai (*11*). Five milliliters cold RPMI-1640 medium containing 10 U sodium heparin/ml (Fellows Medical Manufacturing Co., Inc., Anaheim, Calif.) and 1% FCS was injected into the peritoneal cavity. The fluid was withdrawn after a short massage.

We pooled the cells from 3 animals and assessed their viability by the trypan blue exclusion test. After centrifugation, we resuspended the cells at the concentration of 5×10^6 cells/ml in cold RPMI-1640 medium with 1% FCS and placed 0.1 ml of the suspension into wells of a Falcon MicroTest II plate (style 3040; Falcon Plastics, Oxnard, Calif.). After adherence for 60 minutes at 37°C in 5% CO_2, we removed nonadherent cells by washing twice with warm PBS and by suction through a Pasteur pipette. Then we added 0.1 ml fresh warm medium containing 10% FCS to the chambers and incubated the plates for 18–24 hours at 37°C in 5% CO_2.

Cytostasis assay.—We used a modified version of the procedure described by Goldman and Bar-Shavit (*12*). After the 24-hour incubation, we added to the wells 0.1 ml RPMI-1640 with 10% FCS containing the desired concentration of EL 4 cells. We set up controls of 0.2 ml RPMI-1640 medium with tumor cells alone, reincubated the plates for 7 hours, and added 0.5 μCi [^{3}H]dThd (20 Ci/mmol; New England Nuclear Corp., Boston, Mass.). Controls containing macrophages alone with [^{3}H]dThd were included. We incubated the plates at 37°C and 5% CO_2 for an additional 24 hours and then harvested the samples with a MASH unit (M.A. Bioproducts). We dried the filter strips, placed the disks in toluene scintillation fluid, and counted them in a Beckman LS 100C liquid scintillation counter.

Cytotoxicity assay.—We labeled the EL 4 cells by incubating 5×10^6 cells for 3 hours in 1.0 ml RPMI-1640 medium with 10% FCS containing 10 μCi [^{125}I]IdUrd (5 Ci/mg; Amersham Corp., Arlington Heights, Ill.) (*13*). After incubation we washed the cells three times with medium and resuspended them at 5×10^6 cells/ml.

We added the desired concentration of labeled EL 4 cells in 0.1 ml medium to wells containing 5×10^5 macrophages that had been incubated for 24 hours. Wells were set up for spontaneous and maximum release for each tumor cell concentration used. We ran all samples in triplicate. We incubated the plates for an additional 27–30 hours at 37°C and 5% CO_2, added 0.1 ml of a 2 *N* HCl solution to the maximum-release wells to obtain total counts, and centrifuged the plates for 15 minutes at 200× *g*. We then removed 0.1-ml samples and counted the radioactive label in a Packard Tri-Carb gamma counter. The percentage of specific lysis was obtained with the use of the formula: Percent specific lysis = [(cpm test sample − cpm spontaneous release)/maximum cpm of target cells]×100.

SEM of EL 4 lymphoma cells and macrophages.—After the harvest of the peritoneal cells, a 5.0-ml suspension of 1×10^6 cells/ml was plated in petri dishes that contained three glass cover slips. After 60 minutes at 37°C and 5% CO_2, all nonadhering cells were washed away with warm PBS. We added fresh warm medium containing 10% FCS and incubated the culture for 18–24 hours at 37°C in 5% CO_2.

After 24 hours, we replaced the medium with fresh medium containing 5×10^3 EL 4 cells/ml and incubated it for various time intervals up to 48 hours at 37°C and 5% CO_2. The medium was then aspirated, and the cover slips were fixed with 0.5% glutaraldehyde in PBS at room temperature for 18–24 hours.

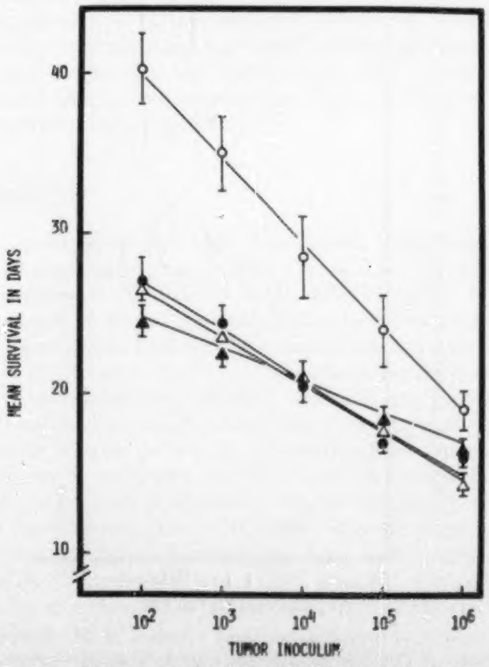
We further prepared the samples for SEM by submitting them to a series of ethyl alcohol dehydrations. The cover slips were critical point dried in a Pelco Critical Point Dryer (No. 99 model H; Ted Pella Co., Trustin, Calif.) with the use of liquid CO_2 at a critical pressure of 1,072 pounds per square inch. The samples were then gold coated in a Technics Hummer sputter coater and examined in an International Scientific Instruments Super II scanning electron microscope at the noted magnifications with an accelerating voltage of 25 kV.

Chromium release assay.—We evaluated the cytotoxic activity of lymphocytes with the use of an established procedure (*14*). EL 4 cells, 1×10^7 in 1.0 ml, were incubated in serum-free RPMI-1640 medium containing 100 μCi ^{51}Cr–sodium chromate (500 mCi/mg; Amersham Corp.) for 1 hour at

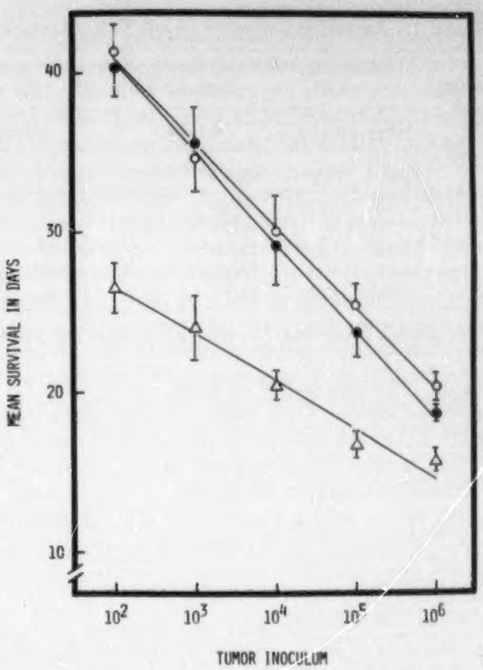
37°C in 5% CO_2. After incubation, the cells were washed twice and adjusted to 2×10^5 cells/ml (target cells) in RPMI-1640 with 10% FCS. Spleen or lymph node cells (effector cells) from mice showing tumor suppression at 10 or 15 days were adjusted to 1×10^7 cells/ml. Then 0.1 ml of the target cells were placed in a round-bottomed microtiter plate (Linbro Scientific Co., Inc., Hamden, Conn.). The plate was incubated at 37°C in 5% CO_2 for 4 hours. At the end of this time, we centrifuged the plate at 200×*g* for 15–20 minutes, removed carefully 0.1 ml supernatant, transferred it to a 7.5×100-mm disposable glass tube, and counted the radioactivity for 10 minutes in a Packard Tri-Carb gamma counter. The percent cytotoxicity was obtained by the formula: Percent specific lysis = [(counts of test group − spontaneous release)/maximum cpm of target cells]×100.

RESULTS

Preimmunization effects on survival of mice.—We then preimmunized the mice with *B. dermatitidis* in Freund's incomplete adjuvant. Footpad tests with representative mice demonstrated a delayed hypersensitivity pattern that is consistent for *B. dermatitidis* (*8*), with a peak response at 15–18 days post primary injection. We then challenged the remaining mice with various tumor inocula at different times post primary immunizing dose. The results are presented in text-figure 1. Mice challenged 3 days after the initial *B. dermatitidis* injection showed a significant increase in mean survival time. The lower the initial tumor inoculum, the more significant was the increase in mean survival time compared to that of controls.



TEXT-FIGURE 1.—Preimmunization of C57BL/6J mice with *B. dermatitidis* in Freund's incomplete adjuvant. Survival at: ○——○, 3 days post primary infection; △——△, at day 0; ▲——▲, at 15 days post primary infection; ●——●, controls (received no treatment prior to the EL 4 challenge). Results are mean survival times ± SE.



TEXT-FIGURE 2.—Preimmunization of C57BL/6J mice with 1.0 mg (○——○) and 0.1 mg (●——●) *B. dermatitidis* by ip injection 5 days prior to challenge with EL 4. ▲——▲, controls. Results are mean survival times ± SE.

In some experiments, mice were given ip injections of 0.1 or 1.0 mg killed *B. dermatitidis* in PBS without adjuvant 5 days prior to tumor challenge. Both doses of yeast cells caused significant (and similar) increases in mean time of survival of treated mice compared to that of control mice (text-fig. 2). The increase in survival was very similar to that seen in mice immunized 3 days before tumor challenge with *B. dermatitidis* in Freund's incomplete adjuvant (text-fig. 1).

Mixing of EL 4 cells with B. dermatitidis.—We mixed a dry equivalent weight of 0.1 or 1.0 mg killed *B. dermatitidis* with 10^2–10^6 EL 4 cells and immediately injected the mixture ip into mice to determine if *B. dermatitidis* could induce a host response capable of suppressing tumor growth. EL 4 cells in these mixtures showed no significant decrease in viability even after 4 hours as determined by trypan blue exclusion test. Within several days, all mice that had received the mixture developed an inflammatory response at the site of injection. Mice that received EL 4 alone showed no such response. At 30 days, the inflammation had receded in a majority of the animals that received *B. dermatitidis*. By 60 days, all mice in the control groups were dead as the result of tumor growth, but a significant number of animals that received the mixture were alive and free of tumors (table 1). At 65 days, the living mice were challenged with 1×10^4 EL 4 cells given by ip injection. The mice all died as a result of tumor development.

Treatment of EL 4 cells with B. dermatitidis.—To determine if *B. dermatitidis* could cause regression of established tumors,

TABLE 1.—*Suppression of tumor growth by* B. dermatitidis

No. of EL 4 tumor cells injected	Tumor suppression 60 days post treatment with *B. dermatitidis*[a]					
	None, control		0.1 mg		1.0 mg	
	Expt 1	Expt 2	Expt 1	Expt 2	Expt 1	Expt 2
10^6	0/10	0/10	0/10	0/10	0/10	0/10
10^5	0/10	0/10	1/10	0/10	2/10	1/10
10^4	0/10	0/10	10/10	6/10	10/10	8/10
10^3	0/10	0/10	10/10	10/10	10/10	10/10
10^2	0/10	0/10	10/10	10/10	10/10	10/10

[a] No. of animals tumor-free/No. given EL 4 tumor cell injections.

we treated mice inoculated with EL 4 cells with 1.0 mg *B. dermatitidis* at various times (table 2). Animals that received 10^5 or 10^6 EL 4 cells showed no regression of tumor growth. There was no significant increase in the mean survival of these animals compared with that of the controls. Mice given 10^2, 10^3, or 10^4 EL 4 cells showed a significantly high survival if treated with *B. dermatitidis* within 2 hours of tumor cell injection. The amount of survival decreased at least threefold if the treatment was given 1 day after tumor cell injection. No animal treated between 3 and 11 days with a single dose of *B. dermatitidis* showed significant increase in survival (text-fig. 2).

Effect of macrophages on tumor proliferation.—To determine if peritoneal macrophages could halt the growth of EL 4 cells in vitro, we examined [^{3}H]dThd incorporation by EL 4 cells in the presence of various macrophage preparations (text-fig. 3). At a 100:1 E:T, resident macrophages reduced [^{3}H]dThd incorporation into EL 4 by 44%. A significant difference in the amount of incorporation was not seen in the presence of macrophages from mice given 0.1 or 1.0 mg *B. dermatitidis* 5 days before harvesting. The results obtained with the use of macrophages derived from animals given sc injections of *B. dermatitidis* 3 days before harvesting were almost identical to those seen with animals given ip injections 5 days prior to harvesting (data not shown). Macrophages from mice that received a mixture of 10^4 EL 4 and *B. dermatitidis* 10 days earlier caused 90% inhibition of [^{3}H]dThd incorporation at a 100:1 E:T. This was greater than a 45% difference when compared to resident macrophages at the same concentration. The difference between these 2 groups was even greater at 1:1 and 10:1 E:T.

TABLE 2.—*Regression of established tumors after treatment with* B. dermatitidis

	2 days	4/10	0/10	<0.08

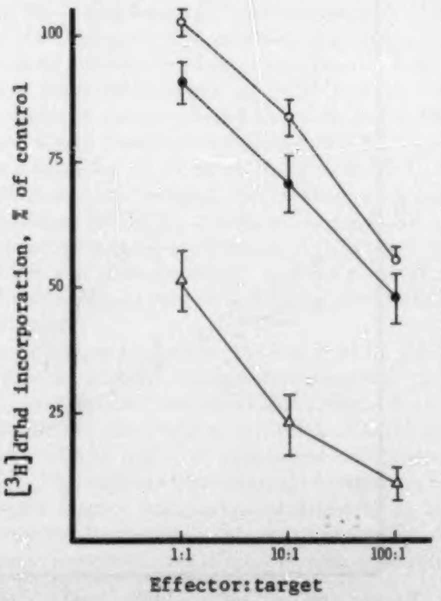
[a] No. of animals tumor-free/No. given injections of tumor.

[b] Chi-square test with Yates' correction. NS=not significant; $P \geq 0.10$.

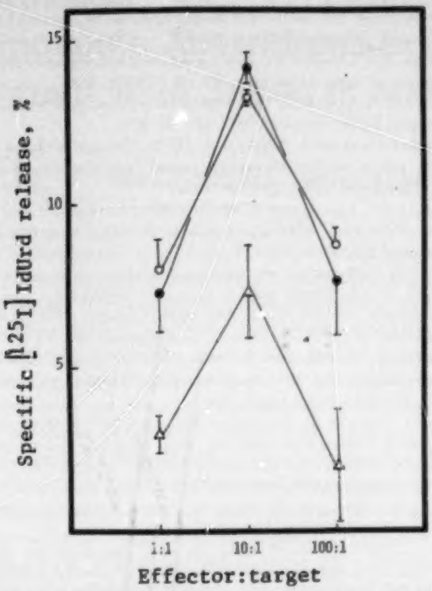
In vitro cytotoxicity of peritoneal macrophages.—We tested peritoneal macrophages taken from mice 10–15 days after receiving 0.1 or 1.0 mg *B. dermatitidis* mixed with 10^4 EL 4 cells for their ability to release [^{125}I]IdUrd-prelabeled EL 4 cells. The data in text-figure 4 show that there was at least a twofold difference in the amount of lysis caused by macrophages from treated mice compared to the amount from normal resident macrophages. There was a consistent drop in the amount of lysis when the E:T was increased from 10:1 to 100:1.

Interaction between activated macrophages and target cells.—The EL 4 lymphoma cells were readily identifiable in the SEM. When EL 4 cells were seen in the presence of resident macrophages, there was no evidence of macrophage aggression toward the lymphoma cells. Macrophages collected from mice 10 days after receiving 1.0 mg *B. dermatitidis* mixed with 10^4 EL 4 cells (test macrophages) were examined for their ability to interact in vitro with EL 4. Test macrophages showed strong evidence of interaction with tumor cells as early as at 4 hours. However, there were no apparent morphologic alterations in the EL 4 cells at this point. By 30 hours, there was visible evidence of lysis of EL 4 cells by test macrophages.

Lymphocyte cytotoxicity.—We performed tests to investigate whether cytotoxic lymphocytes were present in the spleen and lymph nodes of mice that received ip injections of 0.1



TEXT-FIGURE 3.—Macrophage-mediated cytostasis of EL 4 assessed by inhibition of [^{3}H]dThd incorporation. ○——○, Resident macrophages or macrophages collected from normal mice; ●——●, macrophages from mice that had received 1.0 mg *B. dermatitidis* 5 days earlier; △——△, macrophages from mice showing complete suppression of tumor growth at 10 days after having received 10^4 EL 4 + 1.0 mg *B. dermatitidis*. Data are means ± SE.



TEXT-FIGURE 4.—Release of ^{125}I from EL 4 target cells after 30 hr in culture. The target cells were cultured with effector macrophages: △——△, resident macrophages collected from normal mice; or macrophages from mice showing complete suppression of tumor growth at 10 days (○——○) or 15 days (●——●) after receiving 10^4 EL 4 + 1.0 mg *B. dermatitidis*. Data are means ± SE.

or 1.0 mg *B. dermatitidis* mixed with 10^4 EL 4 cells. The tests were done at 10 and 15 days after injection of the mixture. In one experiment, lymph node and spleen cells were taken at 10 days from mice that had received the mixture on days 0, 3, and 5. No cytotoxic lymphocytes were detected in spleen and lymph node preparations from mice that showed suppression of tumor growth.

DISCUSSION

The results presented here demonstrate that thimerosal-killed *B. dermatitidis* yeast cells can cause suppression of EL 4 lymphoma in C57BL/6J mice. Other studies on the mechanisms of tumor regression by immunopotentiating agents have shown that macrophages are important effector cells (*1, 3*). Previous studies in this laboratory have shown that *B. dermatitidis* can activate macrophages to become fungicidal (McDaniel LS, Cozad GC: Submitted for publication). It is possible that *B. dermatitidis*-dependent tumor suppression is mediated by activated macrophages. Although the possible involvement of other mechanisms in the tumor suppression cannot be ruled out, our experiments show that peritoneal macrophages from mice treated with nonviable *B. dermatitidis* yeast cells plus EL 4 lymphoma cells have an enhanced potential for in vitro tumor cell stasis and killing.

Nonviable *B. dermatitidis* yeast cells appear to be more effective than *C. parvum* at stopping the growth of EL 4 tumor in vivo. As evidence, O'Neill and Stebbing (*15*) recently reported that preimmunization of mice with *C. parvum* failed to inhibit the growth of EL 4 in C57BL/6J mice. Conversely, preimmunization with *B. dermatitidis* significantly increased the mean survival time of mice challenged with EL 4. This protective effect was seen at 3–6 days after sc or ip injection of *B. dermatitidis*. It is curious that the route of injection had little effect on the time sequence of protective effects.

It was originally thought that the highest degree of enhanced survival would coincide with the peak in phagocytic activity of peritoneal macrophages (i.e., 15–18 days post primary *B. dermatitidis* injection). However, our experiments showed that this was not the case. The protective effects dropped off, and the mean survival time returned to that of the controls by day 15, even though peritoneal macrophages remained activated. An interpretation of these results may include the possible involvement of natural killer cells. Alternatively, the lack of correlation between antitumor and phagocytic activities could be the result of induction of functionally different macrophage populations as has been reported in other systems (*16*).

B. dermatitidis produces a granulomatous reaction in tissue (*17*). Such reactions have been reported for other agents currently used in immunotherapy (*18*). *B. dermatitidis* yeast cells are known to contain cell wall-associated toxin (*19*). Although the *B. dermatitidis* endotoxin has not been extensively characterized, it is doubtful that this toxin is identical to bacterial endotoxin that is capable of activating macrophages in vitro to a tumoricidal state (*5*). As evidence, it has been reported that *C. albicans* possesses an endotoxin that shares some of the properties of bacterial LPS but is not exactly comparable to it (*20*). Nevertheless, such a substance could mediate the protective effects we observed.

We have considered the possibility of direct interaction between nonviable *B. dermatitidis* and EL 4 tumor cells. Our data suggest that some interaction may be important since the highest degree of protection was obtained by the mixing of yeast cells with tumor cells prior to injection. However, we do not believe that the protective effects result solely from an adverse action of yeast cells against tumor cells. For example, significant protection was obtained by preimmunization of mice with *B. dermatitidis* alone. There were no adverse effects on EL 4 observed by the light microscope. Also, at a 10:1 ratio of nonviable yeast cells to tumor cells in vitro, the EL 4 cells continued to incorporate [^{3}H]dThd at near normal levels (data not shown). In addition, the protective effects were not limited to mixing yeast cells with tumor cells in vitro; the same results could be obtained by the injection of yeast cells and tumor cells separately on opposite sides of the peritoneum.

The preliminary results we obtained on the therapeutic potential of *B. dermatitidis* indicate that the yeast cells had a therapeutic effect only if administered within 24 hours after tumor transplantation. It has been reported that immunoadjuvants can generate cells that are capable of suppressing cell-mediated immune responses (*21*). Possibly, *B. dermatitidis* suppresses cellular immunity in tumor-bearing mice, thereby enhancing tumor growth. However, no conclusion can be drawn until further data have been gathered on the effects of *B. dermatitidis* on tumor-bearing mice. A regimen that involves several doses of *B. dermatitidis* over a period of time probably would be more therapeutically effective than a single dose.

The SEM revealed that there was strong interaction between macrophages from mice that showed complete suppression of tumor growth and EL 4 cells in vitro. A lack of such interaction between EL 4 and resident macrophages was also noted. Also, it has been reported that intimate contact between target cells and macrophages is required for tumor cell lysis in vitro (*22, 23*). Our observations of EL 4 with the SEM agree with these findings.

We were unable to detect cytotoxic lymphocytes in the spleen or lymph nodes of mice that showed suppression of tumor cell growth. Local immunity could have generated cytotoxic lymphocytes within the peritoneum, but we did not test for such cells. However, the fact that mice showing tumor suppression were not resistant to further EL 4 challenge indicates a lack of specific immunity. This observation supports the idea of nonspecific suppression of tumor growth by macrophages.

Our experiments indicate that nonviable *B. dermatitidis* yeast cells can significantly effect the outcome of tumor growth in the mouse system. This preparation may offer a significant advantage over other agents because it is not viable, and when applied in human beings, the possibility of infection in relatively immunodeficient cancer patients would be eliminated.

Suppression of 7,12-Dimethylbenz[*a*]anthracene-Induced Chromosome Aberrations in Rat Bone Marrow Cells After Treatment With Sudan III and Related Azo Dyes[1,2]

Yoshiaki Ito,[3,4,5] Sakan Maeda,[3] Tetsuo Fujihara,[3] Norifumi Ueda,[3] *and* Taketoshi Sugiyama[3]

ABSTRACT—Noninbred Long-Evans rats fed Sudan III at 24 hours before they were given an injection of 7,12-dimethylbenz[a]anthracene (DMBA) displayed prominently suppressed DMBA-induced chromosome aberrations (CA) in their bone marrow cells. Rats fed Sudan III simultaneously with the DMBA injection showed no suppressed CA effect. The suppressive effect of Sudan III on DMBA-induced CA paralleled the dose rate of Sudan III when given in the range between 1 and 10 mg Sudan III/kg body weight; higher doses produced no additional suppression. The capacity of various Sudan III-related chemicals to prevent DMBA-induced CA paralleled their capacity to prevent DMBA-induced adrenal apoplexy and mammary cancer. Among the azo dyes investigated, Sudan III was most efficient in protecting against DMBA-induced CA. Polychlorinated biphenyl and phenobarbital, inducers of drug-metabolizing enzymes, also suppressed DMBA-induced CA.—JNCI 1982; 69:1343–1346.

The powerful hydrocarbon carcinogens DMBA and TMBA induce not only cancers in various animals (*1–4*) but also massive adrenal necrosis in the rat (*5, 6*). Since 1965, Huggins and Pataki (*7*) and Huggins et al. (*8*) have reported that pretreatment of rats with Sudan III [1-(*p*-phenylazophenylazo)-2-naphthol] and the related azo dyes prevents mammary cancer (*7*), leukemia (*8*), adrenal apoplexy (*7*), and fatal toxicity (*8*) induced by these chemical carcinogens and that the protection from PAH-induced adrenal apoplexy in these rats provides a useful preliminary screen for compounds that suppress PAH-induced cancer (*7*). This phenomenon is explained by inactivation of PAH with drug-metabolizing enzymes induced by Sudan dyes (*8*). Evidence of DMBA-induced chromosome damage in the rat bone marrow cells as the earliest host reaction to DMBA (*9*) stimulated us to study the effect of Sudan III and the related azo dyes on DMBA-induced CA.

MATERIALS AND METHODS

Animals.—Noninbred Long-Evans male rats at 28–35 days of age and weighing 50–80 g were used. They were kept in an air-conditioned room and fed NMF (Oriental Ferment Co., Tokyo) and permitted water ad libitum.

Chemicals.—DMBA and NBU were purchased from Eastman Organic Chemicals, Rochester, N.Y., and Izumi Chemical Research Laboratory, Tokyo, Japan, respectively. A 15% lipid emulsion containing 0.5% (wt/wt) of recrystallized DMBA was produced by a Manton-Gaulin submicron homogenizing system in our laboratory by the method of Schurr (*10*). NBU was dissolved at 20 mg/ml of sesame oil before use. Sudan III and Sudan IV [1-(*o*-tolylazo-*o*-tolylazo)-2-naphthol] (Chroma, Stuttgart, Federal Republic of Germany) and Sudan I (1-phenylazo-2-naphthol), yellow AB (1-phenylazo-2-naphthylamine), α-naphthyl red (4-phenylazo-1-naphthylamine), *p*-aminoazobenzene, and azobenzene (Tokyo Chemical Synthetic Industry Co., Ltd., Tokyo, Japan) were recrystallized from appropriate solvents and dissolved in sesame oil by gentle heat. These azo compounds were selected from the list of chemicals tested for protection of DMBA-induced adrenal apoplexy (*7*). They were administered by gastric instillation to lightly ether-anesthetized rats. Control animals were given sesame oil only. PCB (Kanechlor-400; Kanegafuchi Kagaku Kogyo Co., Osaka, Japan) was dissolved at 2.0 mg/ml of sesame oil, and PB (Yoneyama Yakuhin Kogyo Co., Osaka, Japan) was dissolved at 2.0 mg/ml of physiologic saline. PCB and PB were given to the rat for comparative inhibition studies of the DMBA effects.

A lipid emulsion of 50 mg DMBA/kg was injected into the caudal vein. NBU was dissolved in sesame oil and fed by gastric instillation at 200 mg/kg. CA were analyzed at various times after the DMBA and NBU treatments. Sudan III was also given at various times before the carcinogen treatment, and the effects of these administrations on carcinogen-induced CA were studied. Each experimental group consisted of 6 animals.

Chromosome analysis.—Colchicine (0.3 mg/rat), dissolved in physiologic saline, was injected ip 1 hour before the rats were killed. Chromosome specimens were prepared from the femoral bone marrow by the conventional method and were stained in 2% Giemsa solution. Metaphase cells having one CA or more were scored from 50 well-spread metaphases/rat or 300 metaphases/each group, and the frequency of CA was expressed by the percent of aberrant metaphase cells. CA consisted of gaps, breaks, and chromosome exchanges. Gaps were defined by an achromatic lesion with chromatid continuity, and breaks were defined by discontinuity shown by chromatid dislocation. Multiple CA were defined by uncountable (numerous, >5) CA per cell.

ABBREVIATIONS USED: CA=chromosome aberration(s); DMBA=7,12-dimethylbenz[*a*]anthracene; NBU=*N*-nitroso-*N*-butylurea; PAH=polycyclic aromatic hydrocarbon(s); PB=phenobarbital; PCB=polychlorinated biphenyl; TMBA=7,8,12-trimethylbenz[*a*]anthracene.

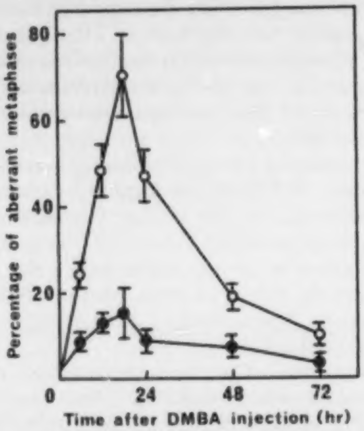
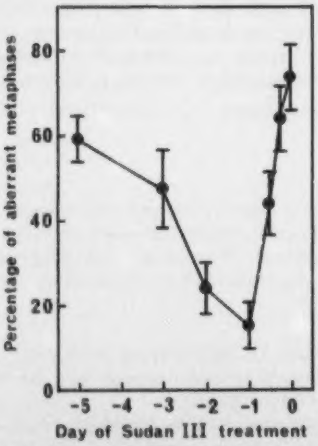
RESULTS

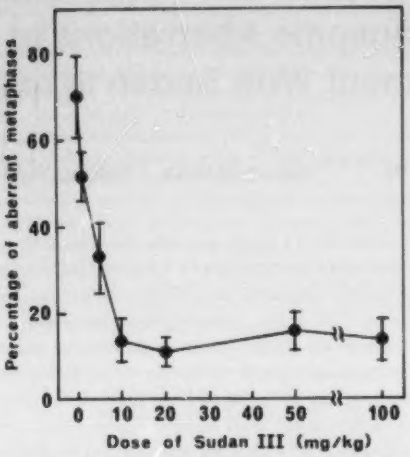
Suppression of DMBA-induced CA by Sudan III pretreatment.—A single iv injection of DMBA, 50 mg/kg body weight, induced an increase in the percentage of aberrant metaphase cells in the bone marrow at a maximum level of 70.0±9.7% at 18 hours after the DMBA treatment. Rats fed 1 mg of Sudan III at 24 hours before they were given an injection of DMBA displayed a considerably suppressed incidence of DMBA-induced CA in their bone marrow cells, with a peak percentage of aberrant metaphases of 15.3±6.2% (text-fig. 1). The number of gaps, breaks, exchanges, and multiple CA per 100 cells was 46.7±6.8, 6.8±3.5, 0.8±1.2, and 27.7±10.1, respectively, at 18 hours in the DMBA (50 mg/kg)-injected group, and it was 14.2±5.1, 1.2±1.7, 0.1±0.5, and 0.7±1.3, respectively, in the Sudan III-fed–DMBA-injected group. Rats fed Sudan III simultaneously with the DMBA injection showed no suppressed CA effect, and the maximum suppression was obtained in rats fed Sudan III 24 hours before they received the DMBA treatment (text-fig. 2). The suppressive effect of Sudan III on DMBA-induced CA paralleled the dose rate of Sudan III when given between 1 and 10 mg/kg body weight; higher doses produced no additional suppression (text-fig. 3).



TEXT-FIGURE 1.—Effect of Sudan III on DMBA (50 mg/kg)-induced CA. In group 1 (●), rats were fed 1 mg of Sudan III 24 hr before DMBA injection. In group 2 (○), rats were fed sesame oil without Sudan III 24 hr before DMBA injection. *Each point* represents the mean ± SD for 6 rats.



TEXT-FIGURE 2.—Suppression of DMBA (50 mg/kg)-induced CA by Sudan III administered various times before DMBA injection. Sudan III was given orally at 1 mg/rat on the day designated (*abscissa*) before DMBA treatment. Chromosome specimens were prepared 18 hr after DMBA injection. *Each point* represents the mean ± SD for 6 rats.



TEXT-FIGURE 3.—Suppression of DMBA (50 mg/kg)-induced CA by various doses of Sudan III. Sudan III was administered orally 24 hr before DMBA injection. Chromosome specimens were prepared 18 hr after DMBA injection. *Each point* represents the mean ± SD for 6 rats.

TABLE 1.—*Suppression of DMBA-induced CA by azo dyes, PCB, and PB*

Compounds[a]	CA, %[b]	Suppression, %[c]	P[d]
None	70.0±9.7	—	
Sudan III	10.7±3.5	85	<0.01
Sudan IV	39.3±4.1	44	<0.01
Sudan I	55.7±6.3	20	<0.05
α-Naphthyl red	63.7±4.1	9	
p-Aminoazobenzene	66.8±3.4	5	
Yellow AB	67.0±6.0	4	
Azobenzene	68.0±9.3	3	
PCB			
Expt 1	27.3±6.2	61	<0.01
Expt 2	10.3±3.9	85	<0.01
PB			
Expt 1	62.3±2.0	11	
Expt 2	35.3±5.0	50	<0.01

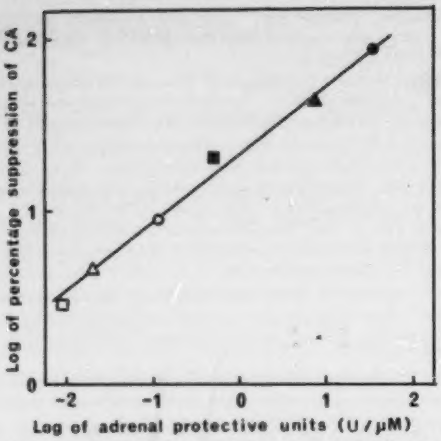
[a] For azo dyes and PCB or PB in expt 1, 56.8 μM/kg body wt was administered by gastric instillation 24 hr before DMBA injection. For PCB or PB in expt 2, administration was that usually used for drug-metabolizing enzymes: For 5 days before DMBA injections, 500 mg PCB/kg body wt was administered ip, and for 1 wk before DMBA injections, 0.1% PB was administered in the animal's drinking water.

[b] Chromosome specimens were prepared and analyzed 18 hr after 50 mg DMBA/kg body wt was injected iv. Values are means ± SD for 6 rats.

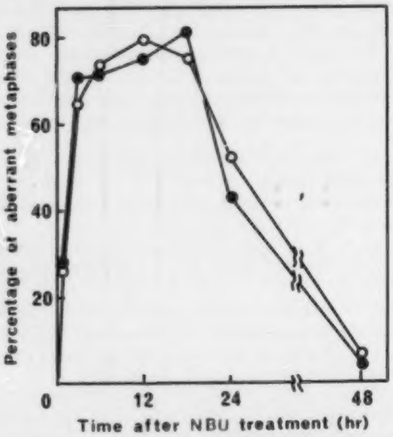
[c] Each value represents mean suppression expressed as maximum incidence of DMBA-induced CA at 18 hr for 6 rats. —=not applicable.

[d] Statistical significance was determined by Student's *t*-test.

Protective action of various azo dyes and enzyme inducers.—The protective action of various azo dyes was tested by percent aberrant metaphases 18 hours after DMBA administration.



TEXT-FIGURE 4.—Relationship between the capacity of various azo dyes to protect DMBA-induced CA and the capacity to prevent DMBA-induced adrenal apoplexy. Data for adrenal apoplexy were cited from the report of Huggins and Pataki (*7*). ●=Sudan III; ▲=Sudan IV; ■=Sudan I; ○=naphthyl red; △=*p*-aminoazobenzene; □=azobenzene.



TEXT-FIGURE 5.—Effect of Sudan III on NBU (200 mg/kg)-induced CA. In group 1 (●), rats were fed 20 mg of Sudan III/kg body wt 24 hr before oral NBU administration. In group 2 (○), rats were fed sesame oil without Sudan III 24 hr before NBU administration. *Each point* represents the mean for 6 rats.

Protection was shown with all compounds tested, although it was statistically significant only with Sudan I, Sudan IV, and Sudan III (table 1). These results paralleled those of Huggins and Pataki (*7*) and showed a clear positive relationship between protection against CA and protection against adrenal apoplexy (text-fig. 4). Two azo dyes, Sudan IV and yellow AB, induced CA in 5% of the metaphase cells at the oral doses used without DMBA, although the percent aberrant cells remained within the normal level (<2%) with other compounds.

PCB and PB given similarly suppressed the incidence of DMBA-induced aberrant metaphase cells by 61 and 11%, respectively. PCB and PB suppressed aberrant metaphase cells by 85 and 50%, respectively, when they were given in a manner usually used for induction of hepatic microsome enzymes (*11*, *12*).

Effect of Sudan III on NBU-induced CA.—NBU also induced elevations of CA which lasted for 3–24 hours. However, Sudan III pretreatment did not suppress the incidence of NBU-induced CA (text-fig. 5).

DISCUSSION

The present studies indicated that rats fed 1 mg of Sudan III as a single dose before they were DMBA treated showed manifestly suppressed DMBA-induced CA in their bone marrow cells. DMBA-induced CA consisted mainly of gaps and breaks. Exchanges were observed infrequently (<1%). Gaps, breaks, exchanges, and multiple CA were suppressed as well by Sudan III pretreatment.The most efficient inhibitory effect of Sudan III was shown when it was given at 24 hours before DMBA treatment. The maximum inhibition was obtained above the dose of 10 mg Sudan III/kg body weight. Huggins and Pataki (*7*) and Huggins et al. (*8*) have shown inhibition of PAH-induced mammary cancer [10/10=100% inhibited to 4/10=40% (*7*)] and leukemia [13/14=93% inhibited to 3/15=20% (*8*)] by Sudan III pretreatment. Therefore, the present results are consistent with these results reported by Huggins and his co-workers.

CA are generally considered to be lethal to cells. Therefore, the present results essentially indicate that Sudan III pretreatment suppresses the fatal toxicity of DMBA to cells. However, the positive correlations among CA, mutagenicity, and carcinogenicity as well as between DNA repair and CA have been widely recognized. Therefore, we consider that the number of viable cells with subtle genetic changes might be increased in proportion to the increase of aberrant cells induced by chemical carcinogens.

Among the azo dyes investigated, Sudan III was the most efficient in protecting cells against DMBA-induced CA. The capacity of various Sudan III-related dyes to protect against DMBA-induced CA paralleled the capacity of the azo dyes to prevent DMBA-induced adrenal apoplexy. In protecting the cells against the effects of DMBA, the size, geometry, and solubility of the Sudan dyes are important (*7*). Adrenal apoplexy is a phenomenon specific to DMBA, TMBA, and the related PAH (*7*). Therefore, the present system provides another useful screen for the identification of compounds that suppress carcinogenesis.

PAH carcinogens such as DMBA and TMBA require metabolic activation by mixed function oxidases contained in microsomes of mammalian cells (*13–15*). PAH carcinogens are metabolized into compounds such as phenols, dihydrodiols, quinones, and epoxides (*16–18*). Recent studies (*19*) indicate that a major ultimate form of DMBA is a bay region diol-epoxide (DMBA-*trans*-3,4-diol-1,2-epoxide). Metabolic formation of the diol-epoxide is believed to proceed by a sequence involving epoxidation with mixed function oxidases, hydration with epoxide hydrase, and further epoxidation. Moschel et al. (*20*) also reported that reaction with DNA occurred through formation of diol-oxide in the 1,2,3,4-ring of DMBA. Another possibility of metabolic activation of DMBA may be that the methyl group on the benzene ring is hydroxylated by mixed function oxidases and that an active carbonium ion which is formed alkylates DNA or other biopolymers (*18*, *21*). Analogous to *N*-nitroso-

N-methylurea metabolism (*22–24*), however, NBU is converted into nitrosobutylamine nonenzymatically, and the product is converted rapidly through butyldiazohydroxide to the butylcarbonium ion. This reaction proceeds chemically and does not require drug-metabolizing enzymes.

Huggins and Pataki (*7*), Huggins et al. (*8*), and Huggins and Fukunishi (*25*) have shown induction of NAD(P)H dehydrogenase (quinone) after Sudan III pretreatment. PCB and PB are used to induce drug-metabolizing enzymes (*26–28*). Our results also showed suppression of DMBA-induced CA after the PCB and PB treatment. Inasmuch as NBU-induced CA were not influenced by Sudan III, the present results are consistent with the view that Sudan III pretreatment induces drug-metabolizing enzymes which detoxify carcinogens subsequently introduced.

Growth of Mouse Mammary Glands After Neonatal Sex Hormone Treatment [1,2,3]

Yasuhiro Tomooka [4] *and* **Howard A. Bern** [4,5,6]

ABSTRACT—Mammary gland growth was examined in female mice immediately and during 1 month after neonatal treatment with sex hormones. BALB/c mice were given daily injections of hormones for the first 5 days after birth. As a criterion of growth, the number of ductal branchings was counted in stained wholemounts of the fourth (inguinal) pair of glands. At day 6, the growth of the glands was significantly inhibited in animals treated with 17β-estradiol (E) or diethylstilbestrol (DES); after treatment with progesterone (P) or androgens no immediate effect was evident. At day 33, neonatal treatment with E stimulated growth, as did neonatal treatment with testosterone (T) or 5α-dihydrotestosterone (5α-DHT); treatment with a high dose of DES inhibited growth. Treatment with P or 5β-dihydrotestosterone had no effect. In conclusion, neonatal treatment with sex hormones has two distinct effects on the growth of mouse mammary gland: 1) inhibition by estrogens, observed immediately after treatment, and 2) stimulation by E, T, and 5α-DHT, observed 4 weeks after treatment.—JNCI 1982; 69:1347–1352.

Neonatal injections of sex hormones are known to cause a permanent functional change in the hypothalamus of female rats and mice resulting in an "anovulatory syndrome." Ovaries of these animals produce continuously low levels of estrogen, which induce persistent vaginal cornification. The vaginal and cervical epithelia of these animals develop hyperplastic areas and downgrowths into the stroma (*1*). The persistent vaginal cornification is abolished by ovariectomy of mice given low doses of sex hormones neonatally. If large amounts of hormones are injected into neonatal mice, irreversible changes may occur in the cervicovaginal epithelium, which persistently cornifies even after ovariectomy. The cervicovaginal epithelium of these ovariectomized animals also shows hyperplastic areas and downgrowths into the stroma and occasionally develops tumors (*2*).

Mori (*3, 4*) first reported a higher incidence of mammary tumors among mice neonatally exposed to estrogens. Subsequent studies in our laboratory show that neonatal exposure to various sex hormones enhanced tumorigenesis in the mammary glands of mice with expressed MTV and enhanced lobuloalveolar development generally, whether MTV was expressed or not (*5*).

Little information is available regarding immediate mammary gland responses to neonatal sex hormone exposure. Warner (*6*) found that mammary growth was stimulated at 5 weeks of age in mice given high doses of estrogen neonatally. In the present report, growth responses of mammary glands are followed quantitatively during the 1st month after neonatal exposure to various sex hormones.

MATERIALS AND METHODS

BALB/cCrgl female mice were used. From the day of birth (day 1), litter size was kept between 4 and 6 pups per mother by addition, if needed, of male pups born on the same day. Animals were given sc injections of hormones (text-fig. 1; tables 1, 2) dissolved in sesame oil for 5 consecutive days, starting within 24 hours after birth. Control animals were either given injections of oil vehicle or left untreated. In series I, groups of animals were autopsied weekly for 4 weeks beginning on day 6. In series II, animals were autopsied on day 6 and day 33. In series III, animals were autopsied on day 33. The mammary glands were fixed in 10% Formalin and stained as wholemounts with iron-hematoxylin. The numbers of mammary ductal branchings in the fourth inguinal pair of mammary glands were counted under a dissecting microscope (*6, 7*). Statistical analysis was performed with the use of Dunnett's two-sided multiple comparisons test.

RESULTS

Series I.—In this experiment the effect of the major natural sex steroids was examined. On day 1, mammary glands showed a rudimentary ductal system, and a mean of 42.8±6.7 (8 animals) ductal branchings was counted. In the control group the number of ductal branchings almost doubled by day 6 but remained constant for the following 3 weeks. The number of ductal branchings then doubled again between day 26 and day 33 (text-fig. 1).

Administration of 5 μg E for 5 days significantly inhibited the increase of ductal branchings from day 1 to day 6. This inhibitory effect was more prominent in animals treated with 20 μg E (figs. 1, 2). The number of ductal branchings in the group given 5 μg E remained constant for the following 3 weeks. In the group given 20 μg E, the number of ductal branchings increased slightly, but not significantly, on day 19 and day 26. However, the number of ductal branchings almost tripled by day 33 in the group given 5

TEXT-FIGURE 1.—Mammary gland responses of female BALB/c mice to neonatal sex hormone exposure—series I. Animals were treated with 5 μg E (5E), 20 μg E (20E), 20 μg T, 100 μg P, or oil vehicle as control (C) for 5 consecutive days, starting within 24 hr after birth. Eight animals were autopsied without treatment on day 1 (the day of birth). Number of ductal branchings was counted as described in "Materials and Methods." *Vertical bar* indicates SEM. *Figure above the bar* is the number of animals in each group. * $P<0.05$ and ** $P<0.01$ (different from oil-treated control by Dunnett's two-sided multiple comparisons test).

μg E and in the group given 20 μg E (text-fig. 1; figs. 3, 4). In contrast to both treatments with E, treatment with 20 μg T did not affect branching when glands were examined on day 6; however, this treatment induced a precocious increase in branching by day 26, which on day 33 was also significantly higher than that seen in the control group. The group treated with 100 μg P did not differ significantly from controls from day 6 to day 33.

Series II.—In this experiment the effects of additional sex hormones and doses were examined on the two critical days for inhibition (day 6) and stimulation (day 33) (table 1).

Again, an inhibitory effect with both doses of E by day 6 was observed. Both doses of DES also had an inhibitory effect. Neither the androgens nor P significantly affected the number of ductal branchings at this age. The stimulatory effect observed on day 33 in series I was also observed in animals treated with 20 μg T and 20 μg 5α-DHT; the increased branching in groups treated with 5 and 20 μg E, 5 μg T, and 10^{-1} μg DES was not statistically significant from that seen in controls. The number of ductal branchings in the groups treated with 2 μg DES and 100 μg P was not significantly lower than that in the controls. 5β-DHT at 20 μg had no effect on the number of ductal branchings on either day 6 or day 33.

Series III.—This experiment was done to reexamine the effects of hormones giving differing results at day 33 in series I and II. Table 2 shows the stimulatory effect of T and E on the number of ductal branchings. DES at 2 μg significantly lowered the number of ductal branchings, indicating a sustained inhibitory effect. P at 100 μg had no effect.

DISCUSSION

During the first 3 weeks of postnatal life, there is little change in the gross morphology of the mammary glands in the mouse; the glands normally begin to increase in size by the beginning of the 4th week (*8*). The number of branchings in the ductal system remains almost constant from day 7 to day 21, and then there is a rapid increase in area and ductal junctions of the glands around day 24 (*7*). Text-figure 1 indicates that the pattern of growth in our control animals is similar to that reported earlier.

E and DES consistently inhibited growth of the mammary glands immediately after the completion of the 5-day neonatal treatment. Androgens (T, 5α-DHT, and 5β-DHT) and P had no immediate inhibitory effect on the glands, indicating that this effect seems to be specific to estrogenic hormones. Higher doses of E and DES resulted in more prominent inhibition. This immediate inhibitory effect of neonatal estrogenic hormone treatment has not been previously reported, although high doses of estrogen administered to pregnant mice inhibited mammary growth when offspring were examined on day 35 (*9*). The glands recovered by day 80. In the present study, treatment of newborn mice with 2 μg DES daily resulted in significantly less ductal branching at day 33 than seen in control animals (table 2); however, mammary glands treated with 20 μg E recovered from the initial inhibition and showed more ductal branching at day 33 (text-fig. 1).

The mechanism involved in the immediate inhibitory effect of estrogenic hormones on mammary growth is unknown. Prenatal exposure of rats to DES during midpregnancy inhibits DNA and RNA syntheses by mammary ductal epithelium at 5 days of age (*10*). Direct responses to neonatal sex hormone treatment occur in mouse cervicovaginal epithelium (*2, 11*), resulting in irreversible and permanent changes. The growth of neonatally steroid-exposed mammary glands was indistinguishable from that of host glands after their transplantation into cleared host fat pads immediately after completion of treatment (*12*). This observation and that of Jean (*9*), in addition to findings from our studies, indicate that the glands may recover from the immediate inhibitory effect of estrogens in later life. However, if the treatment is intense enough, recovery may not occur. In series III the number of ductal branchings in the group given 2 μg DES was significantly less than that in controls. Neonatal treatments with higher doses of DES (5 or 20 μg) for 5 days after birth resulted in atrophic mammary glands in mice when examined at 7 and 15 months of age (Bern HA, Kohrman AF, Mills KT, Louie JK: Unpublished observations). The inhibitory effect of DES may arise from its estrogenic potency (toxicity?) owing to absence of binding to α-fetoprotein, which is known to bind E specifically (*13*); it is not known whether DES or its metabolites influence mammary growth by an effect other than that consequent to their estrogenicity.

Neonatal estrogen and androgen exposure resulted in another effect on the mammary glands, evident when they were examined at around day 30. At this time ductal branching increased sharply in animals neonatally treated with E, T, and 5α-DHT. This delayed response does not seem to be a long-lasting effect of neonatally administered hormones because the number of ductal branchings remained almost constant for the preceding 3 weeks. Rather, the changes appear to be mediated by the hypothalamo–hypophysio–ovarian axis. This neuroendocrine pathway is known to be permanently altered by neonatal treatment of mice with E (*14–16*), T (*14, 16*), P (*15*), and presumably the nonaromatizable androgen 5α-DHT (*17*). Precocious activation of the hypothalamo–hypophysio–ovarian axis by neonatal sex hormone exposure would accelerate and enhance the growth of mammary glands. Neonatally sex hormone-exposed mice (*18*) and rats (*19–22*) show precocious vaginal opening, indicating that ovaries functionally secrete estrogen which might stimulate the secretion of prolactin from the pituitary gland. In the mouse prolactin levels in plasma increase toward the time of puberty (*23, 24*). The number of prolactin cells significantly increases in mice treated neonatally with steroids (*25*), and blood prolactin levels may be higher than those in control mice (*16, 26*), at least at some stages in some strains.

Warner (*6*) reported that only doses over 25 μg E stimulated growth of mammary glands in BALB/c mice examined at 5 weeks of age. In the same mouse strain under the same experimental conditions, we found that 20 μg E consistently showed a stimulatory effect; even 5 μg E resulted in significant stimulation in two of three sets of our experimental series.

P (*15*) and 5β-DHT (*27*) reportedly alter the development of the hypothalamus, resulting in a higher incidence of mouse mammary tumors in MTV-expressed strains of mice. In our experiments, neither P nor 5β-DHT had an effect on ductal branching from day 6 to day 33. Possibly, the altered hypothalamus exerts its influence in mice only at later ages after these steroid treatments.

Because of variation in some of the results obtained on day 33 from the three series of experiments, statistical analysis (multiple comparison test of Duncan) was performed on combined results in the following groups: 5 μg E (series I–III), 20 μg E (series I, II), 5 μg T (series II, III), 100 μg P (series I–III), 2 μg DES (series II, III), and control (series I–III). The number of ductal branchings was significantly higher ($P<0.01$) in the groups treated with 5 μg E, 20 μg E, and 5 μg T than in the controls, but significantly lower ($P<0.01$) in the group treated with 2 μg DES. There was no significant difference in the number of ductal branchings in the groups given 100 μg P from that in the control groups.

Our experiments have demonstrated that mammary growth is inhibited after E or DES exposure immediately after cessation of neonatal treatment and that mammary growth accelerates around 30 days of age in animals treated neonatally with E, T, and 5α-DHT. Warner and associates (*28–30*) have shown increases in growth, hormone responsiveness, and casein mRNA levels in mammary explants from mice 34–39 days old that had been neonatally treated with estrogen and primed in vivo with steroids at 4 weeks of age. A relationship between these early stimulatory effects mediated by the hypothalamo–hypophysio–ovarian axis and later mammary tumorigenesis has yet to be established. However, if, as it appears, the hypothalamic change involves increased mammary gland exposure to endogenous prolactin (increased levels and/or continuous secretion), the increased tumorigenesis that occurs in MTV-expressed mice as a consequence of neonatal sex hormone exposure (*14*) becomes explicable.

Effects of Nicotinamide, Isonicotinamide, and Bleomycin on DNA Synthesis and Repair in Rat Hepatocytes and Hepatoma Cells[1,2,3]

Rosemary Barra,[4,5] **Verrell Randolph,**[6] **MariaElaina Sumas,**[4] **Kevin Lanighan,**[4] *and* **Michael A. Lea**[6]

ABSTRACT—Because inhibitors of poly (ADP-ribose) synthetase have been found to influence DNA synthesis in some systems, the possibility that nicotinamide or isonicotinamide might potentiate the effect of bleomycin on DNA replication and repair was examined. After a 30-minute incubation with bleomycin (200 μg/ml), tritiated thymidine ([^{3}H]dThd) incorporation into DNA was stimulated during a subsequent 30-minute incubation with hepatocytes of inbred BUF rats but was decreased in HTC cells of BUF rats. When unscheduled DNA synthesis was measured in the presence of 10 m*M* hydroxyurea, bleomycin (200 μg/ml) increased [^{3}H]dThd incorporation in both cell types. A dose of 20 m*M* nicotinamide and isonicotinamide caused an approximately 50% inhibition of total [^{3}H]dThd incorporation in HTC cells. Significant inhibitory effects of 20 m*M* nicotinamide and isonicotinamide on unscheduled DNA synthesis were observed after preincubation of hepatocytes and HTC cells with bleomycin. When the effects of bleomycin on DNA structure were assessed fluorometrically with ethidium bromide after mild alkaline incubation, nicotinamide and isonicotinamide did not significantly affect the damage revealed with bleomycin alone. When HTC cells were incubated for 48 hours with bleomycin (20 μg/ml), the increase in cell numbers was about 50% of that in control cultures. Nicotinamide and isonicotinamide also inhibited the proliferation of HTC cells, but the effects were not additive with the effect of bleomycin.—JNCI 1982; 69:1353–1357.

The poly (ADP-ribosylation) of nuclear proteins has been correlated with diverse aspects of the regulation of macromolecular synthesis (*1*, *2*). In some systems poly (ADP-ribose) synthetase activity appears related to changes in the rate of DNA replication (*3–5*) or repair (*6–9*). Although there are many conflicting observations on the relationship between poly (ADP-ribose) synthetase and DNA synthesis (*2*, *10*, *11*), there have been several reports that the activity of poly (ADP-ribose) synthetase can be increased by agents that damage DNA (*6*, *12*, *13*). There is evidence that the magnitude and regulation of poly (ADP-ribose) synthetase activity differ in rat liver and hepatomas (*14–18*). While semiconservative DNA replication is generally enhanced in hepatomas relative to that in normal livers, the capacity for DNA repair may be diminished (*17*, *19*). Nduka and coworkers (*20*) observed enhanced cytotoxicity for L1210 cells with DNA-damaging agents in the presence of inhibitors of poly (ADP-ribose) synthetase. In the present work we have examined the influence of nicotinamide and isonicotinamide, two inhibitors of poly (ADP-ribose) synthetase, on DNA synthesis in hepatocytes and hepatoma cells. The response of cells to DNA damage was determined after exposure to bleomycin and was followed by measurement of cellular proliferation, the incorporation of [^{3}H]dThd into DNA, and the integrity of DNA as judged by fluorescent dye binding. The objective of this study was to determine if the effects of bleomycin on DNA could be enhanced by nicotinamide or isonicotinamide. A preliminary communication of the work has been presented (*21*).

MATERIALS AND METHODS

Cells.—Hepatomas were maintained as subcutaneous transplants in BUF strain rats. Hepatocytes were isolated from the livers of control rats of the same strain. The hepatocytes and hepatoma cells were isolated by collagenese digestion as previously described (*22*).

Chemicals and isotopes.—Bleomycin was donated by Bristol Laboratories Inc., Syracuse, N.Y. Materials for tissue culture media were obtained from Grand Island Biological Co., Grand Island, N.Y. ICN Pharmaceuticals Inc., Irvine, Calif., was the source of [*methyl*-^{3}H]dThd (70 Ci mmol^{-1}).

Assay conditions for [^{3}H]dThd incorporation.—Incubations for [^{3}H]dThd incorporation into DNA were performed in a volume of 0.8 ml EMEM at 37°C. The incubation was terminated by the addition of 1.2 ml 16.7% TCA and 8.35% sodium pyrophosphate. Following centrifugation at 800×*g* for 10 minutes, the pellet was washed three times with 4 ml 10% TCA and 5% sodium pyrophosphate. The pellet was dissolved in 1 ml 0.33 *N* KOH and incubated at 37°C for 45 minutes. The tubes were cooled, and additions were made of 0.3 ml 1 *N* HCl and 1.3 ml 20% TCA and 10% sodium pyrophosphate. After centrifugation at 800×*g* for 10 minutes, the pellet was washed with 4 ml 10% TCA and 5% sodium pyrophosphate. DNA was extracted from the pellet in 1.5 ml 5% TCA at 90°C for 20 minutes. Radioactivity was measured by liquid scintillation counting in a system with a counting efficiency of 30–32% for ^{3}H.

Fluorometric analysis of DNA unwinding.—The procedure for fluorometric analysis of DNA unwinding was essentially as described by Birnboim and Jevcak (*23*) using the fluorescence given by ethidium bromide in the presence of double-stranded DNA. The conditions for alkaline incubation of cell lysates were such that there was minimal unwinding of DNA from control cells but there was a readily measurable increase of unwinding in DNA with strand breaks. Preceding

this assay, 6.5×10^6 cells were incubated at 37°C for 30 minutes in 3 ml EMEM or EMEM containing the drugs under study. The cells were centrifuged at $50\times g$ for 3 minutes. The supernatant was discarded, and the cells were suspended in 5 ml 0.87% NH_4Cl and 10 m*M* Tris-HCl (pH 7.2). After being held on ice for 20 minutes the cells were centrifuged at $50\times g$ for 3 minutes and washed with 5 ml 0.87% NH_4Cl and 10 m*M* Tris-HCl (pH 7.2). The pellet was suspended in 1.3 ml 0.25 *M meso*-inositol, 10 m*M* sodium phosphate, and 1 m*M* $MgCl_2$ (pH 7.2). Aliquots of this suspension (0.2 ml) were distributed to six disposable glass tubes designated in duplicate as T, P, or B. The remaining procedures were exactly as described by Birnboim and Jevcak (*23*) except that the P- and B-tubes were not subjected to incubation at 15°C because the effects of bleomycin were of sufficient magnitude to be detected during alkaline incubation on ice. In this procedure the DNA in the T-tubes is not exposed to a sufficiently high pH to cause unwinding as is the case in the P- and B-tubes. In addition to a pH of 12.8 in the P- and B-tubes, the DNA in the B-tubes is subject to sonication to ensure complete denaturation. We have used the relationship of fluorescence readings $(P-B) \div (T-B) \times 100$ to describe the percent double-stranded DNA remaining after alkaline incubation as suggested by Birnboim and Jevcak (*23*). In addition, we have found that treatment of cells with bleomycin could significantly decrease fluorescence in the T-tubes. In "Results" we have presented the relationship of fluorescence readings $(T-B)$ experimental $\div$ $(T-B)$ control $\times$ 100 as the apparent double-stranded DNA expressed as a percent of control incubations.

Effects on cell proliferation.—HTC cells grown in monolayer cultures in Swim's 67 medium containing 10% calf serum were harvested and resuspended in 5.0 ml medium. Triplicate flasks were prepared for each experimental condition containing 1×10^5 cells in a total volume of 10 ml Swim's 67 medium. The flasks were incubated at 37°C for 48 hours. After washing the monolayer with a 0.9% NaCl solution, we harvested the cells and determined the total cell number by using a Royco cell counter.

Expression and evaluation of results.—Data are presented as means ± SE. The results were subjected to statistical evaluation by the *t*-test, which was a paired test where appropriate. Differences between means giving $P<0.05$ were considered to be significant.

RESULTS

In a preliminary experiment in which the incorporation of [^{3}H]dThd into DNA of HTC cells was determined in a 60-minute incubation, it was found that the incorporation was decreased in the presence of 10 m*M* nicotinamide or 10 m*M* benzamide to 55 and 50%, respectively, of control values. When the concentration of these two inhibitors of poly (ADP-ribose) synthetase was increased to 20 m*M*, the incorporation was 42% of control values in the presence of nicotinamide and 38% of control values with benzamide (data not shown). To determine if compounds of this type have effects on DNA replication and repair synthesis in normal and neoplastic hepatic cells, we also examined the incorporation of [^{3}H]dThd into DNA in hepatocytes and HTC cells which had been preincubated with bleomycin and then washed and suspended in fresh medium (table 1). The incorporations for control hepatocytes and HTC cells were 669±133 and 22,624±6,091 cpm per 2×10^5 cells, respectively. Incubation with bleomycin (200 mg/ml) stimu-

lated the incorporation in HTC cells. The data in table 1 revealed a statistically significant inhibition of [^{3}H]dThd incorporation in hepatocytes when incubated with 20 m*M* nicotinamide or 2 and 20 m*M* isonicotinamide. In HTC cells the incorporation of [^{3}H]dThd was significantly inhibited by 2 m*M* nicotinamide and 20 m*M* isonicotinamide. When cells were incubated with 10 m*M* hydroxyurea to inhibit preferentially the replicative synthesis of DNA, it was found that bleomycin caused a greater response in DNA repair synthesis in hepatocytes than in the hepatoma cells. A paired analysis of cells preincubated with bleomycin and incubated with 10 m*M* hydroxyurea indicated that 20 m*M* nicotinamide and 20 m*M* isonicotinamide inhibited [^{3}H]-dThd incorporation into DNA of both hepatocytes and HTC cells.

Incubations similar to those described in table 1 were performed in which bleomycin was retained with the cells during the incubation with [^{3}H]dThd. Under these conditions, in the presence of 10 m*M* hydroxyurea, incubation with bleomycin (200 μg/ml) stimulated the mean incorporation of [^{3}H]dThd in hepatocytes and HTC cells to 427 and 257%, respectively, of values obtained with hydroxyurea alone (data not shown). With this experimental protocol, nicotinamide and isonicotinamide at 2 and 20 m*M* did not have a statistically significant effect on the stimulation of incorporation caused by bleomycin in the two cell types. There was also no significant effect in an additional experimental protocol which differed from that described in table 1 in that [^{3}H]dThd was not added until the end of the second 30-minute incubation and incorporation was measured in HTC cells over a subsequent 4-hour period (data not shown).

Evidence for damage of DNA by incubation of cells with bleomycin was obtained by the change of fluorescence with ethidium bromide which is dependent on the double-stranded character of the DNA (table 2). This could be seen for hepatocytes and hepatoma cells both in the initial fluorescence and in the more rapid decrease in fluorescence after an alkaline incubation, where the unwinding of strands would be facilitated by strand breaks. Incubation with 20 m*M* nicotinamide did not have a significant effect on fluorescence and, when present together with bleomycin, had little or no effect beyond that seen with bleomycin alone. In another series of experiments presented in table 3, these conclusions were further supported by additional HTC cell preparations, and it was found that 20 m*M* isonicotinamide did not significantly affect DNA structure as judged by the fluorometric analysis. When HTC cells were examined 30 minutes after a preincubation with bleomycin (procedure 2 in table 3), there was an indication of a limited degree of recovery from the effects of the bleomycin but very little, if any, effect of incubation with 20 m*M* nicotinamide or 20 m*M* isonicotinamide.

Longer term studies on the effects of bleomycin were performed with a concentration of 20 μg/ml, which caused an approximately 50% inhibition of the proliferation of HTC cells over a 48-hour period (table 4). In the studies with nicotinamide, the number of cells in control cultures increased from 1×10^5 to $4.05\pm0.09\times10^5$ after 48 hours. The proliferation of HTC cells was significantly inhibited in the presence of 20 m*M* nicotinamide and at all isonicotinamide concentrations examined (2–20 m*M*). Neither nicotinamide nor isonicotinamide caused a significant inhibition of cell proliferation beyond that seen with bleomycin alone.

TABLE 4.—*Effects of bleomycin, nicotinamide, and isonicotinamide on proliferation of HTC cells*[a]

[a] The increase in cell number after a 48-hr incubation was determined as described in "Materials and Methods." Data represent the means of three experiments with triplicate incubations for each experiment and are presented as percentages of the increase in numbers in control cultures. Experiments with nicotinamide and isonicotinamide were done at different times with their own control incubations in the absence and presence of bleomycin.

[b] Means ± SE.

DISCUSSION

Subcellular distribution studies of mono and poly (ADP-ribosyl) proteins in rat liver indicate that the latter are mainly confined to the nucleus (*24*). The activity of poly (ADP-ribose) synthetase is inhibited by nicotinamide, but nicotinamide is also a precursor for the substrate of this enzyme, NAD. Diminished concentrations of NAD have long been recognized as a frequent finding in neoplastic tissues (*25*). Isonicotinamide does not serve as a precursor for NAD synthesis, and the interpretation of its action may be simpler than for nicotinamide. However, it is probable that there is no inhibitor of poly (ADP-ribose) synthetase with absolute specificity (*26*).

In the present work nicotinamide and isonicotinamide inhibited cell proliferation and the incorporation of [^{3}H]-dThd into DNA of hepatoma cells. This inhibition was also seen for the action of nicotinamide on mouse L-cells in the work of Colyer et al. (*3*). However, another inhibitor of poly (ADP-ribose) synthetase, i.e., 5-methylnicotinamide, was shown to be capable of inhibiting division in HeLa cells under conditions in which DNA synthesis was not affected (*27*). Some of the effects of nicotinamide may be remote from nucleic acid synthesis. For example, nicotinamide was found to cause a large stimulation of glycolysis in homogenates of rat liver but not in homogenates of Morris hepatoma 7777 (*28*).

Bleomycin is believed to influence DNA synthesis primarily by strand scission of the DNA template, but there may be some direct inhibition of DNA polymerase α (*29*). Differences in cell sensitivity to bleomycin may arise not only from differences in the activity of repair enzymes but also from differences in cell membrane permeability and the rate of inactivation of bleomycin (*30*). Because there is little semiconservative DNA replication in hepatocytes, the action of bleomycin in stimulating unscheduled DNA synthesis was more apparent than in hepatoma cells. It was necessary to inhibit DNA replication with hydroxyurea before a stimulation of unscheduled DNA synthesis could be detected in the hepatoma cells. The incorporation of [^{3}H]dThd into DNA in the presence of hydroxyurea may give an estimate of unscheduled DNA which is influenced by the hydroxyurea itself (*31*). One must, therefore, interpret with some caution the relative rates in the hepatocytes and hepatoma cells.

Much evidence suggests a role for poly (ADP-ribosylation) of nuclear proteins in DNA repair with a possible involvement in the activity of an endonuclease (*32, 33*) or in changing chromatin structure (*2, 34*). This hypothesis must be reconciled with observations that nicotinamide can, under some circumstances, stimulate unscheduled DNA synthesis (*17, 35–37*). Miwa et al. (*37*) thought it conceivable that when poly (ADP-ribose) synthesis is inhibited, unscheduled DNA synthesis does not stop at the correct point but continues, resulting in a longer chain of DNA displacing the parental strand. Durkacz et al. (*38*) have suggested that poly (ADP-ribose) may covalently modify protein(s) involved in the process leading to re-ligation. An action on DNA ligation would be expected to influence DNA replication and repair. It appears that other sites must also be involved because inhibitors of poly (ADP-ribose) synthetase have caused greater inhibition of DNA repair after DNA damage by alkylation than after strand scission resulting from ionizing radiation (*38*). In addition, Nolan and Kidwell (*34*) have concluded from their studies on *Drosophila* that repair of DNA strand breaks caused by ionizing radiation is independent of poly (ADP-ribose) synthesis. In our work we have seen some small inhibitory effects on unscheduled DNA synthesis caused by nicotinamide and isonicotinamide but have obtained no evidence for an inhibitory effect on strand rejoining after incubation of hepatocytes and hepatoma cells with bleomycin. It appears, therefore, that the effects on DNA repair of inhibitors of poly (ADP-ribose) synthetase after DNA damage by bleomycin were small or insignificant. This finding is similar to results obtained from previous studies using ionizing radiation (*4, 34, 38*) and may be a common feature of agents that act directly to cause DNA strand breaks.

Inhibitors of poly (ADP-ribose) synthetase activity have been reported to enhance the cytotoxicity of alkylating agents (*20*), and Smulson et al. (*39*) observed that nicotinamide increased the enhancement of survival times of mice bearing L1210 cells that were treated with *N*-methy-*N*-nitrosourea. There was only a small enhancement of the toxicity to L1210 cells of γ-radiation by inhibitors of poly (ADP-ribose) synthetase (*20*). Our studies have revealed no enhancement of the toxicity of bleomycin as judged by its effects on the proliferation of HTC cells. It is possible that inhibitors of poly (ADP-ribose) synthetase will be more effective in increasing toxicity of DNA alkylating agents than of agents that cause DNA strand scission. The present results revealed that nicotinamide and isonicotinamide can inhibit DNA synthesis in normal and neoplastic liver cells, but these compounds appeared to have limited potential for affecting the action of bleomycin.

Tumor-Associated Antigens Produced by Mouse Mammary Tumor Cells in Artificial Capillary Culture [1,2,3]

Jean C. Hager,[4] S. Spiegelman,[5] M. Ramanarayanan,[5] James Bausch,[5] Pierre M. Galletti,[6] *and* Paul Calabresi[7,8]

ABSTRACT—Mouse mammary tumor cells were cultured on a three-dimensional bundle of semipermeable hollow fibers as a prototype system for large-scale in vitro production of mammary tumor-associated antigens. Cells were seeded onto the surface of the hollow fibers that served as an artificial capillary network. The cells grew to tissue-like densities within 3 weeks, achieving the high density and three-dimensional intercellular relationships known to potentiate expression of murine mammary tumor virus (MuMTV) antigens. Significant levels of a 52,000-relative-molecular-weight (M_r) glycoprotein antigen of MuMTV (gp52) were detected on the cell side of the semipermeable membrane of the hollow fibers in a yield at least fiftyfold greater than that produced by monolayer cultures. Antigen could be collected from capillary cultures for 6–12 weeks, rather than days from monolayer cultures. Further, gp52 was collected in an undegraded state. Perfusates contained lesser amounts of cross-reactive antigenic species that were predominantly smaller than 50,000 M_r, which suggests that the fibers may be used to separate antigens from their degradation products. The production of nonviral, mammary tumor-associated antigens by cells on artificial capillaries was also demonstrated. Artificial capillary cell culture systems provide a means to obtain significant quantities of tumor-relevant antigens in a semipurified natural state.—JNCI 1982; 69:1359–1366.

The wide variation in reproducibility reported for many cancer-associated immunologic tests (*1*) may well be due to lack of standardization of the immunologic reagents with respect to both potency and specificity. A major deterrent to overcoming these obstacles has been the difficulty in preparing large quantities of standardized reagents in an unaltered state.

The development of the artificial capillary cell culture technique (*2–6*) may provide a solution to this problem. This technique permits in vitro culture of cells on bundles of parallel hollow fibers (artificial capillaries) resulting in growth of the cells in a dense, tissue-like, three-dimensional configuration. The cells are maintained in a physiologic microenvironment (*2–6*). Studies on tumor-associated antigens such as those of MuMTV indicate that antigen production is strongly favored in three-dimensional relative to monolayer culture (*7–9*). It has also been shown that antigen production is enhanced in high-cell-density cultures (*10–12*). We report here an evaluation of the growth of mammary tumor cells on artificial capillaries for the purpose of producing tumor-related antigens in large quantities and in an undegraded form.

MATERIALS AND METHODS

Cells and monolayer culture.—Cell lines 66, 67, 168, and 68H were isolated from a single spontaneous BALB/cfC3H mouse mammary tumor (*13*) and have been maintained in our laboratories for over 3 years. More than 95% of line 68H cells express MuMTV cell surface antigens detectable by immunofluorescence with the use of a rabbit anti-C3H MuMTV, whereas lines 66, 67, and 168 do not (*13*). Lines 66, 67, and 168 can be induced by 5-iodo-2′-deoxyuridine or 10^{-5} *M* dexamethasone to express viral antigens (*14, 15*). We used as specificity controls in transplantation resistance assays a Moloney sarcoma cell line obtained from Dr. Sylvia Pollack, Fred Hutchinson Cancer Research Center, Seattle, Wash.

Cells were routinely grown in Falcon tissue culture dishes (Falcon Plastics, Oxnard, Calif.) in Waymouth's medium supplemented with 15% heat-inactivated FCS, 2 m*M* L-glutamine, and 20 μg gentamicin/ml (Schering Diagnostics, Port Reading, N.J.) or 100 U penicillin/ml and 100 μg streptomycin/ml and buffered with $NaHCO_3$. Unless otherwise stated, all culture reagents were purchased from

[8] We thank Dr. Roger Hu and Dr. K. Prasad for some of the radioimmunoassays, Dr. I. Keydar and Dr. R. Mesa-Tejada for the immunoperoxidase immunohistochemical staining, Dr. Lowell Kopp for lactate dehydrogenase assays, Dr. L. Roi for statistical analyses, Dr. Barry Solomon for providing Amicon hollow fibers and encouragement, Mr. George Panol for fabrication of the capillary devices, Mr. S. Chester for assistance with the immunogenicity studies, and Dr. I. Diamond for making available the facilities of the Department of Pathology, Roger Williams General Hospital. Excellent technical assistance was provided by Ms. Kim Amoruso McCarthy, Ms. Betsy Vokac, and Ms. Irene Fong. We are grateful to Dr. Gloria Heppner and Dr. Philip Furmanski for their encouragement and many helpful discussions.

GIBCO, Grand Island, N.Y. For routine subculture, cells from monolayers were harvested with 0.125% trypsin and 0.05% EDTA in 0.9% NaCl solution, centrifuged for 5 minutes at $400\times g$, resuspended in Waymouth's medium, and plated in Falcon culture dishes. All cultures were kept at 37°C in a humidified atmosphere of 5% CO_2 in air.

Artificial capillary cell culture.—Artificial capillary cell culture systems were based on those originally described by Knazek et al. (*2–6*) and are schematically presented in text-figure 1. Capillary culture units either were vitafiber units (Amicon Corp., Lexington, Mass.) or were manufactured in the Artificial Organ Laboratory, Brown University. The capillary units consisted of a bundle of 100 microporous hollow fibers (Amicon Corp.), 11 cm long, potted in epoxy at each end, and encased in a polycarbonate shell equipped with shell ports. Vitafiber units (Amicon Corp.) were 11 cm long. Unless otherwise specified, we used XM50-type fibers composed of polyacrylate, with a tight semipermeable membrane on the luminal side that prevents cell passage but allows solute exchange with the culture medium. The XM50 type of fiber has a nominal exclusion of 50,000 M_r. In some experiments, we used P30-type fibers that are composed of polysulfone and have a nominal exclusion of 30,000 M_r. The artificial capillary system, a closed circuit, was perfused with culture medium with the use of a Holter model 911 roller pump (pump and fittings; Extracorporeal Medical Specialties, King of Prussia, Pa.). The culture media were either Waymouth's medium supplemented with 15% FCS or Iemzo medium supplemented with 1% FCS and 0.1 IU insulin/ml; both media were further supplemented with 100 U penicillin/ml, 100 µg streptomycin/ml, and 50 U Trasylol/ml (Mobay, New York, N.Y.) and were buffered with 0.075% $NaHCO_3$. Media for culture of line 68H cells were further supplemented with 10^{-6} *M* dexamethasone.

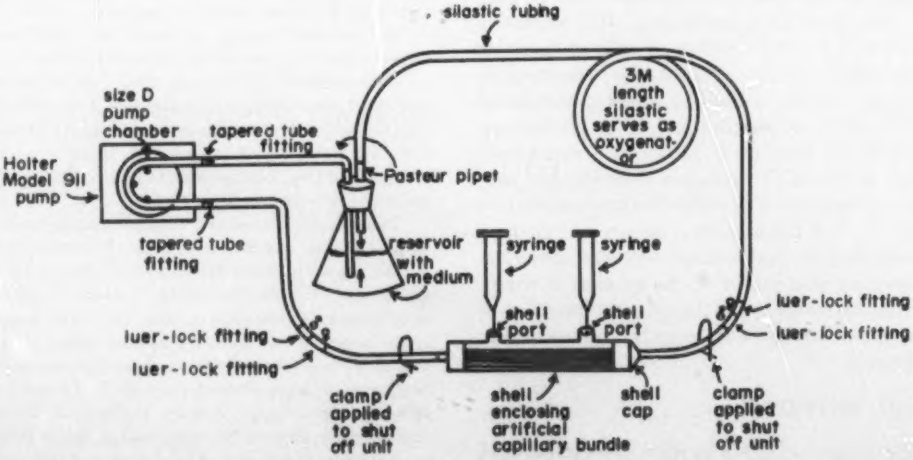
Capillary culture systems were sterilized by ethylene oxide and the fibers wetted by circulation of sterile Hanks' balanced salt solution (GIBCO). For culture studies, 5×10^6 cells in suspension were injected through the shell ports and seeded onto the surface of the hollow fibers. Systems were placed in the incubator, and cells were allowed to attach for 2 hours at 37°C without perfusion of the culture medium. Medium was perfused at 5–10 ml/minute.

Growth of cells on artificial capillaries was monitored by glucose consumption. The glucose concentration in the medium was evaluated by the glucose oxidase test. When the glucose level dropped to less than 50 mg/ml, the medium was changed by replacement of the reservoir with another containing 125 ml fresh medium. Medium was changed approximately three times during the 1st week of culture and daily during the 3d and 4th weeks.

Histologic evaluation of cell growth on artificial capillaries.—Cells were fixed by perfusion with Bouin's fluid for 2 hours. After fixation, the lumina of the hollow fibers and the ECS were filled with 1.5% Noble agar in medium at 45°C. The agar was solidified at 4°C and the encased fiber bundle extracted. Segments of the bundle were tied off with sutures. Sections were cut between sutures and processed for routine paraffin embedding and histologic examination as if the bundle segment were a piece of tissue.

Immunohistochemical detection of MuMTV antigens.—An indirect immunoperoxidase immunohistochemical stain was used to localize the presence of MuMTV antigens in cells grown on artificial capillaries. The staining technique was applied to 5-µm serial sections of Bouin's fluid-fixed, paraffin-embedded segments of fiber bundles. Details of the procedure have been described previously (*16*). The primary antibody was rabbit IgG from animals immunized against whole disrupted RIII MuMTV (*16*). The second antibody was peroxidase-conjugated goat anti-rabbit IgG (*16*). Stained sections were counterstained in dilute methylene blue. Sections were examined by light microscopy, and a positive reaction was indicated by a brownish precipitate.

Sample collection from artificial capillary cultures.—Samples (1 ml) of ECS fluids, from the cell side of the membrane, were collected daily through the ports in the shell surrounding the hollow fiber. An iv injection set was inserted into the



TEXT-FIGURE 1.—The artificial capillary cell culture system. Cells are introduced through the shell ports and grow on the external surface of the capillaries. Medium is perfused through the lumina of the hollow fibers or artificial capillaries and is recirculated by the roller pump. Antigens are collected from the ECS through the shell ports and from the perfusate by sampling medium in the reservoir. The entire system is placed in a 37°C incubator with a 5% CO_2 atmosphere, and the pH of the medium is maintained by gas exchange through the silastic tubing.

shell port, and sample fluids were collected by positive ultrafiltration forces. Samples of the perfusate were also collected daily and stored at −80°C until tested.

RIA detection of MuMTV antigens in culture fluids.—The presence of gp52 and p28 in the ECS and perfusate was determined by blocking RIA in which delayed addition of labeled antigen was used to maximize sensitivity. The gp52 was purified by the method of Ritzi et al. (*17*) and iodinated with ^{125}I-labeled Bolton-Hunter reagent as previously described (*17*). The ^{125}I-labeled gp52 was more than 90% precipitable with 10% trichloroacetic acid.

ELISA detection of gp52 in culture fluids.—The ELISA was applied to culture fluids for detection and quantitation of gp52. Antibody against highly purified gp52 was prepared as previously described (*18*) and conjugated with horseradish peroxidase (*16*). To each well of a microTest plate (Dynatech Laboratories, Inc., Alexandria, Va.) was added 200 µl of anti-gp52 IgG diluted in 50 m*M* carbonate–bicarbonate buffer (pH 9.6) to a final concentration of 10 µg/ml, and the plate was sealed and incubated overnight at 4°C. After incubation, unbound antibody was washed off by PBS with 0.1% Tween 20. The plate was sealed and stored at −20°C until used.

To the antibody-coated wells was added a 200-µl aliquot of either the test sample or standard gp52 or disrupted MuMTV proteins as appropriate. For each test, six different concentrations of sample were made in the range of 0.1–10 µl and diluted to a final volume of 200 µl in PBS containing 5% chicken serum, 5% Trasylol, and 0.1 m*M* Merthiolate. The plate was sealed and incubated overnight at 4°C, and unbound antigen was washed off with PBS–Tween 20 as above. Then 200 µl of conjugate at 10 µg/ml in PBS–chicken serum was added, and the plate was sealed and incubated at room temperature for 4 hours. To each well was added 250 µl of the peroxidase substrate [0.5 mg *o*-phenylenediamine dihydrochloride/ml in McIlvaine's citrate–phosphate buffer (pH 6.0) containing 0.006% H_2O_2]. The plate was incubated at room temperature for 1 hour after which 25 µl of the reaction mixture was diluted to 250 µl with 0.5 *N* H_2SO_4 to stop the reaction. The orange color of the reaction product in 0.5 *N* H_2SO_4 (max, 492 nm) was measured in a spectrophotometer against an appropriate reagent blank. The ELISA gave a linear response to gp52 of 1–30 ng. The gp52 content of test samples was calculated from the linear portions of the standard curve for gp52 generated in the same assay.

Characterization of particulate and soluble gp52.—A 650-µl portion of pooled ECS fluid was centrifuged in a microtube at $189{,}000\times g$ for 45 minutes, and the supernatant was removed and designated "soluble fraction." The pellet was resuspended in 65 µl of disruption buffer (0.2 *M* sodium phosphate at pH 6.8, 0.01 *M* EDTA, 0.2% 2-mercaptoethanol, and 1% Nonidet P40) and incubated at 4°C for 30 minutes and then at 37°C for 30 minutes after which it was made up to 650 µl (original vol of starting sample) with 0.02 *M* Tris-HCl (pH 7.2) and 0.2% 2-mercaptoethanol and designated "particulate fraction." These fractions were evaluated by the ELISA for gp52 content.

Protein determination.—The total protein content of samples was determined by the method of Lowry et al. (*19*). BSA was used as the standard.

Ouchterlony double-diffusion analysis.—The Ouchterlony method of double diffusion in gels (*20*) was used to detect the presence of BSA in samples. The reaction was done with prepared immunodiffusion plates containing agar gel (Hyland Diagnostics, Deerfield, Ill.). Antibody to BSA was obtained from Cappel Laboratories, Cochranville, Pa.

Molecular sizing.—Capillary fluids were applied to a gel filtration column (Ultrogel AcA 54; LKB Instruments, Inc., Rockville, Md.), and the fractions collected were assayed by RIA for the presence of material reactive with antiserum to gp52 in the ELISA. The following standards were used to estimate the molecular weights of the antigenic material: lysozyme, M_r 14,300; trypsinogen, M_r 24,800; ovalbumin, M_r 45,000; BSA, M_r 68,000.

Mice.—BALB/c and BALB/cfC3H mice were used. They were descendants of breeding pairs obtained from the Cancer Research Laboratory, University of California at Berkeley. These mice were maintained by brother × sister mating. The BALB/cfC3H mice carry the standard MuMTV (*21*).

Immunization and challenge.—Fluids were collected daily from ECS of appropriate capillary cultures and pooled, and the total protein and gp52 levels were determined. Mice were immunized by ip injection with varying concentrations of the ECS pool diluted in PBS. The immunized mice were challenged on day 21 with 5×10^5 tumor cells of the appropriate syngeneic cell line. Animals were examined three times per week. Tumor appearance was recorded when a palpable mass was detected.

Immunomodulation.—CTX (Mead Johnson & Co., Evansville, Ill.), 300 mg/kg, was given ip to immunized mice.

Statistical methods.—Data in the immunogenicity tests were analyzed by the chi-square test.

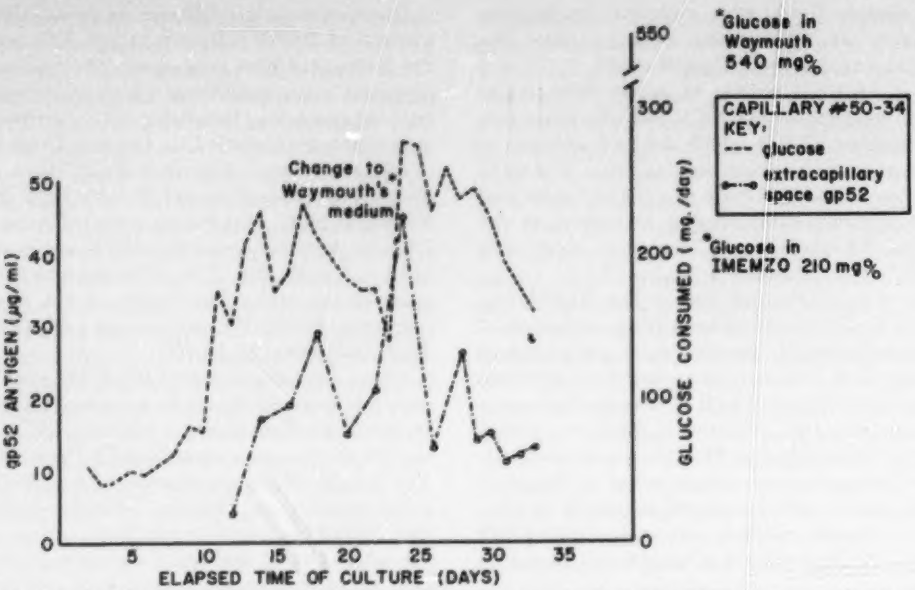
RESULTS

Evaluation of Cell Growth on Artificial Capillaries

All cell lines examined in this study were able to grow on artificial capillary matrices composed of either polyacrylate or polysulfone. Growth of cells on artificial capillaries cannot be visualized as in monolayer culture vessels. In the capillary cultures, growth was monitored by glucose consumption. A typical glucose consumption curve for a capillary culture is illustrated in text-figure 2. The overall pattern was an initial slow rate of glucose consumption, 40–50 mg/100 ml/day, for the first 10 days of culture, followed by an exponential phase, 70–250 mg/100 ml/day, and finally a plateau and eventual decline. Glucose consumption also increased sharply for the 24 hours immediately following each medium change. This glucose consumption pattern was consistent for all cultures tested, although the phases were of variable lengths and amplitude depending on the fiber material, cell type, and number of cells inoculated.

Using other types of perfusion cultures, Kruse (*22*) estimated that 0.9 mg/100 ml glucose is consumed per day for every 10^6 cells (*22*). With the use of this relationship, the number of cells present in a capillary culture was estimated to be 300×10^6 cells on the 25th day of the culture illustrated in text-figure 2. In other cultures, a total of nearly 10^9 cells was obtained.

Cells seeded onto the hollow fibers grew on the surface of



TEXT-FIGURE 2.—Production of gp52 antigen (ELISA) and growth curve (glucose consumption) of cell line 68H grown on artificial capillaries of 50,000-M_r nominal exclusion. mg%=mg/100 ml.

each fiber, extended into the pores of the polymeric substrate, and filled the spaces between the fibers. Tissue-like densities of cells (fig. 1) were achieved within 3 weeks when 5×10^6 cells were seeded onto the capillaries and could be maintained for as long as 3 months.

Immunohistochemical Detection of MuMTV Antigens

To determine whether viral antigens were expressed by cells in capillary culture, we grew line 68H cells on 50,000-M_r exclusion artificial capillaries. After 35 days in culture, the cells on the artificial capillaries were fixed in Bouin's fluid, processed for histologic examination, and stained by the immunoperoxidase procedure. All line 68H cells gave a strong positive reaction for the viral antigens similar to the reaction observed in mouse mammary tumors (*16*). The reaction could be prevented by preadsorption of the antiserum with whole MuMTV.

Sample Collection From Capillary Cultures

One aim of this study was to evaluate the production of soluble antigens by cells grown on artificial capillaries. We therefore had to develop a method of reproducibly sampling the ECS fluids in a way that would minimize disturbance of cellular architecture and would result in minimal antigen dilution. To develop an optimal method, we performed a series of pilot experiments using the enzyme lactate dehydrogenase which could be readily quantitated.

The optimal collection procedure was one using the ultrafiltration forces (created by the fluid passage through the capillary device) in which the sample is pumped into a collection tube at approximately 1–5 ml/minute. Using this technique, we could collect 75% of the lactate dehydrogenase enzymatic activity injected into the ECS in the first 1-ml sample. Similar efficiency of collection was obtained with a Harvard pump withdrawing fluid at the rate of 1 ml/10 minutes. However, the injection set method was more convenient to use routinely. Use of hand-held syringes and evacuation resulted in highly variable collections with perturbation of cellular architecture at the port of withdrawal.

Detection of MuMTV Antigens in Capillary Fluids

To determine whether antigens were shed from cells and could be harvested from capillary fluids, we evaluated the presence of MuMTV-associated antigens in fluids of line 68H cells grown in artificial capillaries. The XM50 (50,000-M_r exclusion)-type hollow fibers were chosen in an effort to retain and concentrate gp52 in the ECS and at the same time exclude the large proteins such as albumin on the luminal side of the membrane.

The fluids in the ECS and the perfusate were sampled daily from two parallel capillary cultures and assayed by RIA and the ELISA for the presence of gp52. The levels of gp52 detected in one culture are illustrated in text-figure 2. The content of gp52 in the ECS fluids in the culture illustrated ranged from 5 to 45 µg/ml in daily 1-ml samples. The ECS fluids also contained 0.2–0.6 µg p28/ml. The perfusates contained 200–300 ng/ml of material that reacted with anti-gp52.

Characterization of MuMTV Antigens From Capillary Cultures

Molecular sieve gel filtration of the capillary fluids was used to characterize the gp52-competitive species. The antigenic material in the ECS fluid ranged in size from 50,000 to 68,000 M_r. The perfusate contained material that ranged from 35,000 to 55,000 with a peak at 46,000 M_r.

ECS fluids from 2 weeks of culture of line 68H cells on two capillary units (not illustrated) were pooled. The pooled fluid was analyzed by the ELISA and contained 14.2 μg gp52/ml. A sample was centrifuged and the particulate and soluble fractions were evaluated. The particulate fraction contained 9,800 ng gp52/ml, whereas the soluble fraction contained 4,500 ng gp52/ml, a ratio of 2 parts particulate: 1 part soluble.

Comparison of Production of MuMTV Antigens in Capillary and Monolayer Cultures

The culture fluids overlaying monolayer cultures of 68H cells were tested for content of gp52 and their content of gp52 was compared with the content of gp52 in capillary cultures. Monolayers produced from 400 to 1,245 ng gp52/ml/day for 4–7 days, which was equivalent to 60–100 ng/ml/10^6 cells/day, depending on the culture and the type of medium used. By comparison, in our overall experience, capillary cultures produced 1,200–51,000 ng gp52/ml/day, which was equivalent to 150–200 ng/ml/10^6 cells/day estimated by the glucose consumption of the cell culture. Generally, capillary cultures produced these quantities of antigens daily for 3–12 weeks.

Contaminating Antigens

The ECS fluids were tested by Ouchterlony analysis for the presence of BSA. Both XM50 (50,000-M_r nominal exclusion) and P30 (30,000-M_r nominal exclusion) hollow fibers were found to allow the BSA to cross from the perfusate to appear in the ECS.

To determine if the albumin was intact or fragmented, a 2-ml sample of ECS fluid from one of the line 68H cultures was reduced tenfold by lyophilization and subjected to gel filtration in a 1×50-cm column of ultrogel AcA 54. Most protein appeared as a sharp peak immediately after the void volume. These protein fractions were found by Ouchterlony analysis to contain BSA, whereas the later fractions did not, which suggests that the albumin in the ECS is intact with an M_r of 68,000.

Antigens Produced by Other Mammary Tumor Cell Lines

Cell lines 66, 67, and 168 do not express MuMTV cell surface antigens in monolayer culture, although lines 66 and 168 appear to express viral antigens as determined by transplantation resistance (*23*) and can be induced to express these antigens in monolayer culture by 5-iodo-2′-deoxyuridine or dexamethasone (*14, 15*). These lines were grown in capillary culture, and the ECS fluid was examined for the presence of gp52. Pooled ECS fluids from a 2-week culture of line 66 contained 674 ng/ml. A pool of ECS fluids from a 2-week culture of line 67 contained 380 ng particulate gp52/ml and 480 ng soluble gp52/ml. Daily samples of a culture of line 168 contained 70–299 ng gp52/ml.

Mammary Tumor-Associated Antigens Produced in Capillary Culture

Mice were immunized with ECS fluids from line 67, since this line had been previously shown to express tumor-associated nonviral antigens (*23*). Both BALB/c and BALB/cfC3H mice were immunized because BALB/c mice can respond to both MuMTV-associated and unique tumor-specific antigens, whereas the BALB/cfC3H mice develop transplantation immunity primarily to the unique antigen (*24, 25*). By using both types of mice, we were able to test for immunity to nonviral tumor antigens. The results of subsequent challenge with the same and syngeneic tumor cells are presented in table 1.

Immunization of BALB/c mice with 100 μg of the line 67 capillary-derived antigen resulted in inhibition of the growth of line 67 tumor cells. In contrast, immunization of BALB/cfC3H mice with 100 μg of the same antigen resulted in specific enhancement of line 67 tumor growth. That this enhancement was due to immunologic mechanisms was indicated by its abrogation by an immunosuppressive regimen of CTX given 2 days prior to immunization (*26*). The specificity of the response for the unique antigen was shown by the failure of immunization with line 67 ECS to enhance line 68H tumor growth. Line 68H tumors do not induce transplantation immunity to the unique antigen (*23*). Further evidence of the specificity of immunization with line 67-derived capillary fluids was shown by the lack of any effect of immunization with these fluids on the growth of Moloney sarcoma cells in either strain of mice.

The immunizing pool of 67 capillary fluids contained a small amount of MuMTV gp52 antigen (690 ng/ml). Only picogram amounts of gp52 are present in 10 μg total capillary fluid. Such low concentrations are not likely to be sufficient for immunization, although they possibly could cause low-dose tolerance.

TABLE 1.—*Immunogenicity of capillary-derived antigens from cell line 67*

Mouse strain	Treatment	Tumor incidence at day 53/No. challenged with line 67 cells (%)[a]
BALB/c[b]	100 μg line 67, day 0	1/10 (10)[c]
	10 μg line 67, day 0	5/10 (50)
	1 μg line 67, day 0	6/10 (60)
	0 μg line 67, day 0	7/10 (70)
BALB/cfC3H[d]	100 μg line 67, day 0	11/20 (55)[e]
	100 μg line 67, days 0 and 7	14/20 (70)[f]
	10 μg line 67, day 0	2/10 (20)
	1 μg line 67, day 0	1/10 (10)
	0 μg line 67, day 0	3/30 (10)

[a] Challenged on day 21 with 5×10^5 tumor cells [*see* (*23*)].

[b] The dose responses in BALB/c mice are independent ($\chi^2=8.32$; $P<0.04$).

[c] Significant reduction in tumorigenicity ($\chi^2=7.5$; $P<0.01$).

[d] The dose responses in BALB/cfC3H mice are independent ($\chi^2=26.45$; $P<0.01$).

[e] Significant enhancement of tumorigenicity ($\chi^2=12.05$; $P<0.0001$).

[f] Significant enhancement of tumorigenicity ($\chi^2=19.25$; $P<0.0001$).

[g] Enhancement of tumorigenicity eliminated, identical to control.

DISCUSSION

We have applied the artificial capillary cell culture technique to the production of antigens by mammary tumor cells. The purpose was to use the unique features of the capillary cell culture system to optimize antigen production. The tridimensional capillary matrix supports cell growth under conditions in which fresh nutrients are continuously supplied while waste products are removed (*2–6*). All the mammary tumor cell lines tested were capable of luxuriant growth on hollow fibers composed of either polyacrylate or polysulfone. Tissue-like densities of cells were achieved within a few weeks, and cultures remained metabolically active for 6–12 weeks.

We have previously demonstrated that normal hepatocytes can similarly be maintained for 6–8 weeks and retain the capabilities of production of plasma proteins, metabolism of drugs, and production of urea (*27*). Using capillary cell culture technology, other investigators have established long-term cultures of choriocarcinoma cells that produce human chorionic gonadotropin (*4*), human pituitary cells that secrete prolactin and growth hormone (*5*), pancreatic beta cells that produce insulin (*28, 29*), and minimally changed hepatoma cells that can conjugate bilirubin (*30*).

Artificial capillary cell culture systems proved to be efficient means for production of MuMTV antigens. It is not possible to accurately determine at this time if the antigen production is increased in capillary cultures on a per-cell basis compared to monolayer cultures or whether the increase is due to the much larger number of cells in the capillary cultures. From the glucose consumption data, we have estimated that the capillary cultures produced at least double the amount of antigen per 10^6 cells and produced antigen for an extended period of time. This suggests an increase in antigen production per cell over and above the increased number of cells in the capillary cultures.

The hollow fibers are constructed with a semipermeable membrane on their luminal surfaces. In initial studies, XM50-type fibers were used with a nominal exclusion of 50,000 M_r. This exclusion was selected to retain and concentrate antigens with an M_r greater than 50,000, like that of gp52, on the cell side of the membrane. The gp52 competitive species in the perfusate were smaller than 52,000, which suggests that these were breakdown products of the gp52. In contrast, the gp52 present on the cell side was in its 52,000-M_r form. It appeared as both particulate and soluble gp52. The particulate gp52 most likely represents virions and membrane-bound antigens. Disruption of the particulate gp52 prior to analysis resulted in a tenfold increase in detectable antigen, which suggested that gp52 is present both in virions and in lipid-bound and lipoprotein-bound complexes, since disruption of virions alone generally gives only twofold to threefold increases in detection.

The p28 in the ECS is most likely present primarily in the form of virions. Free species of 28,000 M_r would be expected to readily cross the membrane barrier.

Another expectation of the membrane barrier had been that large proteins of FCS used in culture media would be retained in the perfusate. This expectation was not fully realized. The XM50 and P30 membranes are sufficiently leaky to consistently permit intact BSA (M_r 68,000) to cross the barrier into the ECS. Thus the capillary culture system failed to fulfill the initial expectation that it would provide antigen completely free from contamination with FCS proteins.

This is the first demonstration that viral antigens can be harvested in large quantities from capillary cultures and that such culture systems are feasible for large-scale production of tumor virus products. Previously, Johnson et al. (*31*) have shown that several cell types could be infected with Venezuelan equine encephalitis virus in capillary culture with the production of a high titer of infectious virus.

Interestingly, cell lines 66 and 67, which do not express MuMTV antigens under conventional monolayer conditions (*13*), did so under capillary culture conditions. These lines do express these antigens in monolayer when treated with various inducers (*14, 15*) and appear to do so in vivo (*23*). This finding provides further evidence that capillary conditions potentiate the expression of antigens. The mechanism for this antigen-induction effect remains to be explored.

The MuMTV antigen studies were initiated to use well-characterized antigens as a model for the development of a means to produce tumor-relevant nonviral antigens. The next step in this development was to generate tumor-associated non-MuMTV antigens. For these experiments, we used line 67 cells that had been shown to immunize against only the unique, tumor-specific antigens of mouse mammary tumors (*23*). The results of pilot studies indicate that it is, in fact, possible to harvest tumor-associated antigens in a useful form from capillary cultures of tumor cells. The antigens produced were immunogenic in syngeneic animals, and the response to these antigens was modulated with an agent known to influence the immune response (*29*).

Preliminary results have indicated that the mouse mammary tumor cells described here also shed the mouse mammary epithelial antigens described by Ceriani et al. (*32*) when these cells were grown either in monolayer or on artificial capillaries (Hager JC, Ceriani RL: Unpublished observations). Experiments are under way to determine if capillary culture enhances the production of these antigens as well.

In summary, artificial capillary cell culture systems provide a means for long-term culture and production of mammary tumor-associated antigens by tumor cells. We are currently determining whether human breast cancer antigens can similarly be produced by human breast cancer cells in artificial capillary cell culture.

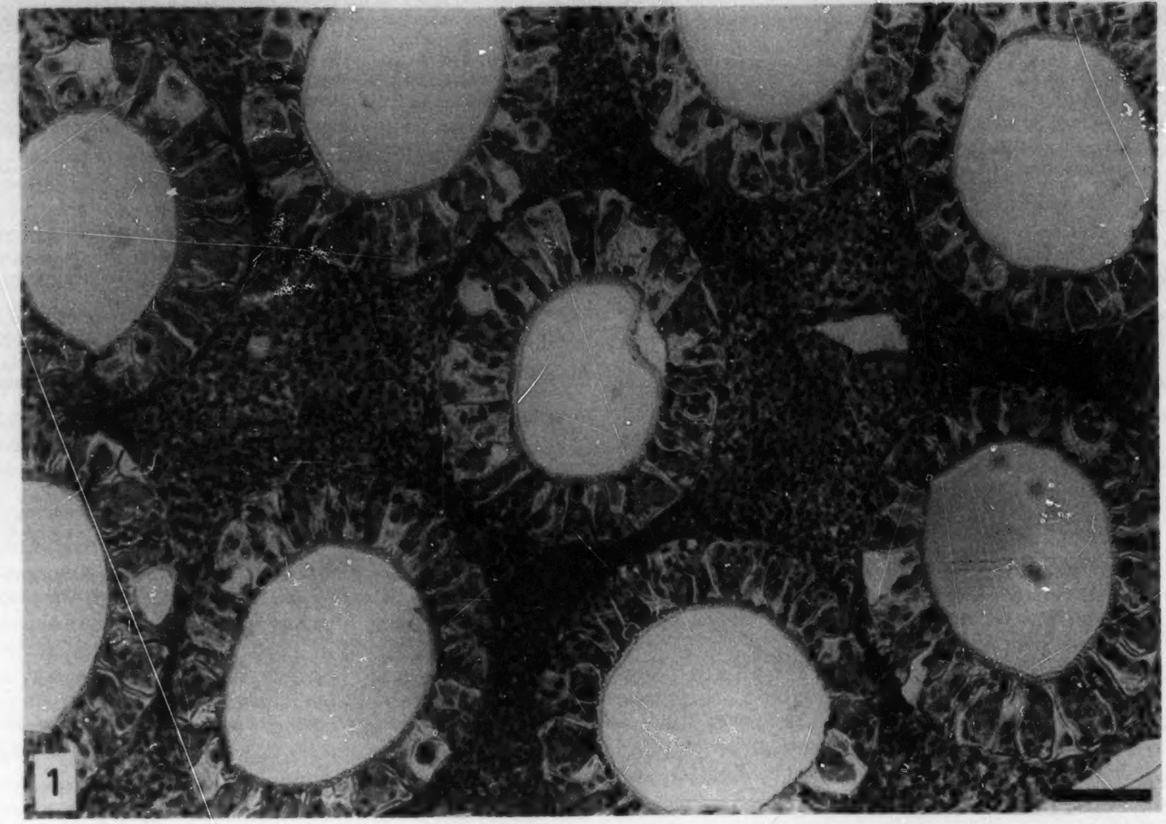

FIGURE 1.—Mouse mammary tumor cells (line 67) grown for 11 wk on a bundle of artificial capillaries have achieved tissue-like density. Artificial capillaries are cut in cross section and appear as thick-walled tubular structures. The semipermeable membrane on the luminal surface of the hollow fibers can be observed in the central lumen where the microtome knife has separated the membrane from the fiber wall matrix. The cells grow in the pores of the matrix of the hollow fibers and on their surface, filling the intercapillary spaces. *Bar*=100 µm. × 630

Glycosylated Podophyllotoxin Congeners: Loss of Microtubule Inhibition and Permission of Invasion In Vitro[1,2]

Marc M. Mareel,[3] Christian H. Dragonetti,[3] Georges K. De Bruyne,[3] *and* Rita M.-L. Van Cauwenberge[3,4]

ABSTRACT—Podophyllotoxin (PPT) and its glycosylated congeners, 4′-demethylepipodophyllotoxin 9-[4,6-*O*-(R)-ethylidene-*β*-D-glucopyranoside] (VP-16-213) and 4′-demethylepipodophyllotoxin 9-[4,6-*O*-(R)-thenylidene-*β*-D-glucopyranoside] (VM-26), were studied for their effects on the following activities of MO$_4$ mouse fibrosarcoma cells in vitro: growth as an aggregate in culture on a gyrotory shaker, directional migration from an aggregate explanted on glass, organization of the cytoplasmic microtubule complex as inferred from immunostaining with an antiserum against tubulin, and invasion into fragments of 9-day-old embryonic chick cardiac muscle. At concentrations that inhibited growth (≥0.03 μg/ml), PPT arrested directional migration, abolished the cytoplasmic microtubule complex, and interfered with invasion. VM-26 (0.1–1.0 μg/ml) and VP-16-213 (1–30 μg/ml) interfered with growth but permitted directional migration, organization of the cytoplasmic microtubule complex, and invasion. These observations imply that microtubule inhibitors are anti-invasive because they interfere with the assembly of the cytoplasmic microtubule complex and not because they inhibit growth.—JNCI 1982; 69:1367–1374.

Previously, we reported that microtubule inhibitors prevent the invasion of MO$_4$ mouse fibrosarcoma cells in organ culture. In contrast, antiproliferative agents that do not affect microtubules permit invasion. The anti-invasive activity of microtubule inhibitors was ascribed to abolishment of the cytoplasmic microtubule complex. This complex is necessary for directional migration presumed to be a vital, but not the only, activity of invading cells (*1–3*).

PPT was shown to prevent microtubule assembly (*4*) and, therefore, could be expected to interfere with invasion. The semisynthetic derivatives of PPT, VP-16-213 and VM-26, no longer affected microtubules but retained the antiproliferative activity of the native PPT (*5, 6*). Obviously, a comparative study of the effect of PPT and its glycosylated congeners on invasion might provide direct evidence of a correlation between anti-invasive activity and microtubule inhibition.

We describe here the effect of PPT, VP-16-213, and VM-26 on the following in vitro activities of MO$_4$ cells: growth as an aggregate in culture on a gyrotory shaker, directional migration from an aggregate explanted on glass, assembly of the cytoplasmic microtubule complex, and invasion into fragments of cardiac muscle in organ culture.

MATERIALS AND METHODS

MO$_4$ cells.—MO$_4$ cells are virally transformed C3H mouse cells (*7*). MO$_4$ cell monolayers have been maintained in our laboratory since 1975, with several periods of storage in liquid nitrogen. They were regularly tested for their malignant status and produced invasive and metastasizing sarcomas in syngeneic animals (*8, 9*). In all experiments with MO$_4$ cells the culture medium consisted of Eagle's minimum essential medium (N.V. GIBCO Europe S.A., Gent, Belgium) plus 10% fetal bovine serum (N.V. GIBCO Europe S.A.) and 0.05% L-glutamine. Aggregates of MO$_4$ cells were prepared from cell suspensions incubated on a gyrotory shaker (New Brunswick Scientific Co., New Brunswick, N.J.) as described previously (*10*). Aggregates with a diameter of 0.2 or 0.4 mm were selected under a stereomicroscope (× 25) and washed in an excess of culture medium before use in the present assays.

Drugs.—PPT (Aldrich-Europe Division, Janssen Pharmaceutica, Beerse, Belgium) was dissolved at 5 mg/ml in 0.2% *N,N*-dimethylformamide, and control cultures were incubated with the solvent only. Dissolved VM-26 and VP-16-213 were from commercial stock. The solvent of VM-26 and VP-16-213 was not investigated. Other authors (*11*) have seen no effect on cells incubated with the solvent alone. Therefore, the culture medium was used as a control in experiments with VP-16-213 or VM-26. Stock solutions were further diluted in culture medium before use to obtain concentrations between 10 and 0.001 μg/ml (PPT and VM-26) and between 100 and 0.01 μg/ml (VP-16-213).

Assay for growth.—Growth of MO$_4$ cell populations was evaluated from daily measurements of the diameters of aggregates incubated individually on a gyrotory shaker. In spheroidal aggregates in vitro and in solid tumors in vivo, growth results from cell proliferation and cell loss; the volume of individual cells and the intercellular space are additional factors, as discussed previously (*12*). In this assay, aggregates with a diameter of 0.2 mm were used. Drugs were added at the beginning of the culture. To determine whether growth arrest resulted mainly from inhibition of proliferation or from the balance between proliferation and

Matthys-De Smet for typing the manuscript. We also thank Bristol Benelux N.V., Brussels, Belgium, for kindly providing the VP-16-213 and VM-26; and Dr. M. De Brabander and Dr. J. De Mey, Janssen Pharmaceutica, Beerse, Belgium, for their generous gift of antiserum against tubulin.

cell loss, the presence of mitotic figures was examined on histologic sections from selected aggregates fixed in Zenker's solution. Reversibility of growth inhibition was studied after removal of drugs and daily refreshment of the culture medium, as reported previously (*3*).

Assay for directional migration.—MO_4 cell aggregates with 0.2-mm diameter were explanted on a cover slip in a Leighton tube (VEL, N.V., Leuven, Belgium) as described earlier (*12*). The circular area covered by MO_4 cells that had migrated radially from the aggregate was calculated from daily measurements of the mean diameter (microscope, × 40) and used as an index of directional migration (for discussion, *see 13, 14*). Drugs were added to the culture medium 2 days after explanation of the aggregate. At the end of the assay (7 days after addition of drug), cultures were fixed either in a solution of alcohol:Formalin:acetic acid (75:20:5) for staining with H & E or in glutaraldehyde (1% in cacodylate buffer, 0.1 *M*, pH=7.4) for staining with an antiserum against tubulin (dilution, 1/200 in Tris-buffered saline), according to the method described by De Mey et al. (*15*).

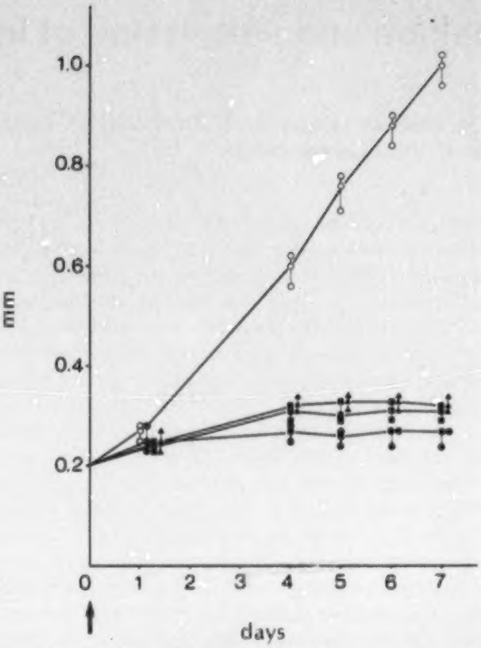
Assay for invasiveness in vitro.—MO_4 cell aggregates with 0.2-mm diameter were confronted with precultured fragments of 9-day-old embryonic chick cardiac muscle (diameter, 0.4 mm) in individual cultures on a gyrotory shaker (*10*). The relevance and the specificity of this method were recently reviewed (*16*). At growth inhibitory concentrations of the drugs, MO_4 cell aggregates with 0.4-mm diameter were also used to compensate for the lower number of cells. Drugs were added at the onset of the culture on the gyrotory shaker. Confronting pairs were fixed in Bouin Hollande's solution (*17*) for embedding in paraffin and complete sectioning into 8-µm-thick sections, or in glutaraldehyde for embedding in Araldite and sectioning into 2-µm-thick sections. Selected areas on these sections were processed for transmission electron microscopy. Details of the histologic and ultrastructure techniques were provided in a previous paper (*3*). Consecutive 8-µm-thick sections were stained with H & E and with an antiserum against embryonic chick heart (*17*). In all experiments triplicate cultures were used, and each experiment with active concentrations of drugs was repeated at least once. Control cultures without drug were included in each series of assays.

RESULTS

Growth

The effects of PPT, VP-16-213, and VM-26 at selected concentrations on the growth of MO_4 cell aggregates in culture on the gyrotory shaker are shown in text-figure 1. Mitoses were absent in the aggregates, the growth of which was completely inhibited. This indicates that inhibition of proliferation was responsible for growth arrest. However, individual cells were larger than in control cultures, suggesting that cellular hypertrophy might compensate to some extent for cell loss. Disintegration of aggregates was observed only with VM-26 at concentrations of 10 µg/ml.

Reversibility of growth inhibition was observed in most aggregates treated with 0.1 µg PPT/ml for 2 or 4 days. Reversibility was also observed in some aggregates treated with 1 µg VM-26/ml or with 10 µg VP-16-213/ml for 2 or 4 days, so that these drugs could not be considered as fully irreversible inhibitors of the growth of MO_4 cell aggregates.



TEXT-FIGURE 1.—Growth of MO_4 cell aggregates: untreated (○), with 0.1 µg PPT/ml (●), with 1 µg VM-26/ml (■), and with 10 µg VP-16-213/ml (▲). *Ordinate*: mean diameter of aggregates (median and extreme values from 5 cultures). *Abscissa*: time of incubation. *Arrow* indicates addition of drug.

Directional Migration

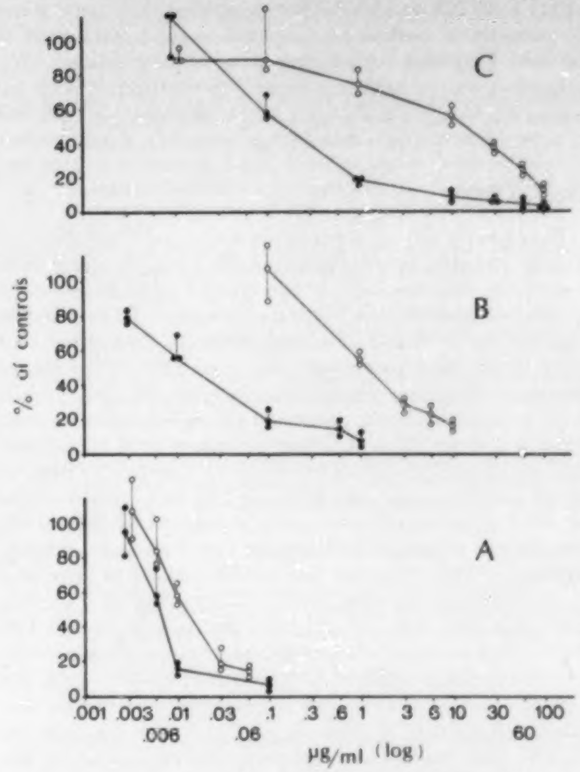
The effects on directional migration of PPT, VP-16-213, and VM-26 at concentrations that fully inhibited growth (text-fig. 1) are shown in text-figure 2. Obviously, VP-16-213 and VM-26, in contrast to PPT, hardly affected directional migration during the first 4 days after addition of the drugs. Dose-response curves are shown in text-figure 3. Inhibition of directional migration and inhibition of growth occurred at approximately the same concentration of PPT. VM-26 or VP-16-213 concentrations that inhibited growth were two orders of magnitude lower than concentrations that produced an effect in the assay of directional migration.

Cultures treated with PPT (fig. 1B) at concentrations of 0.03 µg/ml or higher, and fixed 7 days after addition of the drug, showed the following histologic alterations: appearance of abnormal metaphases, as described by Levan (*18*), and of multimicronucleated cells, as defined by De Brabander et al. (*19*); absence of postmetaphase figures; alteration of cell shape from bipolar to polygonal or round; and loss of radial orientation of cells in the corona. Cultures treated with VM-26 (fig. 1C) at concentrations between 0.1 and 1 µg/ml or with VP-16-213 (fig. 1D) at concentrations between 1 and 10 µg/ml showed hypertrophic cells with large nuclei (diameter, 25–50 µm as compared to 10–20 µm in controls). Most cells were mononucleated, but some were polynucleated (2–6 nuclei of approximately normal size); mitotic figures were absent. Large variations in the shape of cells (bipolar, stellate, and polygonal) occurred, but radial orientation of cells in the corona was still obvious. Treatment with higher doses (10 μg VM-26/ml, 100 μg VP-16-213/ml) had little effect on the size of the cells (nuclei diameters, 10–25 μm). Some of them were vacuolated; the appearance of round cells and an obvious decrease in the total amount of cells suggested extensive cell loss at these higher doses.

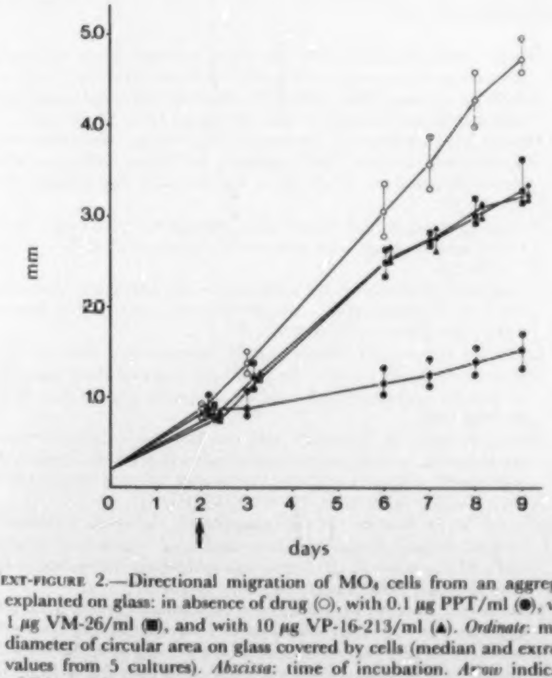
Organization of the cytoplasmic microtubule complex was evaluated as follows in cultures fixed, permeabilized, and stained with antiserum against tubulin: normal—when long tracks of microtubules irradiated from the perinuclear area and were oriented toward the cell periphery; disturbed—when short tracks were scattered over the cytoplasm without distinct orientation; absent—when the cytoplasm was diffusely stained. A normal cytoplasmic microtubule complex was found in most (≥80%) interphase cells of controls and of cultures treated with VP-16-123 or VM-26. In large cells produced by VM-26 (1 μg/ml) or by VP-16-213 (10 μg/ml), the cytoplasmic microtubule complex was normally organized but hypertrophic (fig. 1C, 1D). After treatment with 0.1 μg PPT/ml, the cytoplasmic microtubule complex was absent in most cells (≈80%) and disturbed in the others. At 1 μg/ml, all cells were diffusely stained (fig. 1B).

Invasion Into Chick Cardiac Muscle

In all control cultures, MO$_4$ cells invaded the cardiac muscle, as described previously (*10*). When such cultures (original diameters of MO$_4$ cell aggregate and heart fragment were 0.2 and 0.4 mm, respectively) were fixed after 4 days, small remnants of cardiac muscle were found mostly in the center of the majority of MO$_4$ cells (fig. 2). At concentrations of 0.03 μg PPT/ml or higher, invasion was inhibited in all cultures when aggregates of both 0.2 or 0.4 mm were used (fig. 3) in a way similar to that described for the vinca alkaloids (*3*). In contrast, treatment with VM-26 (0.1–1.0 μg/ml) or VP-16-213 (1–30 μg/ml) permitted invasion of MO$_4$ cells into the cardiac muscle in all cultures (figs. 4, 5). Quantitation of invasion was not possible. Nevertheless, differences between cultures treated with PPT and with VP-16-213 or VM-26 were distinct with regard to both the occupation of the cardiac muscle by MO$_4$ cells and the amount of immunoreactive tissue that remained at the end of the assay (cf. fig. 3 with figs. 4, 5). With VP-16-213 and VM-26 the amount of cardiac tissue that remained after 4 days was larger when aggregates of 0.2 mm instead of 0.4 mm were used, but occupation of the cardiac muscle by MO$_4$ cells occurred with both types of aggregates.



TEXT-FIGURE 3.—Inhibition of growth (●) and inhibition of directional migration (○) by PPT (A), VM-26 (B), and VP-16-213 (C). *Ordinate*: volume of aggregates (●) and surface of circular area covered by cells (○) as percent of controls 4 days after addition of drug. *Abscissa*: concentration of drug.



TEXT-FIGURE 2.—Directional migration of MO$_4$ cells from an aggregate explanted on glass: in absence of drug (○), with 0.1 μg PPT/ml (●), with 1 μg VM-26/ml (■), and with 10 μg VP-16-213/ml (▲). *Ordinate*: mean diameter of circular area on glass covered by cells (median and extreme values from 5 cultures). *Abscissa*: time of incubation. *Arrow* indicates addition of drug.

Transmission electron micrographs of selected areas showed that PPT produced ultrastructure alterations typical of microtubule inhibitors, as described previously in (*20*, *3*): scarceness or absence of microtubules, accumulation of 10-nm filaments, scattering of Golgi complexes, and appearance of annulate lamellae. The ultrastructure of MO$_4$ cells treated with VP-16-213 or with VM-26 suggested that most, if not all, subcellular systems participated in the hypertrophy of the cells. Degenerative alterations, as reported earlier (*21*), were observed in cardiac muscle cells confronted with invading MO$_4$ cells (fig. 6). Such alterations were not observed in areas of the cardiac muscle that were free of MO$_4$ cells.

DISCUSSION

The present experiments provided a new argument in favor of the opinion that microtubule inhibitors were anti-invasive in vitro because they interfered with the assembly of the cytoplasmic microtubule complex (*1, 3*). Recent experiments by Atassi and co-workers (*22*) suggested that microtubule inhibitors might also exert their anti-invasive activity in vivo. The present observations with PPT, known to prevent microtubule assembly (*4*), confirmed the anti-invasive activity of microtubule inhibitors. Structural modification of PPT resulting in loss of its capacity to bind to tubulin (*6*) was accompanied by loss of anti-invasive activity. PPT at antiproliferative concentrations abolished the cytoplasmic microtubule complex (fig. 1B) and inhibited invasion of MO$_4$ cells into the cardiac muscle in vitro (fig. 3), in contrast to the effects with VM-26 (figs. 1C, 4A, 4B) and VP-16-213 (figs. 1D, 5A, 5B). In the VM-26 and VP-16-213 cultures, even when larger aggregates (0.4 mm) were used to correct the number of potentially invasive cells, the disposition of MO$_4$ cells and remnant cardiac muscle was different from that in controls (cf. fig. 2 with figs. 4A, 4B, 5A, 5B). One factor contributing to this difference was the absence of proliferation of cells that had already occupied the cardiac muscle.

Alteration of the capacity to bind to tubulin was, however, not the only consequence of the modification of the PPT molecule. VP-16-213 and VM-26 prevented entry of cells in mitosis (M-phase) by arresting them in the G$_2$ phase (*23–25*). PPT permitted transition of cells from G$_2$ phase to M-phase. Since PPT was considered to arrest cells in metaphase by interference with the mitotic spindle (*26*), one might argue that differences in the anti-invasive activity of PPT and its glycosylated congeners were due to the arrest of cells in different phases of the mitotic cycle. In our opinion this was unlikely for the following reasons: 1) The effect of PPT or other microtubule inhibitors (*27*) on cycling MO$_4$ cells could not be considered as metaphase arrest. PPT produced multimicronucleated cells that respread after M-phase and developed undulating membrane activity all around their periphery. Such cells were unable to invade. 2) We have been able to demonstrate the anti-invasive effect of microtubule inhibitors on MO$_4$ cells arrested before M-phase with 5-fluorouracil (*1*). Obviously, our present results could not rule out that both abolishment of the cytoplasmic microtubule complex and arrest of growth in any phase of the cycle were necessary to inhibit invasion.

The differential effects on directional migration of PPT and its glycosylated congeners at antiproliferative concentrations confirmed that directional migration was a more important activity of invading cell populations in vitro than was growth. We wish to emphasize that this statement does not imply that directional migration was the only vital activity of invading cells or that growth was without influence on invasion. Our data further confirmed that the simple and rapid assay for directional migration may predict the anti-invasiveness of PPT—in contrast to VP-16-213 and VM-26 which permit invasion—illustrating the value of this assay for screening potentially anti-invasive drugs (*28*).

Comparison of the effect of PPT and of its glycosylated congeners also stressed the role of the cytoplasmic microtubule complex in directional migration as reported earlier (*19, 29, 30*). Cells arrested in G$_2$ phase by VP-16-213 or VM-26 displayed a well-elaborated cytoplasmic microtubule complex and were able to perform directional migration. The hypertrophy of the cytoplasmic microtubule complex was most probably one aspect of the continuation of macromolecular synthesis in G$_2$-arrested cells (*23*). It is known that cells stop locomoting during the mitotic cycle. The activities of G$_2$-arrested cells observed in our study indicated that MO$_4$ cells stopped migration only when they reached the M-phase.

Extrapolation of our in vitro findings to the mechanism of action of VP-16-213 or VM-26 in vivo necessitates that consideration be given to the following possibilities: 1) Aglycone metabolites of VP-16-213 or VM-26, which are tenfold more active than the parent drugs, might be produced in vivo (*31*), and 2) inasmuch as the glycoside moiety of the drugs sterically interfered with binding to tubulin (*6*), the aglycone metabolites of VP-16-213 or VM-26 might act as microtubule inhibitors in vivo.

Our data on the reversibility of growth inhibition do not support the opinion that G$_2$ arrest by VP-16-213 or VM-26 is totally irreversible (*5, 11, 24*). Continuation of invasion by these G$_2$-arrested cells, therefore, cannot be considered to be completely harmless.

Detection of Aflatoxins and Related Metabolites by Radioimmunoassay[1,2,3]

Philippe Sizaret,[4] Christian Malaveille,[4] Ruggero Montesano,[4] *and* Charles Frayssinet[5,6]

ABSTRACT—Rabbit (outbred albino New Zealand White) antisera have been raised against aflatoxin B_1 (AFB_1) using as immunogen conjugates in which the hapten was coupled to bovine serum albumin (BSA) either through C1 or C8 with the oxime and the dichloride derivatives of AFB_1 as intermediates. Radioimmunoassay (RIA), with [^{3}H]AFB_1 as tracer, showed that the antiserum prepared with the conjugate in which BSA was coupled to the AFB_1 oxime derivative was highly specific to AFB_1, whereas the antiserum raised against the conjugate in which BSA was coupled to AFB_1 through the AFB_1Cl_2 derivative (C-antiserum) cross-reacted to a large extent with other aflatoxins, including aflatoxin M_1, an important urinary metabolite of AFB_1 in several species including humans. AFB_1-related metabolites in the urine of inbred BD IV adult male rats given AFB_1 orally at doses from 600 pmol to 385 nmol can easily be followed over 9 days by RIA in which the "cross-reactive" C-antiserum is used. This suggests that similar methodologies could be used for the monitoring of human exposure to AFB_1.—JNCI 1982; 69:1375–1381.

Epidemiologic studies indicated associations between various risk factors and specific types of cancer (*1*). The causality of many of these associations, however, is not direct, since they are based on linkages between cancer cases and exposures to risk factors that were either estimated from questionnaires or derived from environmental data. This limitation may be overcome by the development of methodologies that would permit the monitoring of exposure to a suspected or known carcinogenic agent at an individual level. The recent development of immunologic techniques (*2-5*) that use antibodies with a high degree of sensitivity and specificity against certain carcinogens, or against DNA adducts resulting from exposure to various carcinogens including AFB_1 (*6*), opens the possibility to determine individual exposure in a relatively large human population.

It has been shown that chronic infection by hepatitis B virus (*7, 8*), as well as high levels of AFB_1 in food (*9, 10*), is associated with high incidences of primary liver cancer among Africans and Asians. The hepatocarcinogenicity of AFB_1 in various experimental animals (*11*) indicates that exposures to AFB_1 and hepatocellular carcinoma in humans are causally related. The test of this hypothesis requires a technique that can monitor exposure at an individual level.

This paper describes the characterization of antibodies against AFB_1 and the development of an RIA technique aiming at the detection of AFB_1 and/or AFB_1 metabolites in body fluids of individuals potentially exposed to this carcinogen.

MATERIALS AND METHODS

Chemicals.—The following products were used: Cl_2 gas from Compagnie Française des Produits Oxygénés (Vénissieux, Rhône, France); carboxy methoxylamine hemichloride, 94% pure, from EGA-Chemie, Steinheim, Federal Republic of Germany; 1-ethyl-3,3-dimethylamino-propylcarbodiimide and fatty acid-free BSA from Sigma Chemical Co., St. Louis, Mo.; [^{3}H]AFB_1 (30 Ci/mmol) from Moravek, Brea, Calif.; AFM_1, AFP_1, AFB_1-N^7-guanine, and AFB_1-FAPY. The other mycotoxins were purchased from Makor Chemicals, Jerusalem, Israel. All other chemicals were of the purest available grades. Traces of water that may have been present in the methylene chloride and DMSO used for the preparation of AFB_1Cl_2 were removed with molecular sieve beads (3 Å, 2 mm; E. Merck A. G., Darmstadt, Federal Republic of Germany).

Preparation of conjugates.—For the measurement of optical densities (Beckman spectrophotometer), AFB_1 was dissolved in methanol, and BSA and AFB_1 conjugates were dissolved in saline. The protein content of conjugates was determined

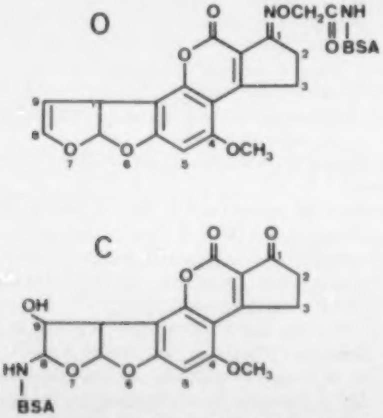
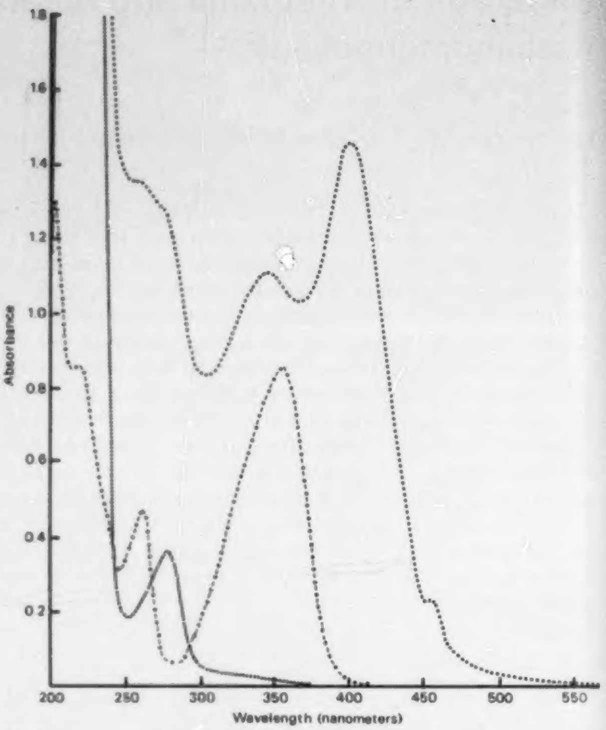
according to the method of Lowry et al. (*12*). Radioactivities were counted by liquid scintillation spectrometry with the use of Picofluor 30 as scintillation liquid. Counting efficiency was 40%.

Two types of AFB_1 conjugates were prepared. The first one was an AFB_1 oxime, prepared according to Langone and Van Vunakis (*13*) and coupled to BSA (text-fig. 1) according to Chu and Ueno (*14*). The number of AFB_1 molecules that bound to BSA was determined by spectrophotometry at 362 nm, according to Chu et al. (*15*). We prepared the other conjugate (text-fig. 1) by first synthesizing AFB_1Cl_2 according to a protocol derived from that of Swenson et al. (*16*). We dissolved 6.5 mg AFB_1 and 1.9 ng $[^3H]AFB_1$ in 3 ml methylene chloride; chlorine gas was bubbled through the solution until a yellow color appeared. For determinations of R_f, AFB_1Cl_2 was dissolved in methylene chloride; thin-layer chromatography plates (DC Alufolien Kieselgel 60; E. Merck A. G.) were developed with methylene chloride-acetone (19:1 vol/vol), dried, and developed a second time with the same eluent (*16*). In a parallel experiment, the R_f of the major chlorinated product was determined by thin-layer chromatography to be 0.58. After drying the AFB_1Cl_2 solution in vacuum, we quickly added 4.5 ml 0.01 *M* sodium phosphate buffer (pH 7.4) that contained 9.3 mg BSA; immediately thereafter, we added 0.5 ml DMSO drop by drop under magnetic stirring. We kept the mixture for 30 minutes at 37°C in a water bath under shaking. We removed the insoluble material by centrifugation for 15 minutes at 3,500×*g*. We then precipitated the conjugate by sequential addition of 43 mg NaCl, 6 ml ethyl acetate, and 12 ml acetone under magnetic stirring. We kept the mixture on ice for 15 minutes, then centrifuged it for 15 minutes at 3,500×*g*. We washed the precipitate twice with 22 ml ethanol and once with the same volume of ether. After removal of the ether, we dissolved the conjugate in 8 ml of 0.14 *M* NaCl and sterilized it by filtration through a 0.22-μm Millipore membrane (Millipore Corp., Bedford, Mass.). We then divided the solution into aliquots and stored it at −30°C. The number of molecules of AFB_1 bound to 1 molecule of BSA was determined by measurement of the specific radioactivity of the conjugate.



TEXT-FIGURE 1.—Structure of AFB_1 oxime-BSA conjugate (O) and presumed structure of AFB_1Cl_2–BSA conjugate (C) used for the preparation of anti-AFB_1 antisera [adapted from Chu and Ueno (*14*) and Swenson et al. (*16*)].



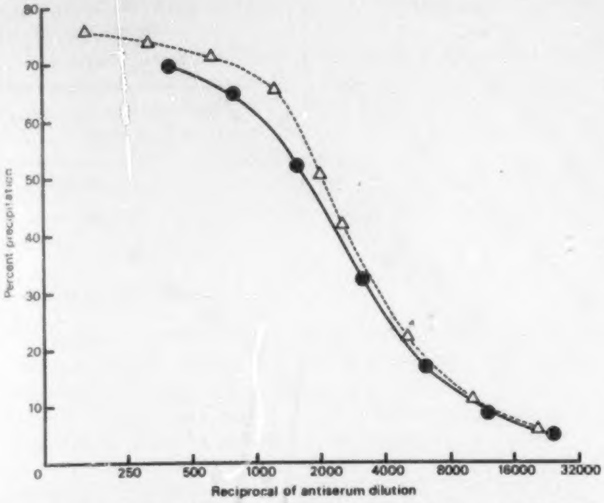
TEXT-FIGURE 2.—Absorption spectra of BSA (····), AFB_1 (·-·-·-), and AFB_1Cl_2–BSA conjugate (—).

Antisera.—Pairs of outbred albino New Zealand White rabbits were immunized with each of the two conjugates by injections into multiple sites of 250 μg immunogen 6 weeks apart according to Chu and Ueno (*14*); after the second injection, 1 rabbit of each pair with the best antiserum titer was kept for further immunization. Altogether, three courses of injections with O-conjugate and five courses of injection with C-conjugate were given to each of the 2 rabbits.

Gel diffusion.—For the study of C-antiserum, we performed double-gel diffusion in 1% agarose A45 (Industrie Biologique Française, Gennevilliers, France) in 0.02 *M* barbital buffer (pH 8.6). After the gel was washed thoroughly, the plates were dried and precipitin lines stained with Coomassie brilliant blue R250 (*17*).

RIA.—We performed RIA with the use of $[^3H]AFB_1$, diluted to introduce about 10^4 cpm (≈0.37 pmol) into each tube (milliR 6PE; Luman, Basel, Switzerland). AF were first dissolved in DMSO and then serially diluted in 0.05 *M* sodium borate buffer containing 1/1,500 thiomerosal and 10% (vol/vol) normal chicken serum; the highest concentration of DMSO in mycotoxin solution was 5% (vol/vol). Rat urine, antisera, and the tracer were also diluted in the borate chicken serum buffer. We assayed in duplicate all dilutions of specimens to be titrated; reagents were introduced in the order of 1) 250 μl mycotoxins or rat urines, 2) 25 μl antiserum, and 3) 25 μl $[^3H]AFB_1$.

After 30 minutes of incubation at 4°C, we precipitated the $[^3H]AFB_1$ bound to the antibodies with half-saturated



TEXT-FIGURE 3.—Titration curve with RIA of two rabbit anti-AFB_1 antisera with $[^3H]AFB_1$ as tracer. △--△, anti-AFB_1 oxime–BSA conjugate antiserum; ●—●, anti-AFB_1Cl_2–BSA conjugate antiserum.

ammonium sulfate (4.3 ml/tube). The tubes were then centrifuged at 1,000×*g* at 0°C for 1 hour and emptied. Precipitates were dissolved in 250 µl distilled water; we filled the tubes with 4 ml Picofluor 30 (Packard Instruments, Paris-Rungis, France) and agitated them thoroughly. We determined the net percentage of precipitation (antisera) or of inhibition (mycotoxins) as described previously (*18*), affinity constants of antisera according to Müller (*19*), and AFB_1 potencies of rat urines by an RIA with the use of C-antiserum. The percentage of inhibition by the urines was converted into AFB_1 equivalent quantities by reference to a standard curve obtained with known amounts of AFB_1.

Experiments on rats.—We used adult inbred BD IV male rats with about 300 g body weight, bred at the International Agency for Research on Cancer for studies on AFB_1 urinary metabolite excretion. Individual doses of mycotoxins (3.1 µmol sterigmatocystin and doses of AFB_1 ranging from 600 pmol to 385 nmol) were dissolved in 100-µl aliquots of DMSO that were thoroughly mixed with 400 µl olive oil and administered through gastric tubes. We then kept the rats in metabolic cages throughout the experiment and fed them a Charles River CRF diet; we collected urines each day in graduated cylinders and stored them at −20°C until the assay. After the urines thawed, we agitated them thoroughly at room temperature and centrifuged them for 10 minutes at 1,000×*g* to remove insoluble materials.

RESULTS

Preparation of Conjugates

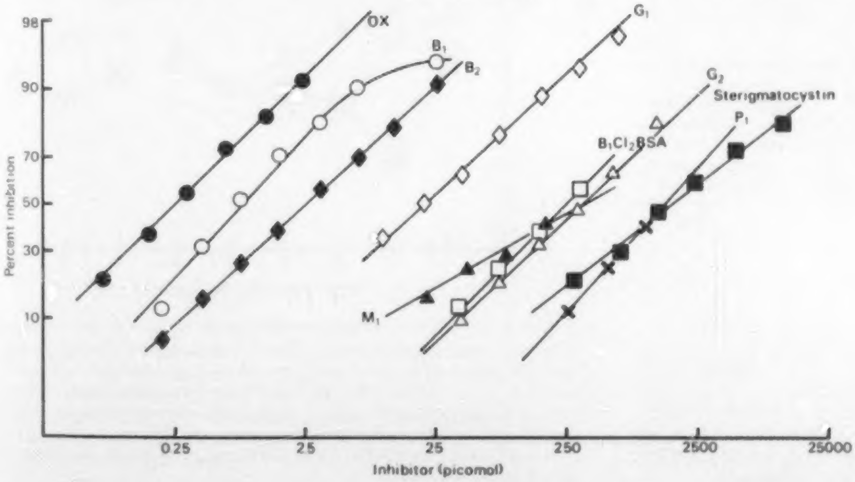
As shown in text-figure 2, the major peak of absorption of the C-conjugate was 405 nm, identical to that found by Swenson et al. (*16*). The amount of AFB_1Cl_2 coupled to BSA was 10.5%. The number of AFB_1 molecules per BSA molecule was 23 for the O- and 14 for the C-conjugate.

Antisera

In double-gel diffusion, C-antiserum precipitated both the corresponding conjugate and BSA (fig. 1). After addition of BSA to the C-antiserum, no more precipitation against the carrier protein was observed, whereas there was still a precipitin line against the conjugate. O-antiserum did not precipitate BSA or O- or C-conjugates. In RIA, dilutions of 1:2,000 O-antiserum and 1:1,800 C-antiserum were capable of precipitating 50% of the tracer (text-fig. 3). We selected these dilutions for inhibition assays. The coefficients of affinity were 2.5×10^9 for the O-antiserum and 2×10^9 for the C-antiserum. Since the presence of anti-BSA antibodies in C-antiserum did not modify the titration curves (data not shown), all assays in which C-antiserum was used were performed with the crude antiserum.

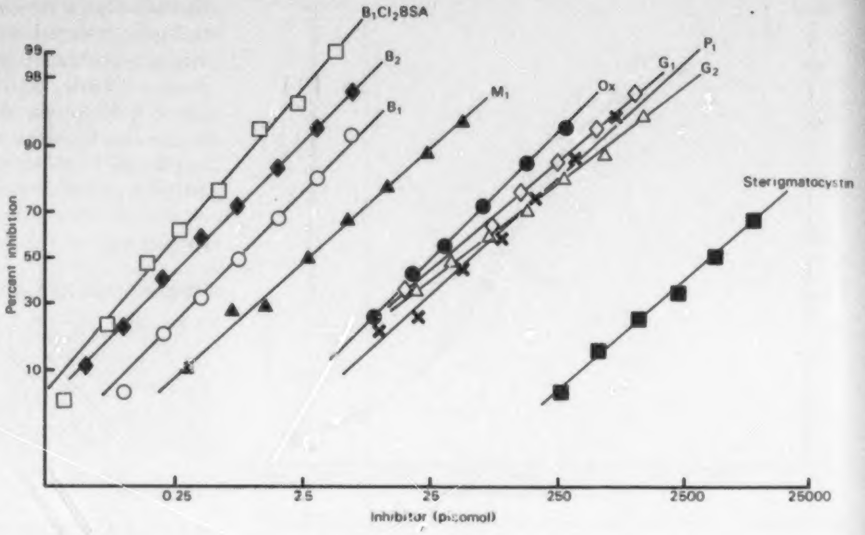
Mycotoxin Assays

The amounts of AFB_1 that inhibited the $[^3H]AFB_1$ precipitation by 50% were 0.72 pmol for the O-antiserum and 0.8 pmol for the C-antiserum (text-figs. 4, 5). As expected, other mycotoxins cross-reacted to various degrees with both



TEXT-FIGURE 4.—Dose-response curves of various AF and sterigmatocystin obtained by RIA with $[^3H]AFB_1$ as tracer; the O-antiserum was raised in a rabbit with the use of AFB_1 oxime–BSA derivative as immunogen. OX=AFB_1 oxime; B_2=AFB_2; G_1=AFG_1; M_1=AFM_1; B_1Cl_2BSA=AFB_1-8,9-dichloride-BSA conjugate; G_2=AFG_2; P_1=AFP_1.

TEXT-FIGURE 5.—Dose-response curves of various AFB$_1$ derivatives and sterigmatocystin obtained by RIA with [^{3}H]AFB$_1$ as tracer. The C-antiserum was raised in a rabbit with the use of AFB$_1$Cl$_2$-BSA derivative as the immunogen. Abbreviations are the same as in the legend to text-fig. 4.

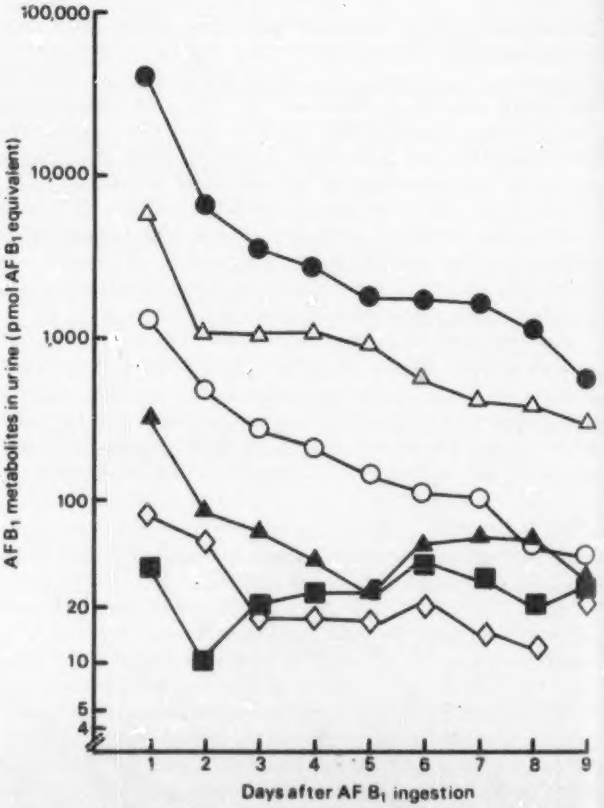


antisera (text-figs. 4, 5; table 1); with O-antiserum about 3.6 times more AFB$_2$ than AFB$_1$ was required to inhibit [^{3}H]AFB$_1$ immune precipitation by 50%, whereas with C-antiserum a smaller amount of AFB$_2$ was necessary. This reduction was not due to the use of higher (AFB$_2$) or lower (AFB$_1$) concentrations of mycotoxin than those stated by the producer, as checked by spectrophotometry. AFG$_1$ cross-reacted with each of the antisera in a rather similar way; however, the lack of a double bond between C8 and C9 considerably diminished the cross-reactivity of AFG$_2$ with O-antiserum, whereas only a slight decrease was observed with C-antiserum compared to AFG$_1$. AFM$_1$ cross-reacted to a large extent with the C-antiserum, which is in keeping with results of Lawellin et al. (*20*) who used AFB$_{2a}$ oxime-BSA conjugate as immunogen. However, the presence of the hydroxyl group at C10 decreased the immune precipitation of [^{3}H]AFB$_1$ by O-antiserum proportionally more. Similarly, AFP$_1$ cross-reacted more with C-antiserum than with O-antiserum. In general, the doses of AFM$_1$ and AFP$_1$ required to inhibit the immune precipitation of [^{3}H]AFB$_1$ by 50%

TABLE 1.—*Inhibition of [^{3}H]AFB$_1$ immune precipitation in RIA*[a]

Inhibitor	Amount of inhibitor required to inhibit tracer–antibody binding by 50%	
	O-antiserum	C-antiserum
AFB$_2$	3.6	0.42
AFG$_1$	29	34
AFG$_2$	520	49
AFM$_1$	210	3.7
AFP$_1$	2,100	60
AFB$_1$ oxime–BSA conjugate	0.35	36
AFB$_1$Cl$_2$–BSA conjugate	370	0.24
Sterigmatocystin	2,400	4,300

[a] The degrees of inhibition are expressed as multiples of AFB$_1$ quantities corresponding to the molar ratio of inhibitor:AFB$_1$. The amounts of AFB$_1$ required to inhibit tracer–antibody binding by 50% were 0.72 pmol for O-antiserum and 0.8 pmol for C-antiserum.



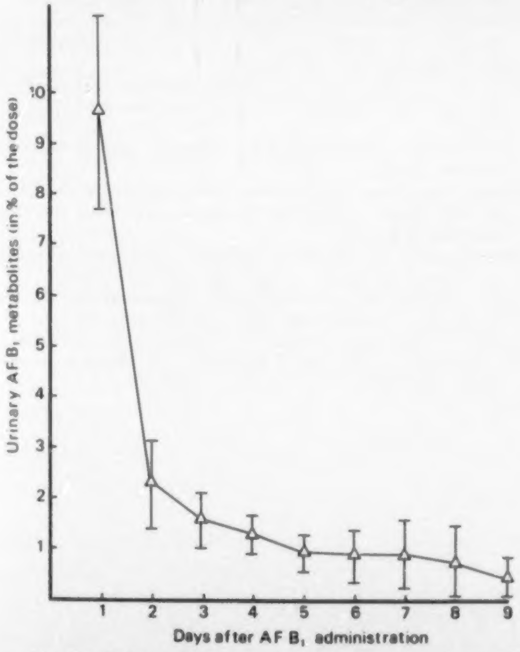
TEXT-FIGURE 6.—Daily urinary excretion of C-antiserum-cross-reacting substances in mycotoxin-treated BD IV adult male rats. On day 0, rats were given oral AFB$_1$ doses, nmol: ●—●, 385; △—△, 77; ○—○, 15.4; ▲—▲, 3.1; ◇—◇, 0.6; or ■—■, 3.1×10^3 nmol sterigmatocystin. Quantities of substances cross-reacting with AFB$_1$ excreted each day were determined by RIA and expressed as pmol of AFB$_1$ equivalent, with reference to a standard AFB$_1$ curve. Other technical details are the same as in legend to text-fig. 5.

were about fiftyfold smaller for the C-antiserum than for the O-antiserum.

The respective AFB_1 conjugates reacted primarily with the corresponding antisera and, on a molecular basis, were even more potent than AFB_1. BSA produced no inhibition at a 500-fold higher molar concentration than that where AFB_1 caused 50% inhibition of the tracer by C-antiserum. This observation confirms that anti-BSA antibodies present in C-antiserum do not interfere with the toxin–antitoxin reaction.

Assays of Rat Urines

Amounts of AFB_1 cross-reacting substances excreted in the urine of rats treated with AFB_1 (600 pmol–385 nmol) and with 3.1 µmol sterigmatocystin are indicated in text-figure 6. Since the inhibition of immune precipitation of $[^3H]AFB_1$ is likely to be due to AFB_1 urinary metabolites, results are expressed as AFB_1 *equivalent*, i.e., amounts of AFB_1 giving equivalent degrees of inhibition. In rats treated with AFB_1, there was an obvious relationship between the dose administered and the "AFB_1 potency" of urines, which decreased with time. Urines of the rats treated with sterigmatocystin also exerted some inhibition on the immune binding of $[^3H]AFB_1$. However, this inhibition was weaker than that of the rats having received the four highest doses of AFB_1 and was relatively stable with time. Text-figure 7 shows the excretion of AFB_1-like substances in the urine of those 4 rats, expressed as the mean value ± standard deviation of doses administered. Amounts less than 1% of the dose could still be detected 9 days after AFB_1 administration.



TEXT-FIGURE 7.—Daily urinary excretion in AFB_1-treated rats of substances cross-reacting with C-antiserum. Quantities excreted by the 4 rats treated with AFB_1 doses ranging from 3.1 to 385 nmol (*see* text-fig. 6) were used for the calculation of daily urinary excretion ± SD as percentage of administered doses. RIA was performed as indicated in legends to text-figs. 5 and 6.

DISCUSSION

The stronger reactivity of AFB_1 conjugates with their respective antisera, as compared with AFB_1, is probably due to the presence of several hapten epitopes on each molecule of the carrier protein. We think that the slight cross-reactivity observed with the sterigmatocystin can be explained by the polyclonality of both antisera: It is likely that those parts of the sterigmatocystin molecule that are similar to AFB_1 structures can compete with $[^3H]AFB_1$ for antibody binding.

Landsteiner (*21*) has shown that changes in the structure of haptens that take place near the site of attachment to carrier proteins have little effect on their capacity to react with antibodies directed against the unmodified structure. Swenson et al. (*16*) have shown that AFB_1 reacts with proteins and/or DNA through AFB_1-8,9-oxide primarily at C8. To obtain antibodies that react with various AFB_1 metabolites, it is therefore logical to use conjugates as immunogen in which AFB_1 is bound to the carrier through C8. Such compounds should be able to elicit antibodies that react with parts of the AFB_1 molecule that are located opposite to the site of attachment and which are slightly or not at all modified by metabolism. The greater reactivity of most AF tested with C-antiserum, compared with O-antiserum, is likely to be due to that explanation.

In addition to free AF in the urine of rats treated with AFB_1, possible products cross-reacting with C-antiserum include conjugated AFB_1 metabolites and AFB_1-N^7-guanine (*22*). In the RIA in which we used C-antiserum, AFB_1-N^7-guanine and AFB_1-FAPY formed by hydrolysis of the imidazole ring inhibited the immune precipitation of $[^3H]$-AFB_1, giving dose-response curves parallel to the dose-response curve of AFB_1 (data not shown). For quantitation of individual urinary metabolites, it would be necessary to use specific antisera raised with corresponding immunogens in which haptens are coupled to the carrier protein in the appropriate position.

Dilutions of urines from AFB_1-treated rats that gave 50% inhibition ranged from 1:11 to 1:1,330. At 1:11 dilution, some urine samples from rats that did not receive AFB_1 were also weakly inhibitory (data not shown), corresponding to a maximum theoretical excretion of about 40 pmol AFB_1 equivalent/day. We therefore considered this level to be the "background" level. The level was not increased by administration of the DMSO–olive oil mixture we used as the AFB_1 vehicle. Under the conditions of our experiment, daily urinary excretion of amounts below the background level probably does not indicate exposure of rats to AFB_1. Similar levels were found in the urine of rats that received 600 pmol AFB_1 1 or 2 days previously, which gives an indication of the sensitivity limit of the method.

Why the urine from "normal" rats inhibited slightly the binding of $[^3H]AFB_1$ to antibodies is not known; since the diet was not checked, it is impossible to rule out the presence of small amounts of AFB_1 in the regimen. A more probable explanation is the presence of non-AFB_1-derived but somewhat structurally related compounds in the urine.

If allowance is made for a nonspecific inhibition, it is apparent from text-figure 6 that substances, capable of "specific" inhibition of [^{3}H]AFB$_1$ binding to C-anti-AFB$_1$ antibodies, are released into the urine in increasing quantities with increasing doses of AFB$_1$.

For various reasons, few attempts have been made to isolate AF metabolites in the urine of humans. Campbell et al. (*23*) isolated AFM$_1$ by chloroform extraction and thin-layer chromatography from the urine of individuals who had eaten peanut butter contaminated with AFB$_1$. The results were positive only when more than 48 nmol AFB$_1$ was ingested per day, and no more than 1-4% of AFB$_1$ was excreted in the urine as AFM$_1$. With an assumption of similar yields and a daily excretion of 1,100 ml of urine per person, and depending on the amounts ingested ($\leq$610 nmol), the samples analyzed would have been expected to contain from 0.1 to about 5 pmol of AFM$_1$/250 μl urine. By comparison, with experimental models, it can be anticipated that urines from exposed individuals contain not only chloroform but also water-soluble AFB$_1$ metabolites—both of them theoretically capable of reacting with antibodies present in C-antiserum. However, it is not yet clear whether the technique we used would be suitable for screening purposes.

Our preliminary results were obtained with a technique that has the advantages of not requiring prior clean up or volume reduction of the urine, and its sensitivity can be increased by various refinements, such as solid-phase methods (*24, 25*). We consider these sufficient justifications for further efforts in this direction.

Carcinogenic Effect of Carbazole in the Liver of (C57BL/6N × C3H/HeN)F_1 Mice[1,2,3]

Hiroyuki Tsuda,[4] Akihiro Hagiwara,[4] Michiko Shibata,[4] Masato Ohshima,[4] *and* Nobuyuki Ito[4]

ABSTRACT—The carcinogenic effect of carbazole (9*H*-carbazole) in (C57BL/6N × C3H/HeN)F_1 (B6C3F_1) mice was examined. Groups of 50 mice of both sexes were given a basal diet containing 0.6, 0.3, or 0.15% carbazole for 96 weeks and were then placed on an unsupplemented basal diet until they were killed at week 104. Mice surviving longer than 52 weeks were included in effective numbers. Significant increases in the induction of neoplastic lesions were found in the livers and forestomachs of mice given carbazole as compared to the control groups. The lesions in the livers were classified into two types, neoplastic nodules or hepatocellular carcinomas. The incidences of both types of lesions were almost 100% in mice treated with carbazole, and both types of lesions were significantly increased in all mice except the males given 0.6% carbazole in their diet. The incidences of hepatocellular carcinomas were in general higher than those of neoplastic nodules. Though not statistically significant, increased incidences of pulmonary metastases were found in the groups given carbazole. Significantly increased incidences of neoplastic lesions and papillomas in the forestomach in all groups of female and male mice were also noted in the mice fed 0.6% carbazole. Squamous cell carcinoma induction was significantly different in male mice given 0.6% carbazole as compared to controls. These results indicate that carbazole is carcinogenic to the liver and forestomach in B6C3F_1 mice and suggest that carbazole may be an environmental carcinogen relevant to cancer risk in humans.—JNCI 1982; 69:1383–1389.

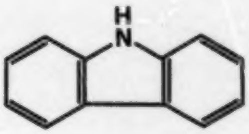
Carbazole (9*H*-carbazole) is widely used industrially as a dye intermediate and is also used in making photographic plates sensitive to UV light. A detectable amount of carbazole was found in air emissions from factories and automobiles and was mixed with many carcinogenic polycyclic aromatic hydrocarbons (*1*). 7*H*-Dibenzo[*c,g*]carbazole, a derivative of carbazole, was found to be present in cigarette smoke (*2*). Since the carcinogenicity of 7*H*-dibenzo[*c,g*]carbazole was first demonstrated by Boyland and Brues (*3*) in mouse skin, evidence for its carcinogenicity has been increasing. The carcinogenicities of several derivatives of carbazole have also been examined, and nitrogen derivatives have been shown to be carcinogenic in mice (*4*). Sellakumar et al. (*5*) also have reported that 7*H*-dibenzo[*c,g*]carbazole when instilled intratracheally induced squamous cell carcinoma in the trachea and bronchi of Syrian golden hamsters of both sexes.

Extensive experimental and clinical studies have been done on the pharmacologic effects of a wide variety of carbazole derivatives. Results showed that these compounds have anti-inflammatory, antiasthmatic, and antiviral effects (*6–8*). They also have antidepressant activity associated with norepinephrine reuptake and amine oxidase (flavin containing) inhibition (*9*). The practical use of carbazole in the chemical industry and the therapeutic use of carbazole-related compounds prompted us to investigate its carcinogenicity in mice fed this compound in a long-term test.

MATERIALS AND METHODS

Animals and diet.—Five-week-old (C57BL/6N × C3H/HeN)F_1 (B6C3F_1) mice of both sexes were obtained from Charles River Japan Inc., Atsugi, Japan. The animals were housed 5 to a plastic cage with wood chips for bedding in an air-conditioned room at controlled temperature (23±1°C) and humidity (55±2%) with a 12-hour light–12-hour dark cycle. Animals were given commercial diet (Oriental M; Oriental Yeast Co., Ltd., Tokyo, Japan) for 1 week before the experiments were begun and tap water ad libitum throughout the experiment.

Chemical.—Carbazole, technical grade at 96% purity, was purchased from Nihon Jyoryu Kogyo Inc., Ichikawa, Japan. It was mixed with Oriental M powdered diet. The chemical structure of carbazole is shown in text-figure 1.



Carbazole

TEXT-FIGURE 1.—Chemical structure of carbazole.

Treatment.—From the age of 6 weeks, groups of 50 mice of each sex were given a diet containing 0.6, 0.3, or 0.15% carbazole. An additional 50 age-matched animals of each sex were fed basal diet without carbazole. Body weight and food consumption were measured weekly throughout the experiment. Animals were fed a carbazole-containing diet for 96 weeks and unsupplemented basal diet for the next 8 weeks and were killed when ether anesthetized (in experimental wk 104). All organs were removed, fixed in 10% buffered Formalin, and routinely stained with H & E for histologic examination. Animals that died or became moribund during the experiment were also autopsied, and mice surviving longer than 52 weeks (the time at which the first liver tumor was found in an animal that subsequently died) were included in effective numbers.

ABBREVIATION USED: H & E=hematoxylin and eosin.

RESULTS

Annual Maintenance Data

Food consumption.—There were no consistent differences in the food consumption of either sex in any group during the experiment. The mean food consumption and cumulative carbazole intake are shown in table 1. The total intake of carbazole was approximately proportional to its concentration in the diet (table 1).

Body weight.—The mean body weights of female mice given carbazole were lower for mice fed the higher carbazole concentrations; the dose-dependent effect was clear after week 72. However, from weeks 40 to 72, the body weights of the animals given 0.15% carbazole were higher than those of the controls. Males showed a proportional decrease in body weight as the concentrations of carbazole were increased.

Survival time.—Survival rates for both sexes decreased significantly with increasing concentrations of carbazole during the later stages of the experiment. The main cause of death was massive intraperitoneal hemorrhage due to rupture of liver tumors. All mice given 0.6% carbazole died before the end of the experiment (text-figs. 2, 3).

Histopathologic Findings

Neoplastic lesions in the liver.—Classification of lesions: The neoplastic lesions in the liver observed in the present experiment were tentatively classified histologically into two types: neoplastic nodules and hepatocellular carcinomas.

Neoplastic nodules, occurring either as a single lesion or as multiple lesions, consisted of a proliferation of hepatocytes. They varied in size from small, microscopic lesions to those so massive as to involve a complete liver lobe. The cellular arrangement of the lesions varied from closely packed single liver cell plates that differed little from normal liver structure (fig. 1) to more atypical cells in multicell layers that were devoid of an obvious central vein (terminal hepatic vein) or portal triad (fig. 2). The latter more atypical cells showed expansive growth and compressed the surrounding areas as compared to the former closely packed single liver cell plates.

Hepatocellular carcinomas had a trabecular or papillary structure with cellular or nuclear atypism (fig. 3). Some of these lesions directly invaded the surrounding liver tissue or metastasized to the lung (fig. 4) or adrenal gland.

Incidence of lesions: The results in table 2 show that the incidence of neoplastic nodules was significantly higher in mice of both sexes when treated with any of the carbazole doses used here except in males treated with the highest dose of carbazole (0.6%). Carbazole had a clear dose-dependent effect on the induction of neoplastic nodules in females.

The incidence of hepatocellular carcinomas was also significantly different from that in controls of both sexes. It was highest (77.1%) in males given 0.6% carbazole, whereas it was 4.4% in female controls and 19.6% in male controls. Though no clear dose-dependent effect of carbazole was found in females, the incidence of hepatocellular carcinomas was very high in all test groups, irrespective of the dose.

TABLE 1.—*Food consumption and carbazole intake*

Sex	Carbazole dose, %	Mean food consumption, g/mouse/day					Average food consumption of all wk, g/mouse/day	Average cumulative dose, g/kg body wt
		Wk 1	Wk 40	Wk 80	Wk 96	Wk 104		
Female	0.6	4.3	4.3	5.8	8.7	—[a]	5.8	747.1
	0.3	4.5	4.9	5.7	8.6	6.1	5.9	366.4

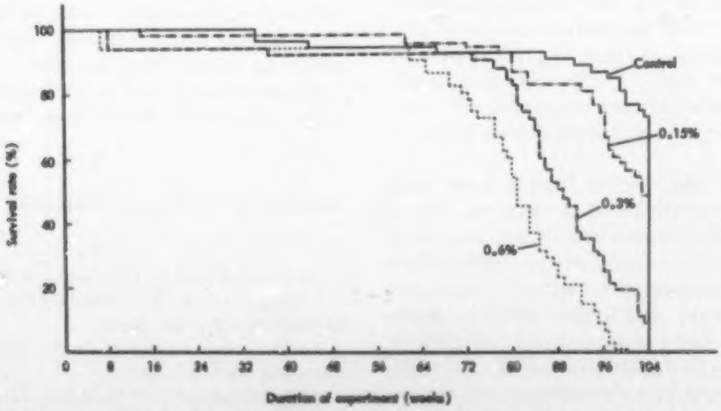
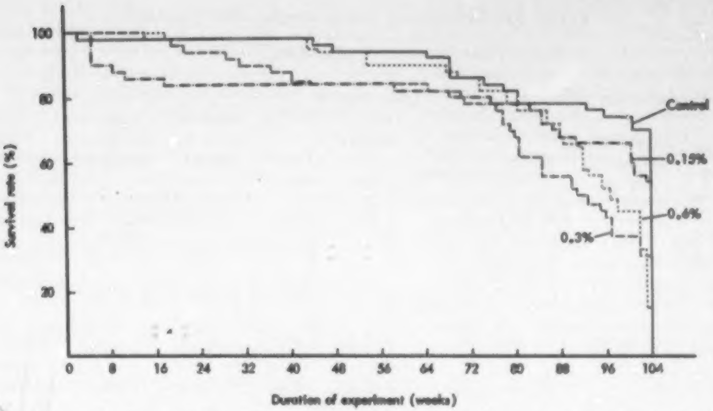
	0	4.1	5.3	5.2	5.7	5.7	5.5	0

[a] All mice died before wk 104.



TEXT-FIGURE 2.—Survival times for females. Percentages of carbazole in the diet are indicated.



TEXT-FIGURE 3.—Survival times for males. Percentages of carbazole in the diet are indicated.

Many mice with hepatocellular carcinomas had metastases to other organs, especially to the lung, and the incidence of metastasis was significantly higher in males given 0.3% carbazole and in females at all carbazole doses tested. Neoplastic nodules and hepatocellular carcinomas did not differ morphologically between experimental and control groups.

Neoplastic lesions in organs other than the liver.—Table 3 shows the incidences of neoplastic lesions in organs other than the liver. The incidence of papillomas of the forestomach was significantly higher in all groups of females given carbazole and for the group of males given 0.6% carbazole than it was in controls. Squamous cell carcinoma of the forestomach showing invasion to the submucosal layer was also significantly increased in males given 0.6% carbazole (fig. 5). The incidence of lymphoma-leukemia was significantly lower in females given 0.6% carbazole. The incidences of tumors in organs other than the liver and forestomach (e.g., lung adenomas or adenocarcinomas, fibrosarcoma-like lesions, uterine fibromas, thyroid adenomas, harderian gland tumors, and adrenal cortical adenomas) were not significantly different from those of controls of either sex in any of the 4 groups.

DISCUSSION

This study clearly showed that carbazole is carcinogenic to mice of both sexes. Several reports have revealed that some carbazole derivatives are carcinogenic under certain conditions (*2–5*). Therefore, the carcinogenic action of carbazole is not unexpected. However, because carbazole is used as an intermediate in the synthesis of dyes, drugs, and photosensitive materials and because it is also present in automobile emissions as an air pollutant (*1, 2, 10*), it may be hazardous to humans as an environmental carcinogen.

The neoplastic lesions seen in this study were classified as neoplastic nodules and hepatocellular carcinomas. This classification warrants some comment. Walker et al. (*11*) classified mouse hepatic neoplasias into two types, A and B, depending on their histologic characteristics. This classification has been generally accepted (*12, 13*), and both types of nodules are transplantable, with a greater percentage of "takes" of the type B nodules, suggesting their more malignant nature (*14*). It was also noted that type A lesions could be differentiated further into two additional types depending on whether the liver cells were arranged as a single layer (type 1) or as multiple layers (type 2) in plates (*15*). The

[e] $P < 0.001$, χ^2 test.

lesions diagnosed as neoplastic nodules in this study include both type 1 and type 2 hyperplastic nodules because in some sections these two types were seen together, making it difficult to distinguish one from the other. Lesions showing well-defined trabecular patterns were classified as hepatocellular carcinomas, inasmuch as they invaded surrounding liver tissue or metastases with high incidence. These lesions correspond to the type B nodules of Walker et al. (*11*). According to Ward's recent investigation (*16*) on the classification of liver tumors in B6C3F$_1$ mice, the tumors were grouped into two main types, hepatocellular adenomas and hepatocellular carcinomas, with further subgroups, tumors with basophilic or eosinophilic cytoplasm. Neoplastic nodules and hepatocellular carcinomas seem to correspond to hepatocellular adenomas and hepatocellular carcinomas, respectively, by their histologic characteristics (*16, 17*).

Incidences of spontaneous tumors in the liver and other organs are not very different from those reported in another study (*18*). Ward (*16*) and Ward et al. (*17*) also reported that neoplastic lesions in the stomach were very low, close to zero.

When specimens had both neoplastic nodules and hepatocellular carcinomas, the more advanced lesion, hepatocellular carcinoma, was used for scoring purposes. Thus in the specimens with hepatocellular carcinomas, the effect of carbazole on the induction of neoplastic nodules was quantitatively assessed conservatively. The total incidence of neoplastic nodules was similar to that of neoplastic nodules plus hepatocellular carcinomas, i.e., almost 100%, in both sexes of mice given carbazole. Therefore, it could be concluded that carbazole is carcinogenic to mouse liver. Inasmuch as the induction of liver tumors in mice is considered as valid evidence of carcinogenicity, as is the induction in rats and/or hamsters of tumors at any site (*16*), carbazole could have carcinogenic effects in other animals including humans. This might also be applicable to the induction of papillomas and squamous cell carcinomas of the stomach because no such lesions were found in the control animals.

ADDENDUM

While this manuscript was in preparation, carbazole was shown at the National Institute of Hygienic Sciences to cause chromosome aberrations in the Chinese hamster fibroblast cell line CHF (Ishidate M: Personal communication).

Hormone Requirements of the Pregnancy-Dependent Mammary Tumor of GR/A Mice: An In Vitro Study[1,2,3,4]

John W. Harbell,[5,6] Jackie S. Papkoff,[5,7] *and* Charles W. Daniel[5,8]

ABSTRACT—The hormones required for cell replication and structural integrity of the inbred GR/A mouse strain-derived, pregnancy-dependent mammary tumor (PDT) were studied with the use of explant organ culture. Through 6 days of culture, a combination of insulin (I), progesterone (P), and prolactin was sufficient to maintain continued cell replication, tissue architecture, and cell integrity. In contrast, the GR/A pregnancy-independent mammary tumors (PIT) required only I to sustain cell replication. Syngeneic transplants of PDT explants after culture yielded predominantly ductal outgrowths with no PIT. These findings are consistent with data obtained in vivo and suggest that the extreme dependence of this tumor on the hormones of pregnancy is best accounted for by considering P to be the pivotal control hormone which, in turn, acts with constitutively present I and pregnancy-stimulated pituitary and placental prolactin activities to promote tumor growth.—JNCI 1982; 69:1391–1402.

The PDT of inbred RIII (*1*), DD (*2*), and GR/A (*3*) mice constitute a unique class of tumors with respect to their extreme hormone dependence. During pregnancy these tumors grow rapidly within the mammary fat pad until parturition, when growth abruptly ceases. The tumors then spontaneously regress, leaving a residue of ductal growth that is similar in appearance to the normal mammary gland of nonpregnant mice. By comparison, mammary adenomas and carcinomas may arise sooner or with increased frequency under the influence of certain hormones, but once induced they show little or no dependence on these hormones for their continued growth (*4*, *5*).

The demonstration by van Nie and Thung (*6*) that exogenous steroid hormones could promote the reappearance of regressed GR/A PDT in nonpregnant hosts strongly suggested that the hormone milieu of pregnancy was the primary promoting agent for their growth. Since this initial study, other workers have attempted to further define the hormone requirements for PDT growth, especially the possible involvement of pituitary and placental hormones (*7–9*).

The present study was done in vitro, with the use of explant organ culture, to obtain a more precise definition of the hormonal milieu and to allow multiple explants from a single primary tumor to be studied under many conditions simultaneously. Explant organ culture rather than monolayer culture was chosen to maintain normal tissue structure and cell interactions. The effects of various hormone concentrations were compared by measurement of the $[^3H]$-thymidine LI and by use of light microscopy and electron microscopy to study structural changes.

MATERIALS AND METHODS

Inbred GR/A mice for breeding were obtained from the Cancer Research Laboratory, University of California, Berkeley. Pregnant females 4–8 months old bearing a spontaneous PDT, usually measuring less than 1 cm across, were anesthetized with Metofane (Pitman-Moore, Inc.) or Nembutal (Abbott Laboratories). Most of the tumor was removed and placed in warm culture medium, while the remaining portion was left in the donor to verify regression after parturition. Following recovery and later delivery of her pups, the donor was monitored by palpation to verify complete regression of the PDT.

The portion of the tumor removed for culture was sliced with a razor blade first into slabs and then into 2-mm explants. All explants were placed in a petri dish partially filled with warm medium. The PDT pieces remained on the dish bottom, whereas any explants of normal tissue that may have been inadvertently taken floated because of their high fat content. Explants of PIT were prepared in the same way from tumors taken from nonpregnant donors 4–8 months old.

Explants were cultured by means of a roller tube culture method previously described (*10*). Each explant was cultured individually in a 16 × 125-mm screw-capped culture tube (Corning Glass Works) containing 5 ml of medium 199 (M.A. Bioproducts) buffered with 20 m*M* HEPES (Sigma Chemical Co.)-5 m*M* bicarbonate and containing 50 IU penicillin/ml and 50 μg streptomycin/ml. A mixture of 95% O_2–5% CO_2 was bubbled through the medium in each tube for 10 seconds, and the tube was sealed. Every 2 days the medium was replaced and the gas saturation renewed.

Hormones were prepared according to standard methods.

ABBREVIATIONS USED: BGH=bovine growth hormone; C=corticosterone; E=17β-estradiol; H=hydrocortisone; HCS=human chorionic somatomammotropin; HEPES=4-(2-hydroxyethyl)-1-piperazine ethanesulfonic acid; I=insulin; LI=labeling index (indices); MCS=mouse chorionic somatomammotropin; oPrl=ovine prolactin; P=progesterone; PDT=pregnancy-dependent mammary tumor(s); PIT=pregnancy-independent mammary tumor(s).

[8] We thank Mrs. Phyllis Strickland and Mrs. Patsy Bolt for technical assistance and Dr. Edith Markoff for advice and encouragement.

The Lente preparation of bovine–porcine I (Eli Lilly & Co.) was used as supplied. C, H, P and E (all from Sigma Chemical Co.) were dissolved in 95% ethanol. BGH (NIH-GH-B17) was dissolved in 0.001 *N* sodium hydroxide, whereas oPrl (NIH-PS-10) and HCS (ICN Pharmaceuticals Inc.) were dissolved in HEPES-buffered water.

Tissue for autoradiography was pulsed with 1 μCi/ml of 60 Ci/mmol [^{3}H]thymidine (New England Nuclear Corp.) for 3 hours just before fixation in Tellyesniczky's fluid. After extensive rinsing, the explants were embedded, sectioned, and processed for autoradiography.

In determining the LI, we found it necessary to take into account variations in cell density that developed with time in culture, particularly in those hormone combinations that favored cell replications (*see* figs. 1–5 and tables 1–3). Areas where the cell density was greatest frequently showed less overall labeling, with more localization of the label into the peripheral layers (≈8 cells deep). Less dense areas frequently showed a more uniform pattern of labeling, presumably due to increased diffusion of precursor nutrients. When determining the LI for different treatment groups, therefore, we always selected for counting areas of similar morphology.

We determined the LI after counting 3,000 cells, consisting of either 1,000 cells from each of three explants or 1,000 cells from each of three widely separated sections of the same explant. Whereas the former method was more desirable, the usual PDT was often too small to permit more than one explant for each time point of a given hormone combination.

Pilot studies using five separately cultured replicate explants to a group yielded a standard deviation of the LI mean of 13% when the LI mean was less than 10% and 10% for LI means above 10%. In addition, the relative proportions of mitotic figures paralleled changes in the LI.

To compare the mean LI (derived from the three 1,000-cell counts) promoted by the different hormone combinations at a given time point, we used the new Duncan-Kramer multiple-range test. This test was chosen so that the large number of treatment groups could be accommodated and because no group could be designated as the base line or control to which the others could be compared. We used the 95% confidence limit throughout the study.

For ultrastructural analysis, explants were fixed in cold 2% glutaraldehyde in 0.074 *M* (314 mosmol) cacodylate buffer at pH 7.4 overnight, followed by postfixation in cold 1% osmium tetroxide in 0.01 *M* cacodylate buffer for 2 hours. After washes and dehydration, each explant was embedded in Epon–Araldite (*11*). Silver sections were stained in uranyl acetate and lead citrate for 10 minutes each.

In some experiments, samples of PDT were transplanted after 6 days in culture into the cleared mammary fat pads of syngeneic female hosts by means of the technique of DeOme et al. (*12*) to detect in vitro selection for the PIT state.

RESULTS

Effects of Pharmacologic Concentrations of Hormones on DNA Synthesis

In the initial series of experiments, PDT explants were subjected to a wide range of hormone combinations, and the data from a representative experiment are given in table 1. With the exception of P and estrogen, these hormones were used at pharmacologic concentrations (*13, 14*).

I and glucocorticoids.—I alone could not sustain a high LI; after 2 days in culture, the LI had dropped precipitously, and by days 4 and 6 it had fallen below 3%. I+C was somewhat more effective through day 2 but allowed a similar LI decline by days 4 and 6. Rather than sustaining even limited PDT maintenance, I+H induced a rapid and consistent depression in the LI and marked degeneration of the tumor epithelium.

[b] Hormone concentrations: I=0.14 IU/ml; C and H=1 μg/ml; P=31 ng/ml; E=27 pg/ml; and oPrl, BGH, and HCS=5 μg/ml.

[c] Donor LI=28%.

[d] HP=highly papillomatous, MP=moderately papillomatous, D=dense, SD=slightly dense, and MD=moderately dense.

Ovarian steroids.—In combination with I, P was the most effective hormone in maintaining a high LI. Not only did I+P promote an LI higher than that obtained with any other two hormones, but also the epithelium within the explant became very dense by the 4th day in culture. In the absence of P, no hormone combination was able to sustain a high LI.

Estrogen did not act alone or in combination with other hormones to produce a significant stimulatory or inhibitory effect on the PDT LI.

Prolactin, growth hormone, and HCS.—While ineffective in the absence of P, oPrl, BGH, and HCS, in combination with I+P, characteristically promoted the highest sustained LI throughout the culture period. At 5 μg/ml, all showed rather similar stimulatory activities. There were, however, a minority of PDT that were maintained as well by I+P as by I+P + the protein hormones.

Effects of Physiologic Concentrations of C and Pituitary Hormones on DNA Synthesis

The second series of PDT maintenance experiments shown in tables 2–4 was undertaken to examine certain specific aspects of hormone-promoted maintenance. Among these were trials to determine the requirement for I and the effects of oPrl, BGH, and C at physiologic concentrations.

Pituitary hormones.—The data in table 2 show the clear difference in PDT LI maintenance between oPrl and BGH, in combination with I and P, when the concentration of each was reduced to 250 ng/ml. In contrast, to the relative parity in stimulation at 5 μg/ml (table 1), at this lower concentration only oPrl showed synergism with I+P. In addition, the inability of C to substitute for P was clearly demonstrated.

C.—In subsequent cultures (table 3), a concentration of 35 ng/ml was used, which was approximately equal to the physiologic concentration of free hormone reported by Barlow et al. (*15*).

I.—Both active and inactive hormone combinations were tested with and without I (table 4). After only 2 days in culture, the differences in LI and structural maintenance of the PDT epithelium were dramatic. By the 4th culture day, explants of medium without I were largely degenerated. The I synergism with P (or P + prolactin) was observed with I concentrations as low as 14 μIU (data not shown).

Morphologic Changes and Cell Selection in Culture

The third series of PDT maintenance experiments centered on structural changes during culture and characteristics of outgrowths of cultured tumor explants after transplantation into cleared fat pads of syngeneic female hosts.

In situ, PDT were characterized by hyperplastic ducts several to many cells thick, which grew through a connective tissue matrix (fig. 1). With time in culture, morphologic changes occurred to yield areas of dense, unstructured epithelium as well as papillomatous and hyperplastic ducts (fig. 2), sometimes within a single explant. Variations in cell density markedly affected cell labeling, with dense areas commonly showing less overall labeling, with more localization of the label into the peripheral layers (figs. 3–5). Morphologic observation at each time point for a given hormone combination given in tables 1–3.

In two separate experiments, ultrastructural features of PDT explants were examined after culture in I, I+P, I+P+E, I+P+oPrl, and I+P+E+oPrl up to 6 days (hormone concentrations as in table 3). Thick sections were prepared and areas of similar morphology selected for thin sectioning from each treatment group.

Figure 6 shows cell clusters from a PDT explant fixed directly from the donor in the 14th day of pregnancy. The tumor epithelium could be divided into two cell classes on the basis of cytoplasmic staining properties. Dark cells were characterized by uniformly electron-dense cytoplasm which resulted from a high density of particles about the size of free ribosomes. The second and largest class, light cells, showed a more sparse distribution of these particles. Both cell types contained rough endoplasmic reticulum and Golgi complexes as well as occasional A-particles. B-particles were often observed budding into lumina.

After culture in I alone or I+H, considerable degeneration was manifest. As seen in figure 7, extensive autolysis was present in many cells. The mitochondria were swollen and had lost much of their internal structure. Large masses of degenerating cytoplasmic debris as well as lamellar inclusions were found in several cells in each field. Nuclear degeneration was not readily apparent by days 4 and 6.

Explants cultured in I+P+oPrl, I+P+E+oPrl, and I+P+E+HCS (fig. 8) stood in sharp contrast to those cultured in I or I+H. Gross degeneration was absent, and very few cells showed any signs of autolysis. Some cells did contain vacuoles, though for the most part other cytoplasmic components were very much intact. Both A- and B-particles were prevalent. Tumor explants in I+P or I+E+P were not as well maintained as those also receiving oPrl or HCS. Overall, a close correlation was observed between maintenance of a high LI by a hormone combination and the absence of ultrastructural degeneration.

Outgrowths of cultured PDT.—As previously described, PDT explants underwent certain morphologic changes during their period in culture. Those cultured in hormone combinations that did not support continued tumor cell replication often remained only moderately papillomatous or even regressed to a simple ductal morphology, whereas those in which active cell replication continued became very dense. The dense areas of PDT epithelium were often quite anaplastic, and it was not clear from their morphology whether or not these cells had progressed to a more neoplastic state. It was also of interest to determine whether cultures in nonsupportive conditions contained surviving tumor cells that were less hormone-dependent (e.g., PIT cells).

The cleared fat-pad transplantation technique of DeOme et al. (*12*) provided a means to examine cultured PDT explants for changes in growth potential. Using this technique, we transplanted representative explants from several experiments after 6 days in culture. Explants maintained in the full range of hormone combinations were used: highly active (I+P+oPrl, I+P+E+oPrl, and I+P+E+HCS), moderately active (I+P, I+P+E, I+P+BGH), and nonsupportive (I, I+H, I+oPrl, I+BGH, I+E+oPrl, and I+E).

No PIT growth was observed in any of the outgrowths of cultured PDT tissue, and after 4 months the hosts were bred and the glands removed between days 10 and 15 of gestation. After fixation and staining, the outgrowths were examined as wholemounts.

Most outgrowths were predominantly PDT or PDT with some tissue that resembled normal gland (fig. 9). A few outgrowths were entirely normal, though no consistent pattern between in vitro maintenance and these normal outgrowths was observed. Even PDT explants taken directly from a pregnant donor sometimes gave rise to normal outgrowth (Harbell JW: Unpublished observation), so the absence of PDT growth in these transplants did not necessarily indicate the loss of tumor burden as a function of the culture conditions.

PIT culture.—Unlike the PDT, the PIT was not expected to require the hormones of pregnancy and perhaps not even the mammotropic hormones of the nonpregnant female. The requirement for only constitutive hormones to sustain the PIT would stand in clear contrast to those hormones required by the PDT. Hormone combinations were selected to include those that would maintain the PDT and those that clearly would not.

The data from one such experiment are shown in table 5. In contrast to the results of a similar PDT culture (table 4), the PIT was about equally sustained by all hormone combinations that contained I. The requirement for I appeared to be absolute, irrespective of which other hormones were added.

DISCUSSION

The organ culture technique has proved to be a reliable method for investigations of hormonal requirements of endocrine target tissues (*16*). In the present studies it was consistently found that even the most supportive hormone combinations permitted some reduction in LI over the very high rate found in some tumors in vivo. This appears to be a constraint of the organ culture system, which may be due to the fact that proliferating epithelium in explant cultures does not have unoccupied stroma available into which it can expand. As a result, proliferation is reflected in increased epithelial density in cultured explants, whereas in vivo the same proliferation would result in increased tumor size. In isolated instances (table 1; P+I+C+oPrl, P+I+C+E+oPrl, P+I+E+oPrl), the LI declined at 4 days in culture but increased at 6 days to a value equaling or surpassing that observed at 2 days. We cannot determine at present whether this rebound phenomenon represents a delayed response to pharmacologic doses of pituitary or adrenal hormones or is a result of sampling error associated with the explants at those time points.

The cumulative data from the maintenance experiments indicated that a combination of three hormones, I, P, and prolactin, permitted the PDT epithelial cells to continue replication in vitro. Of these three, P and prolactin have been previously implicated from in vivo studies (*3, 9, 17*), whereas the role of I has only recently been suggested (*18*).

I.—I has been shown to induce limited epithelial cell replication and to act in concert with glucocorticoids and prolactin (or placental lactogen) to promote differentiation in organ culture of normal mouse mammary gland (*19, 20*), including that from the GR/A mouse (*21*). In this study, I also provided sufficient stimulus to allow PIT cell replication to continue in a way similar to results reported for other murine mammary carcinomas (*22*). In contrast to the PIT, I alone did not sustain a high LI in PDT explants but was essential to the action of other hormones. The decline in the LI observed in PDT explants cultured in I alone was paralleled by ultrastructural degeneration, indicative of tumor regression rather than just the cessation of DNA synthesis. Thus while the transition from pregnancy dependence to pregnancy independence reduced or eliminated the need for ovarian and pituitary (placental) hormones, the I requirement was retained. I appeared to be a ubiquitous requirement of normal, PDT, and PIT GR/A mammary epithelium. Such has also been the case for most mammary tumors studied (*22*), though certain lines of the 7,12-dimethylbenz[*a*]anthracene-induced rat mammary tumor (R3230AC) showed decreased growth when exposed to I (*23*).

P and prolactin.—The requirements for P and prolactin in the promotion of PDT growth have been the subject of numerous studies (*3, 7-9, 17*). Most of these reports were concerned with the induction of regrowth from regressed PDT or steroid-induced tumors, and the determination of an effective response was based on the production of palpable or microscopically visible tumors. van Nie and Thung (*6*) were the first to show that exogenous P alone was insufficient to promote regrowth, but a combination of P and estrone was effective.

The data presented from this study demonstrated the direct action of P on PDT epithelial cells and, as suggested by the data of Yanai and Nagazawa (*8*) the data further demonstrated that P was the pivotal hormone required for growth promotion. In the absence of P no hormone combination promoted more than minimal cell replication, though with the exception of a small minority of the PDT examined, significantly more cells continued to cycle when prolactin (or HCS) was combined with I and P. Surprisingly, estrogen, which was required as an exogenous addition with P for tumor regrowth in vivo, could not be shown to exert a consistent, direct, positive influence on PDT maintenance in vitro.

If I, P, and prolactin are the hormones required for PDT growth in vivo, then one or more of them must exert its PDT growth-promoting influence predominantly during pregnancy. Since tumor growth occurs only during pregnancy (*7*), the presence of the promoting agents above the threshold level must be limited to that period. If all three hormones together are the promoting agent, then the lack of only one should be sufficient to prevent promotion or to terminate growth. Of the three, the omnipresent nature of I makes it unlikely to be the factor missing for promotion in the nonpregnant state. Changes in P and/or prolactin concentration are more likely the difference.

Serum prolactin levels have been determined for several mouse strains, in virgin females as well as throughout pregnancy (*24*). Basal serum prolactin levels vary greatly between the strains tested (27–180 ng/ml). The GR/A strain was not among the strains tested. Measurements taken during pregnancy of the C3H strain indicated elevated prolactin levels during the first 10 days, a return to almost preconception levels from days 10 to 15, and a rapid rise from day 15 to parturition (*24*). This pattern was also reported by Murr et al. (*25*) using the outbred C-stock mouse, though the absolute levels detected were over twice those reported by Sinha et al. (*24*) for the C3H strain. After parturition, the highest levels of prolactin were observed. Therefore, while the rise in serum prolactin that began during early pregnancy coincides with early induction of PDT growth, the equally high prolactin levels at parturition would not be expected to bring a cessation of tumor growth.

In contrast to the serum levels of prolactin, the serum levels of P rise and fall concurrently with the beginning of PDT growth and regression. In an unpublished study (Aidells BD) serum P levels during pregnancy of the GR/A mice followed a pattern similar to that reported by Murr et al. (*25*) for the outbred C-stock. Murr et al. found that total (bound and unbound) serum P rose from 10 ng/ml on day 0 to over 40 ng/ml on day 2. The level remained at between 45 and 55 ng/ml through day 9 and dropped to 35 ng/ml on day 10. Following this temporary decline, the level rose progressively to a maximum of 110 ng/ml on day 15. While the level declined rapidly to less than 10 ng/ml on day 19 (parturition), it was still 40 ng/ml on day 18. Thus if the threshold for P activation of PDT growth is below 30 ng/ml, the P available in the virgin would be insufficient to synergize with I and prolactin. Similarly, the reduction in the level of progesterone after day 18 of gestation would account for the cessation of PDT growth. In serum 30 ng corticosterone/ml is not comparable to 30 ng/ml in culture medium because the former is largely protein-bound while the latter is unbound.

The serum concentrations of three other hormones (C, growth hormone, and chorionic somatomammotropin) also undergo substantial increases during pregnancy. Barlow et al. (*15*) reported a dramatic rise in C levels from 0.20 μg/ml on day 10 of gestation to a maximum of 1.4 μg/ml on day 16. The level then rapidly decreased to 0.20 μg/ml on day 20. These were measurements of total serum C, of which less than 2% was unbound. Therefore, the maximum free (active) level was less than 28 ng/ml.

MCS is produced after day 6 of gestation, and its level rises rapidly while the placenta is intact (*26*). Because HCS was effective in promoting PDT growth in consort with I and P, the murine counterpart may possess similar activity. However, Aidells (*27*) has shown that early PDT growth occurred before the placenta was functional. Thus while MCS may be active in supporting PDT growth in vivo, this stimulation may result from its prolactin-like activity (*28*) rather than some unique property of this hormone.

We propose the following model for the promotion of PDT growth in the GR/A mouse during pregnancy. After conception, the elevated circulating level of P acts in association with I and elevated prolactin to promote replication of mammary epithelial cells whose transformation was previously initiated by the murine mammary tumor virus-plaque. P and MCS from the functioning placenta supplement the maternal factors and account for the rapid growth observed during the second half of pregnancy. Not surprisingly, at least some of these hormones are also responsible for the growth of the normal mammary gland during pregnancy (*21*). The cessation of active growth and subsequent regression result from the precipitous decline in circulating P just before parturition. This model is consistent with our data on the maintenance of PDT cell replication in vitro and with known changes in hormone concentrations throughout pregnancy. This model does not, however, account for the failure of exogenous P + estrogen to maintain PDT growth post partum, though regression was much slower in these supplemented hosts.

Sluyser et al. (*29*) have proposed that the hormone-dependent (steroid-induced) mammary tumor in GR mice contains both hormone-dependent and hormone-independent cells. With successive growth cycles, the percentage of hormone-independent cells increases until finally they predominate yielding a hormone-independent tumor. The PDT might also contain PIT cells, though the lack of PIT growth after regression of most PDT suggests that progression to the independent state is a subsequent rather than concurrent event to PDT induction. In addition, the failure of any hormone combination, even those combinations that would clearly not support the PDT cells, to select for appreciable numbers of PIT cells was revealed by the ductal phase outgrowths of cultured PDT explants in syngeneic hosts.

The possibility that small numbers of PIT cells may have been present cannot be ruled out, however. Transplants containing both normal and nodule cells (*30*) and normal and tumor cells (DeOme KB: Personal communication) have been shown to give rise to normal outgrowths if the percentage of normal cells was sufficiently high. Therefore, the outgrowth study might not have revealed a minority population of independent cells if their numbers were sufficiently small.

Analysis of Lymphoid Cells Responding to Virus- and Tumor-Associated Antigens in Spleens of Syngeneic Mouse Mammary Tumor Systems With Low and High Oncogenic Potentials[1,2,3]

Diana M. Lopez[4,5] *and* **Ronald D. Paul**[4,5,6]

ABSTRACT—Nylon-nonadherent cells obtained from the spleens of tumor bearers of two BALB/c mouse colonies with different oncogenic potentials were found to be the lymphocyte subclass responsive in blastogenesis to their tumor-associated antigens (TAA). Thus Thy 1-positive spleen cells from BALB/cCrgl mice that received implants of a syngeneic, chemically induced mammary tumor and BALB/cfC3H mice bearing spontaneous mammary tumors (SMT) incorporated high levels of $[^3H]$thymidine after in vitro exposure to homologous TAA preparations. These responses were evident in animals at the early stages of tumorigenesis but could not be detected in the T-cells of animals with large tumor burdens. Responses to murine mammary tumor virus (MuMTV) antigens were observed likewise in the nylon-nonadherent spleen cell population of the MuMTV-positive BALB/cfC3H mice bearing small SMT. The responsiveness to viral antigens also decreased with progression of the disease. In BALB/cCrgl mice, which have a low incidence of SMT and are devoid of intact mouse mammary tumor virions, T-lymphocytes appeared to be nonresponsive to MuMTV antigens, but nylon-adherent spleen lymphocytes were capable of being stimulated by MuMTV. The blastogenic response of these B-lymphocytes was not altered by tumor initiation or progression. Depletion studies with the use of either anti-Thy 1 or antisurface immunoglobulin sera plus complement confirmed the validity of the results observed in the nylon wool column separation studies. Flow cytometric analyses of the spleen cells of tumor-bearing mice from both colonies revealed a depression of the levels of T-lymphocytes with increasing tumor burden while there was no decrease in the percentage of B-cells. These results provided a possible explanation for the loss of blastogenic response to tumor antigens and to MuMTV observed in spleen cells of BALB/cfC3H mice with increasing tumor burden and for the unalterable responses to MuMTV that appeared in splenocytes of BALB/cCrgl mice at all stages of tumorigenesis.—JNCI 1982; 69:1403–1409.

Neoplasms induced by a single viral agent appear to have a common tumor antigen (*1–3*). In contrast, tumors induced by chemical or physical agents have been shown to possess antigens specific for each tumor (*4–6*).

Studies in several laboratories including our own laboratory (*7–11*) have indicated that in mammary tumors there may be at least three types of antigens relevant to the host defenses: virion-associated, virus-induced, and nonviral TAA. In our investigations we have used two syngeneic BALB/c colonies, BALB/cCrgl and BALB/cfC3H, in an attempt to elucidate the individual contributions of the various antigenic moieties to the development of resistance to mammary tumors. BALB/cCrgl mice and their splenocytes react to purified MuMTV in cell-mediated immune reactions (*12*). These reactivities correlated with a very low incidence of SMT. In contrast, syngeneic BALB/cfC3H mice obtained by foster nursing BALB/cCrgl mice on C3H mothers contain MuMTV particles and have a high incidence of SMT in which MuMTV can be detected. Splenocytes of these mice have low levels of responsiveness to MuMTV except after development or transplantation with SMT (*13*). Both lines of mice have similar patterns in cell-mediated immune assays to their respective TAA. Thus they show no responses before transplantation, have peaked reactivities 2–3 weeks after implantation of tumors, and fail to respond when their tumors reach maximum size (*14*). A similar pattern is also observed when spleen cells of BALB/cfC3H mice are exposed to MuMTV antigen(s) in vitro, indicating a de novo sensitization, while in BALB/cCrgl mice there appears to be a dissociation of responses to TAA and viral antigens.

The relevance of the responsiveness of lymphoid cells from BALB/cCrgl mice to MuMTV antigens has been explored in in vivo studies (*14*). Inoculation of MuMTV-positive SMT cells in MuMTV-negative BALB/cCrgl mice and in MuMTV-positive BALB/cfC3H mice resulted in a lower incidence of tumors in the MuMTV-negative BALB/cCrgl mice. Moreover, the time of appearance and the progression of the tumors were delayed in the MuMTV-negative mice.

In the present work, we have analyzed the lymphoid cells responding to TAA and to MuMTV in our model systems. Flow cytometric determinations of lymphocyte membrane markers were performed with the use of splenocytes of normal and, at different stages of tumor development, mammary tumor-bearing BALB/cCrgl and BALB/cfC3H mice.

ABBREVIATIONS USED: Con A=concanavalin A; FITC=fluorescein isothiocyanate; HBSS=Hanks' balanced salt solution; LPS Ec=lipopolysaccharide of *Escherichia coli*; MuMTV=murine mammary tumor virus; PHA=phytohemagglutin; sIg=surface immunoglobulin; SMT=spontaneous mammary tumor(s); TAA=tumor-associated antigen(s).

[6] We gratefully appreciate the excellent technical assistance of Mrs. Lynn Herbert and Mr. Mantley Dorsey, Jr. We thank Mrs. Frances Susi for typing the manuscript.

These studies, which reveal significant changes in the relative representations of spleen cell populations in animals with large mammary tumors, may provide an explanation for the results observed.

MATERIALS AND METHODS

Animals and tumors.—Geographically separated colonies of BALB/cfC3H and BALB/cCrgl mice, initially obtained from the Cancer Research Genetics Laboratory of the University of California, Berkeley, Calif., have been maintained by brother × sister mating in our laboratory for the past 8 years. The SMT line arose in a BALB/cfC3H female breeder and expresses MuMTV antigens. The syngeneic transplantable mammary tumor designated as D1-DMBA-3 originated from a hormonally stimulated preneoplastic nodule transplanted to a mouse treated with 7,12-dimethylbenz[*a*]anthracene (*15*) and has been consistently found to be devoid of complete MuMTV particles by means of immunofluorescence studies and in radioimmunoassays. Both lines of tumors are routinely transplanted in the subline of origin by sc injections of minced tumor preparations. All mice were 12–16 weeks of age.

Viral antigen and TAA preparations.—MuMTV purified by a combination of rate zonal and isopyknic centrifugations from RIII milk was provided by the Biological Carcinogenesis Branch, National Cancer Institute, Bethesda, Md., from stocks supplied by the Meloy Laboratories Inc., Springfield, Va. In our studies we used a stock containing 1 mg virus/ml. Tumor antigen extracts were prepared as previously described (*14*).

Preparation of cells.—Cells from aseptically removed spleens from normal and tumor-bearing mice were passed through a stainless steel mesh with siliconized rubber stoppers and washed through with 10 ml HBSS. Clumps were removed by filtration through loosely packed nylon fibers; the resulting suspension was centrifuged and the cell pellet subjected to a hypotonic shock for elimination of contaminating red blood cells. The cells were washed in HBSS and incubated on glass surfaces for 2 hours at room temperature for removal of adherent cells. With this procedure, the final cell population contained mainly T- and B-lymphocytes. Macrophages were reduced to less than 1% as indicated by a lipase staining (*16*, *17*) and by phagocytic studies. No remaining granulocytes could be detected with Wright-Giemsa staining.

Nylon wool column purification.—The method described by Julius et al. (*18*) was used with the modification described by Epstein et al. (*19*). The resulting nylon-nonadherent and nylon-adherent populations were characterized, respectively, as T- and B-lymphocytes by means of cell surface markers, i.e., presence of Thy 1 antigen or sIg, and by functional tests. As previously described (*19*, *20*), the nylon-nonadherent population we routinely obtain possesses 91±3 Thy 1-positive lymphocytes and 4±3 sIg-positive cells. This population responds vigorously to the T-cell mitogens PHA and Con A but not to the B-cell mitogen LPS Ec. The nylon-adherent population possesses 2±2 Thy 1-positive lymphocytes and 89±4 sIg-positive splenocytes and has high levels of responses to LPS Ec but not to PHA and Con A.

Cell-depletion studies.—The spleen cells prepared as described above were incubated for 1 hour at 4°C with a final dilution of 1:10 of goat anti-sIg (provided by the Virus Cancer Program, National Cancer Institute, from stocks supplied by the NCI-Frederick Cancer Research Facility, Frederick, Md.) and with a final dilution of 1:20 of anti-Thy 1 (Accurate Chemicals and Scientific Corporation, Hicksville, N.Y.). The cells were washed twice in RPMI-1640, and 1:10 final dilutions of Low-tox guinea pig complement (Cedarlane Laboratories, Hicksville, N.Y.) were added. The mixtures were incubated at 37°C for 1 hour. Several controls were included in all experiments, i.e., cultures with complement alone and anti-sIg or anti-Thy 1 in the absence of complement. None of the control treatments were toxic to the lymphocytes. B-lymphocytes were significantly depleted (down to 7% sIg-positive) after treatment with anti-sIg and complement, whereas these cells were enriched (up to 74% positive) after anti-Thy 1 and complement treatment. The cells subjected to the various treatments were washed extensively and resuspended to the concentrations appropriate for the blastogenic assays.

Lymphocyte transformation assay.—Various lymphocyte fractions were centrifuged and adjusted to a concentration of 1×10^6 cells/ml in the growth medium described by Click et al. (*21*). MuMTV and TAA were added in 25-µl volumes at final concentrations of 4 and 50 µg, respectively. Cultures were maintained for 3 days in MicroTest culture plates (Linbro; Flow Laboratories, Inc., Rockville, Md.) with 2×10^5 cells/well and were given an 18-hour pulse of [^{3}H]thymidine (0.5 µCi/well; Amersham/Searle Corp., Arlington Heights, Ill.). The cells were collected on glass fiber filter paper with distilled water in a Skatron multiple automated sample harvester. The filters were counted for radioactivity in a Packard scintillation spectrometer, and results were expressed as cpm of stimulated cultures minus the background cpm of cultures containing no stimulus. Unstimulated spleen lymphocyte cultures from normal BALB/cCrgl mice incorporated 649±113 cpm of [^{3}H]thymidine, whereas those from normal BALB/cfC3H mice incorporated 679±181 cpm. Unstimulated lymphocyte cultures from small-tumor-bearing and large-tumor-bearing BALB/cCrgl mice had, respectively, 729±187 and 998±201 cpm. Background cultures of spleen lymphocytes of small- and large-tumor-bearing BALB/cfC3H mice incorporated, respectively, 698±158 and 1,017±227 cpm.

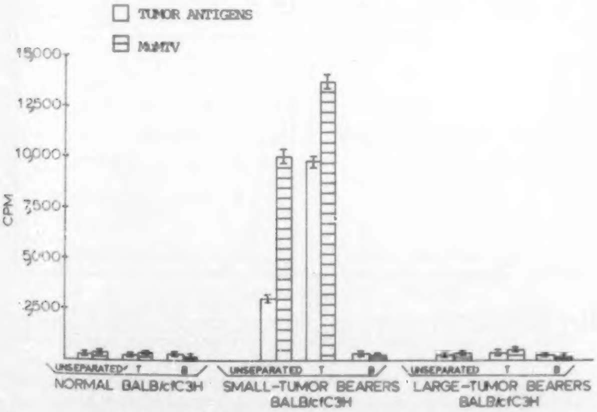
Flow cytometric determinations.—Levels of T- and B-lymphocytes were determined by flow cytometric analysis of fluorescence by use of a fluorescence-activated cell sorter (FACS III; Becton Dickinson Monoclonal Antibody Center, Mountain View, Calif.). FITC-conjugated monoclonal anti-Thy 1.2 was purchased from Beckton Dickinson Monoclonal Antibody Center. FITC-conjugated rabbit anti-mouse immunoglobulin was donated by the Biological Carcinogenesis Branch, National Cancer Institute, from stocks supplied by the NCI-Frederick Cancer Research Facility. Spleen single cell suspensions were stained as described by Rabellino et al. (*22*) with either the anti-Thy 1.2 or the anti-mouse immunoglobulin reagents. One hundred thousand cells were analyzed for each preparation. Fluorescent histograms of stained lymphocytes from normal mice and tumor-bearing mice are presented. Autofluorescence of unstained cells is shown as background. The percentages of fluorescent lymphocytes as determined per 10^5 cells are given in "Results."

RESULTS

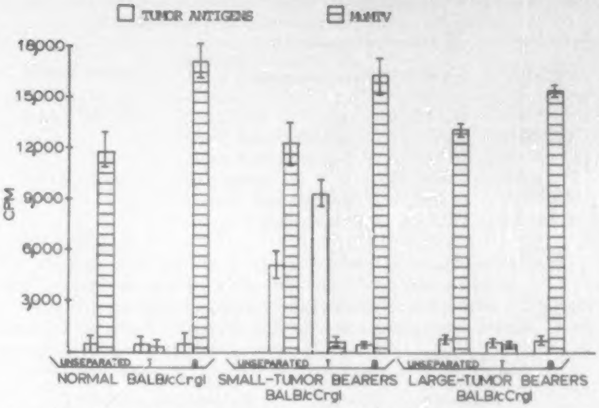
Nylon Wool Separation Studies

The blastogenic responses of unseparated or nylon wool-fractionated spleen cells from normal and SMT-bearing BALB/cfC3H mice were assessed in cultures containing tumor antigen extracts or MuMTV. The results of such studies, presented in text-figure 1, are expressed as the mean cpm plus or minus the standard error of four separate experiments. Animals with tumors of 1–2 g were defined as small-tumor bearers, whereas animals with tumors of 4–5 g were defined as large-tumor bearers. Unseparated or nylon wool-adherent separated spleen cells from normal BALB/cfC3H mice exhibited no reactivity when they were exposed to either MuMTV or to TAA from MuMTV-expressing tumors of spontaneous origin in the BALB/cfC3H colony. BALB/cfC3H mice bearing small SMT had vigorous responses both to extracts of their mammary tumors and to MuMTV, and these responses were restricted to the nylon-nonadherent population. Spleen cells from large-tumor-bearing BALB/cfC3H mice were incapable of being stimulated in the blastogenic assay either to MuMTV or to TAA. This unresponsiveness extended to the nylon wool-separated populations.

A similar study of the responses to TAA and viral antigens was performed with the use of spleen cells of normal and mammary tumor-bearing BALB/cCrgl mice (text-fig. 2). Spleen lymphocytes from normal BALB/cCrgl mice did not respond to TAA from the D1-DMBA-3 tumors but had vigorous responses to MuMTV antigens. Upon separation on nylon wool, these responses were confined to the nylon-adherent population. Mice bearing small D1-DMBA-3 mammary tumors (1–2 g) possessed lymphocytes capable of responding to D1-DMBA-3 TAA, and the cells responding to the TAA were nylon-nonadherent lymphocytes. The responses to TAA were not evident in either the T- or B-cell fractions of spleens from animals bearing large mammary tumors (4–5 g). In contrast, the responses of splenocytes from both small- and large-tumor bearers to MuMTV antigens remained constant during tumor growth and, as was the case in the normal BALB/cCrgl mice, were solely a function of the nylon-adherent cells.



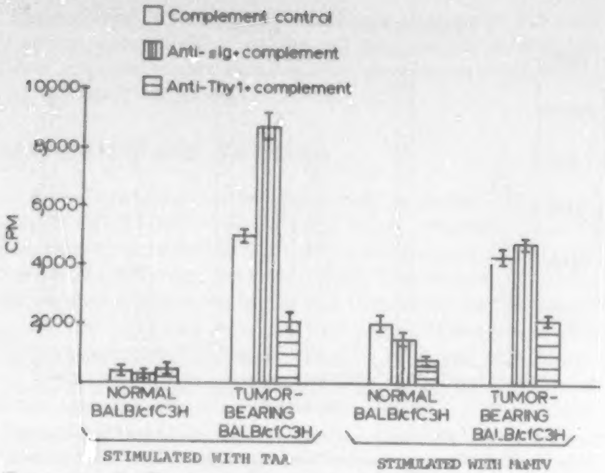
TEXT-FIGURE 1.—[^{3}H]thymidine incorporation of unseparated and nylon wool column-separated splenocytes from normal, small-tumor-bearing, and large-tumor-bearing BALB/cfC3H mice after exposure to TAA and MuMTV. Results are cpm of stimulated cultures minus background cpm and represent the means ± SE of four separate experiments.



TEXT-FIGURE 2.—Blastogenic responses to TAA and MuMTV of unseparated and nylon wool column-fractionated spleen cells from normal, small-tumor-bearing, and large-tumor-bearing BALB/cCrgl mice. Results are cpm of stimulated cultures minus cpm of unstimulated cultures and represent the mean cpm ± SE of four separate experiments.

Depletion Studies With Anti-Thy 1 or Anti-sIg Sera and Complement

Depletion studies were performed to ascertain the validity of the results obtained with the nylon wool separation technique. Since BALB/cfC3H and BALB/cCrgl animals bearing mammary tumors of 4–5 g were unresponsive to TAA in the blastogenic assay, only animals bearing small tumors were used in these depletion experiments. Treatment of unseparated spleen cells from SMT-bearing BALB/cfC3H mice with anti-sIg and guinea pig complement resulted in a significant increase of responses to the TAA in comparison to the responses obtained in nondepleted cultures, which are represented by the complement control (text-fig. 3). When these spleen cells were treated with anti-Thy 1 serum and complement, the blastogenic responses totally disappeared, thus indicating the T-cell nature of the responding population. The responses to MuMTV were assessed in B- and T-cell-depleted spleen cells from normal and small-tumor-bearing BALB/cfC3H mice. The low responses to MuMTV antigens observed in the complement control cultures of normal BALB/cfC3H mice were reduced in the cultures treated with anti-Thy 1 and complement and essentially unaffected in the cultures treated with anti-sIg and complement. This pattern was repeated in the cultures of spleen cells from small-tumor-bearing BALB/cfC3H mice stimulated with MuMTV but with a much more pronounced diminishing effect in the levels of incorporation of [^{3}H]thymidine in the cultures treated with anti-Thy 1 and complement.



TEXT-FIGURE 3.—Blastogenic responses to TAA and to MuMTV of spleen cells of normal and small-tumor-bearing BALB/cfC3H mice after various cytotoxic treatments. Anti-sIg and complement were used to deplete B-lymphocytes, and anti-Thy 1 and complement were used to eliminate T-cells. Results are cpm of stimulated cultures minus background cpm and are the means ± SE of four separate experiments.

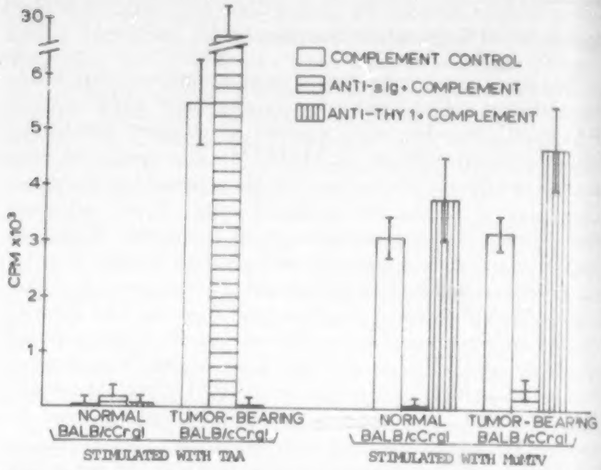
Similar depletion studies performed in the BALB/cCrgl colony (text-fig. 4) confirmed the results obtained in the nylon wool experiments and demonstrated that the responses to TAA were a function of the T-lymphocytes, whereas the MuMTV responses were due to the sIg-positive lymphocytes.

In all these depletion studies, the total cpm incorporated in the cultures that had positive responses were substantially lower than those observed in the nylon wool experiments, a probable reflection of some toxic activity of the complement used in the control and treated cultures.

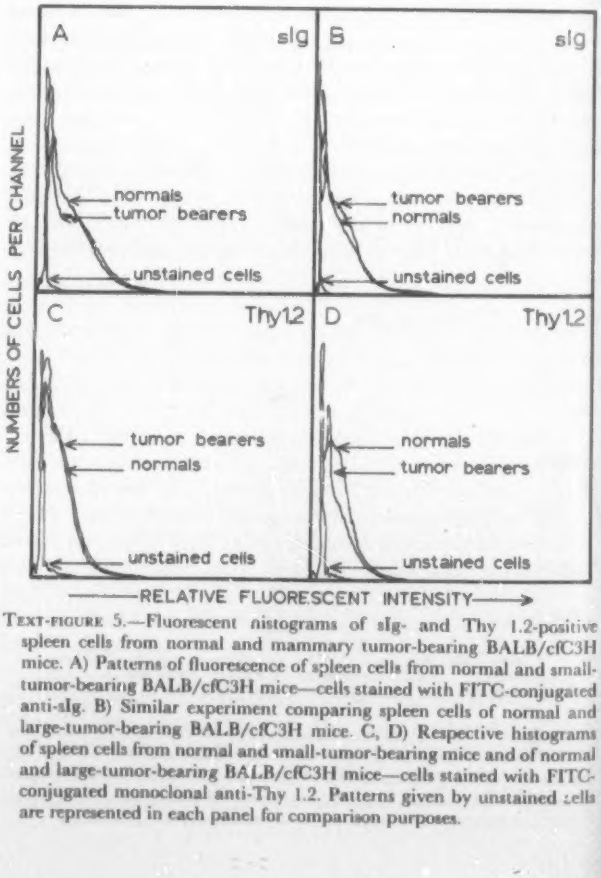
Flow Cytometric Analysis

The effect of mammary tumor development on the percentages of B- and T-lymphocytes present in the spleens of BALB/cfC3H and BALB/cCrgl mice was analyzed by flow cytometry with the use of a fluorescence-activated cell sorter (FACS III). Text-figure 5 shows the fluorescent histograms of the spleen cells from BALB/cfC3H mice bearing small or large SMT. In every histogram is included the pattern given for unstained cells as a reference point, and the fluorescent histograms of normal mice are presented for comparison. No significant differences were seen in the patterns obtained with spleen cells from normal BALB/cfC3H or tumor-bearing mice of this animal colony when the cells were stained for sIg (text-fig. 5, A and B). Analysis of the spleen cells stained with monoclonal antibodies against Thy 1.2 (text-fig. 5C, 5D) revealed that whereas no major differences were seen between the percentages of T-lymphocytes present in the spleens of normal mice and BALB/cfC3H mice bearing small mammary tumors, a decrease was seen in the percentages of lymphocytes with the Thy 1.2 marker in animals bearing large mammary tumors.

We performed similar experiments using spleen cells from normal or tumor-bearing BALB/cCrgl mice. In text-figure 6 (A, B) no significant differences are seen among the percentages of sIg-positive lymphocytes derived from the spleens of the 3 groups of mice tested, i.e., normal mice, small-tumor bearers, or large-tumor bearers. In a previous



TEXT-FIGURE 4.—Effect of treatment with anti-sIg and complement and of anti-Thy 1 and complement on the blastogenic responses to TAA and MuMTV of normal and small-tumor-bearing BALB/cCrgl mice. Results are cpm of stimulated cultures minus cpm of cultures with no added stimulus. *Each bar* represents the mean ± SE of four separate experiments.



TEXT-FIGURE 5.—Fluorescent histograms of sIg- and Thy 1.2-positive spleen cells from normal and mammary tumor-bearing BALB/cfC3H mice. A) Patterns of fluorescence of spleen cells from normal and small-tumor-bearing BALB/cfC3H mice—cells stained with FITC-conjugated anti-sIg. B) Similar experiment comparing spleen cells of normal and large-tumor-bearing BALB/cfC3H mice. C, D) Respective histograms of spleen cells from normal and small-tumor-bearing mice and of normal and large-tumor-bearing BALB/cfC3H mice—cells stained with FITC-conjugated monoclonal anti-Thy 1.2. Patterns given by unstained cells are represented in each panel for comparison purposes.

study (*23*) with FITC-conjugated F(ab')$_2$ rabbit anti-mouse IgG, no differences were detected by immunofluorescence in the percentages of sIg-positive splenocytes from BALB/cCrgl mice that were normal or that bore large mammary tumors. While the percentages of Thy 1.2-positive splenocytes in small-tumor bearers were very similar to those in normal mice, there was a profound depression in the percentages of the T-lymphocytes in the spleens of BALB/cCrgl mice bearing large mammary tumors as compared with their normal counterparts.

Table 1 gives the percentages of sIg-positive and Thy 1.2-positive spleen lymphocytes of normal and mammary tumor-bearing mice from the BALB/cfC3H and BALB/cCrgl colonies. The values obtained represent the mean percent of sIg or Thy 1-positive cells plus or minus the standard error of 3-8 animals/group. One hundred thousand cells were counted per experimental animal. The data clearly demonstrate that the percentages of B-lymphocytes were not altered by the development of mammary tumors in either BALB/cfC3H or BALB/cCrgl mice. Similarly, no changes in the percentages of Thy 1.2-positive cells were observed in either animal colony for mice that had small mammary tumors. However, a 30-40% reduction in the levels of T-lymphocytes was detected in the spleens of animals with mammary tumors of 4-5 g, when compared to normal controls in both the BALB/cfC3H and BALB/cCrgl colonies.

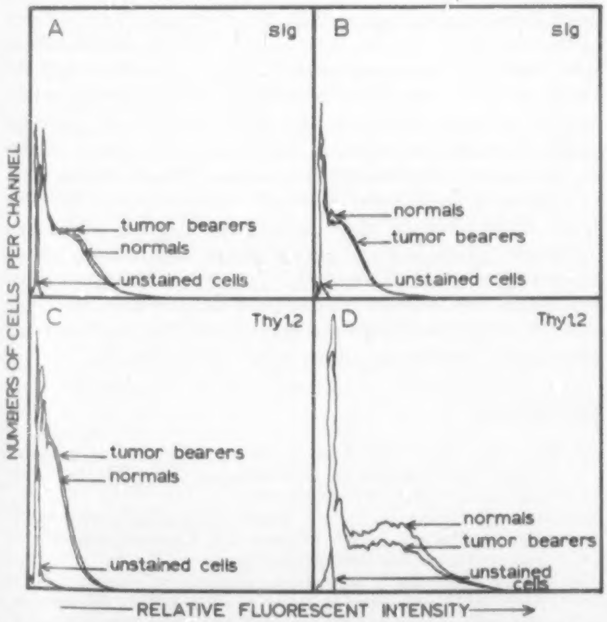
Our laboratory (*24*) has previously shown that mice bearing large tumor burdens have splenomegaly and a concomitant spleen hypercellularity. Thus the absolute numbers of Thy 1-positive cells per spleen of large-tumor-bearing mice (46.0×10^6 in BALB/cCrgl and 47.5×10^6 in BALB/cfC3H) were only slightly reduced or unchanged when compared to those of normal mice (51.6×10^6 in BALB/cCrgl and 48.1×10^6 in BALB/cfC3H) or those of small-tumor bearers (55.2×10^6 in BALB/cCrgl and 48.1×10^6 in BALB/cfC3H). With the same criterion, the absolute numbers of sIg-positive lymphocytes per spleen were significantly increased in animals bearing large tumors (76.0×10^6 in the BALB/cCrgl and 83.6×10^6 in the BALB/cfC3H) as compared to those of normal mice (46.8×10^6 in BALB/cCrgl and 53.3×10^6 in BALB/cfC3H) or those of small-tumor bearers (50.4×10^6 in BALB/cCrgl and 54.6×10^6 in BALB/cfC3H).

TABLE 1.—*Effect of increasing tumor burden on the levels of B- and T-spleen cells as determined by flow cytometry*

Mouse colony	Clinical condition of animals[a]	sIg^{+b}	Thy 1.2^{+b}
BALB/cfC3H	No tumors	41.0±1.94	37.0±0.84
	Small-tumor bearers	42.0±1.91	37.0±1.06
	Large-tumor bearers	44.0±1.60	25.0±4.1
BALB/cCrgl	No tumors	39.0±1.15	43.0±2.11
	Small-tumor bearers	42.0±1.91	46.0±3.78
	Large-tumor bearers	38.0±0.71	23.0±3.00

[a] Animals with tumors 1-2 g are defined as small-tumor bearers. Animals with tumors 4-5 g are defined as large-tumor bearers.

[b] Results are mean percents of fluorescent-positive cells ± SE. One hundred thousand cells were counted per experimental animal. There were 3-8 animals tested per group.



TEXT-FIGURE 6.—Fluorescent histograms of sIg- and Thy 1.2-positive spleen cells from normal and mammary tumor-bearing BALB/cCrgl mice. A, B) sIg-positive cells of normal and small-tumor bearers and of normal and large-tumor-bearing BALB/cCrgl mice, respectively. C, D) Respective histograms of Thy 1.2-positive spleen cells from normal and small-tumor-bearing mice and of normal and large-tumor-bearing BALB/cCrgl mice. Unstained cells are included as reference controls.

DISCUSSION

Resistance against development of mammary tumors is a result of complex interactions between host and tumor factors. It is possible to demonstrate TAA in experimentally induced mammary tumors as well as in mammary tumors of spontaneous origin (*9-11*). Since most mammary tumors that arise spontaneously occur in mouse strains in which MuMTV is readily demonstrable, viral antigens may play an important role in the host-tumor interactions of these systems, regardless of whether the MuMTV is the etiologic agent of these tumors. Common antigens have been described in MuMTV-expressing mammary tumors (*3, 7*) but appear to be lacking in MuMTV-negative tumors originated by the carcinogenic action of 7,12-dimethylbenz[*a*]anthracene (*13, 25*).

Humoral and cellular immune responses to viral antigens and TAA of mouse mammary tumors have been described by several investigators (*26-28*); however, the roles of these responses in providing protection against the appearance of SMT or the development of such tumors are not completely understood. In our studies we have observed a correlation with positive responses to TAA and a good prognosis. BALB/cfC3H and BALB/cCrgl animals with small mammary tumors respond in migration inhibition and lymphocyte transformation assays to extracts of their tumors and these responses are severely diminished by large tumor burdens (*11*). When the tumors are surgically removed, the responses are restored; however, they become depressed if the tumor reappears. Thus a correlation seems to exist between immunologic status and postsurgical fate of the animals (*29*). In our flow cytometric studies a depression in the percentages of T-lymphocytes is apparent in large-tumor bearers of the BALB/cfC3H and BALB/cCrgl colonies. Since T-lymphocytes have been shown to be responder cells to TAA in these animals, these data may explain the decreased responsiveness observed with increasing tumor size. An equally tenable hypothesis is to postulate the appearance of suppressor cells and/or factors in the animals bearing large tumors that could be responsible for the lack of reactivity of their spleen cells to TAA. We have described the emergence in our mammary tumor system of new subsets of T-lymphocytes (*19, 30*) that could be causing such regulatory activities. Since the absolute numbers of Thy 1-positive cells per spleen of large-tumor bearers are equal to or slightly less than those of their normal counterparts, it is conceivable that a shift in T-cell subpopulations might have occurred that could account for the observed results.

In contrast with the above results, the responses to the MuMTV antigen(s) in BALB/cCrgl mice have been shown to be present in both normal mice and tumor bearers and, in addition, to be unaltered by the course of tumor growth. We have speculated about the origin of the sensitivity of spleen cells from MuMTV-negative normal mice to MuMTV antigen(s) (*23*). After considering several hypotheses, we favor the interpretation that this sensitivity represents a recognition of a product resulting from expression of an endogenous MuMTV viral gene(s). Analysis of the cells responding to MuMTV antigen(s) in this colony has revealed that B-lymphocytes are the cells responding in lymphocyte transformation assay to MuMTV antigen(s). In addition, we have observed that B-lymphocytes when stimulated in vitro with MuMTV will differentiate into blast and plasma cells as detected in morphologic studies with Wright-Giemsa stains (Charyulu V, Lopez DM: Unpublished observations).

In our studies, nylon-nonadherent lymphocytes were not stimulated by MuMTV antigens. One could argue that the lack of responses of the T-lymphocytes to viral antigens may be due to the absence of the small percentages of macrophages (<1%) that can be detected by lipase staining in our nylon-adherent population. These cells might be necessary for eliciting positive blastogenic responses in the T-cell population (*31*). In recent experiments (*23*) in which parallel cultures of the various lymphocyte subpopulations were supplemented with macrophage-rich peritoneal exudate cells, addition of these cells exerted no significant enhancement on the rsponses of either B- or T-cells to MuMTV-associated antigen(s). Since in our flow cytometric determinations we observed no changes in the percentages of sIg-positive spleen lymphocyte populations in mice with small or large mammary tumors, one could hypothesize that in the BALB/cCrgl colony the blastogenic responses to MuMTV remain unalterable due to the intactness of the responding cell population.

In the BALB/cfC3H colony, the MuMTV responses appear to reside in the nylon-nonadherent spleen cell population. Blastogenic responses to viral antigens in the T-cell fraction of normal and tumor-bearing MuMTV-positive mice have been demonstrated by Creemers and Bentvelzen (*32*). At the present time, however, we cannot exclude the possibility that only virus-associated antigens are being detected in this assay. In this connection, Westenbrink and Koornstra (*33*) could find no evidence of nonvirion cell surface antigens on virally induced murine mammary tumor cells. The finding that the T-lymphocytes are the responders in the lymphocyte transformation assay in the BALB/cfC3H colony is similar to the situation in human breast cancer, since in recent studies we have reported that the erythrocyte-rosetting lymphocytes of breast cancer patients are the peripheral blood cells capable of being stimulated by antigens of the MuMTV (*34*).

One important question arises: Why do the normal BALB/cfC3H mice lack the high levels of responsiveness to MuMTV that are observed in the syngeneic BALB/cCrgl mice? Several possibilities could account for this apparent paradox: *a*) Since antibodies to MuMTV can be detected in MuMTV-expressing mouse strains (*35*) such as BALB/cfC3H mice, they may form immune complexes with the viral particles, the immune complexes having the ability to suppress the blastogenic reactions. Inhibition of cellular immune responses has been reported to be mediated by immune complexes (*36*), and there is some evidence to this effect in an MuMTV model system (*37*). *b*) A genetic drift may occur between the BALB/cfC3H and BALB/cCrgl colonies, which could account for the differences in responses to MuMTV; however, this is an unlikely explanation, inasmuch as the two colonies are syngeneic as shown by in vivo and in vitro methods (*11, 14*). *c*) In normal BALB/cfC3H mice a deficiency is induced by the presence of the virus in either the levels or the functionality of the B-cell subset involved in the responses to viral antigen in normal BALB/cCrgl mice. *d*) There is a generation of specific suppressor cells in animals actively producing viruses, which could be modulating the immune reactivities of these animals. These suppressor cells could be induced either directly by the virus or indirectly by antigen-antibody complexes (*32, 36, 38*). Such an occurrence may explain the lack of protection afforded by high levels of anti-MuMTV antibody to mammary tumor development (*39, 40*) and could explain why transplanted mammary tumors grow faster in mice in which anti-MuMTV antibodies are present than in mice with no detectable humoral immunity to the virus (*26, 35*).

Genetics of Transplacentally Induced Teratogenic and Carcinogenic Effects in Rabbits Treated With *N*-Nitroso-*N*-ethylurea[1,2,3]

R. R. Fox,[4] **H. Meier,**[5] **H. G. Bedigian,**[4] *and* **D. D. Crary**[4,6]

ABSTRACT—Pregnant rabbits of three partially inbred strains, WH/J, IIIVO/J, and X/J, mated to either IIIVO/J or WH/J males were given ip injections of 60 mg of *N*-nitroso-*N*-ethylurea dissolved in trioctanoin on day 18 of gestation. Genetic differences in tumor susceptibility between strains WH/J (low-tumor-incidence strain) and IIIVO/J (high-tumor-incidence strain) have previously been demonstrated. Of 22 WH/J × IIIVO/J hybrid progeny weaned, 17 developed primary renal tumors at 5.0±0.5 (mean ± SE) months of age. Of 17 IIIVO/J × WH/J hybrid progeny weaned, 16 developed primary renal tumors at 4.0±0.7 months of age. Of 5 X/J × IIIVO/J hybrid progeny weaned, all developed primary renal tumors at 4.2±0.5 months of age. In addition, 8 metastatic nephroblastomas were observed, with the lung being the primary site of metastasis. Neurofibromas were observed in 12 per 22, 12 per 17, and 3 per 5 rabbits, respectively, from the various hybrid groups, many of which also had neurilemmal cysts. In addition, 1 hepatoma and 2 hemangiomas were observed. Also, teratogenic effects of disproportionate miniaturization including a left–right reduction in ear length were observed. Epidermoid cysts also formed and then regressed during the development of these treated animals. The following conclusions can be drawn from the data: The susceptibility to renal tumor and to neurofibroma induction appears to be inherited as a dominant characteristic. The disproportionate miniaturization is greatly dependent on the maternal genotype of the particular hybrid. The presence of this disproportionate miniaturization appears to be related to renal tumor induction. The epidermoid cysts, the renal tumor, and the neurofibromas all appear to be of independent etiologies.—JNCI 1982; 69:1411–1416.

The transplacental induction of primary renal tumors in rabbits by either acute or chronic administration of NEU or its precursors has been demonstrated (*1–6*). Neurogenic tumors can also be induced by the transplacental administration of NEU at certain stages of organogenesis (*6–8*). The pregnant rabbit provides an excellent mammalian model system for the investigation of placental transfer of teratogenic and carcinogenic agents because both rabbits and humans have the same type of placentation (hemochorial), allowing the closest contact between maternal and fetal circulation (*9*).

The spectrum of tumors induced transplacentally by the administration of NEU appears to depend on a number of factors including species, genetic differences within a species, stage of organogenesis, and dosage of NEU. The tumor latency ranged from 3 months to about 2 years of age, probably depending on genetic differences in the breed or strain of rabbit used (*1–6*) and whether the treatment was given in an acute (*3, 4*) or chronic (*6*) regimen. The frequency of renal tumor induction was also dependent on the strain of rabbit used but not on whether the treatment regimen was NEU or its precursors or whether NEU was given in an acute or chronic dosage (*3, 4, 6*). The sex of the progeny did not influence the susceptibility to tumor induction in the rabbit (*3, 4, 6*), as has been demonstrated with the hamster (*10*). The genetic differences in susceptibility to primary renal tumor induction between two of the partially inbred strains of rabbits at The Jackson Laboratory were 35% for strain WH/J and 86% for strain IIIVO/J (*6, 11*). Because of this genotype-dependent susceptibility, we decided to try to determine the genetic basis for these differences by making reciprocal crosses between strains with high and low susceptibilities and to test their progeny for their susceptibility to the transplacental induction of tumors by NEU.

We now report that susceptibility to the oncogenic effects of NEU appears to have a dominant mode of inheritance, whereas the teratogenic effects of NEU are influenced greatly by the maternal genotype.

MATERIALS AND METHODS

Rabbits of three partially inbred strains, IIIVO/J, WH/J, and X/J (*11*), were used. The females were mated to males of either the WH/J or the IIIVO/J strain, and the date and time of day were recorded. Pregnancy was determined by palpation approximately 14 days after mating. Purified crystalline NEU (K & K #22890, lot #1373^{1AP}; K & K Laboratories, New York, N.Y.) was freshly prepared in trioctanoin (Eastman Kodak Co., Rochester, N.Y.) at a concentration of 30 mg NEU/ml immediately before injection. The NEU was preground as described previously (*6*). Pregnant rabbits were given a single ip injection of 60 mg NEU/kg body weight on day 18 of gestation. The progeny were routinely palpated for gross evidence of tumor development, and packed cell volumes were determined from marginal ear vein blood samples. We looked for evidence of hemoconcentration, a feature often associated with renal function failure (*3*). Latency time was recorded as the time from the day of birth to the day tumors were either observed at necropsy or first palpable, whichever occurred first. The treated pregnant females were killed when their litters were

weaned, because they were shown to be only slightly susceptible, if at all, to tumor induction by NEU (*5, 6*).

Rabbits were killed by cervical dislocation or exsanguination, and tissues were obtained for gross morphologic and histologic evaluations. Tissues were fixed in Tellyesniczky's fluid as modified by Fekete (*12*) and processed for histologic examination according to standard procedures; sections were cut at 8 μm and stained with hematoxylin and eosin.

RESULTS AND DISCUSSION

The number of does treated and the progeny born and weaned are illustrated in table 1. Also given are summary data on both teratogenic and carcinogenic effects. Elevated erythrocyte counts (≅1.25 times the normal count) were observed associated with tumor development and probable renal function failure as previously observed (*3, 4, 6*). In past experiments (*3*), because a large volume (3.4 ml) of trioctanoin was required to dissolve 60 mg NEU, the trioctanoin was shown to be extremely toxic. In the present experiment and in accord with our previous work (*6*), we were able to greatly decrease this toxic effect of trioctanoin by pregrinding the NEU so that only 2 ml of trioctanoin was needed to dissolve 60 mg NEU. This toxic effect can be seen in the induction of abortions, resorptions, or death of the doe. The frequency of disproportionate miniaturization was reduced in these hybrid progeny when compared with the effects observed with low chronic administration of NEU to their parental strains (*6*). The maternal strain, however, was important in determining whether we observed such miniaturization or not, indicating a definitely maternal influence on the induction of teratogenic effects in these animals. This maternal effect supports our previous work (*6*) in which the WH/J strain had 28% with disproportionate miniaturization and 52% with holes in the parietal bones in contrast to the IIIVO/J strain where the frequencies were 6 and 2%, respectively. An example of the left–right disproportionate miniaturization is illustrated in figure 1. The disproportionate miniaturization observed only at birth and the holes of the parietal bones have been previously described in detail (*6*). Epidermoid cysts (fig. 2) were observed to appear and regress, usually within the first 8 weeks of life. We have seen as many as three of these cysts at the same time in a given individual hybrid but have not observed these cysts in any of the parental strains similarly treated (*3, 4, 6*). These cysts attained a maximum size of 3 mm^3. The frequencies of renal tumors in the three hybrid populations are not significantly different from each other. Their overall tumor frequency of 86% is in excellent accord with the frequency of 86% reported for the IIIVO/J strain (*6*). However, this frequency is in contrast to that for the WH/J strain where it is only 35% (*6*). Therefore, we conclude that the susceptibility to primary renal tumor induction is associated with a dominant mode of inheritance. Similarly, the presence of neurofibromas at frequencies of greater than 50% in these three hybrid populations is more in accord with the 50% frequency reported for the IIIVO/J rabbits than it is for the 0% frequency observed in the WH/J progeny (*6*). Here if we assume that the chronic treatment of NEU (*6*) elevated the threshold response sufficiently to observe neurofibromas in the parental strains, then we can also conclude that the susceptibility to neurofibroma induction is also associated with a dominant mode of inheritance.

The lack of any sex effect on renal tumor frequency observed in our data is in accord with our previous NEU experiments (*3, 4, 6*) but does not agree with data on the hamster where females were observed to be fivefold more susceptible than males to tumor development when NEU precursors were administered (*10*).

The presence of 2 lymphosarcomas in these WH/J × IIIVO/J hybrid progeny is extremely interesting, particularly because previously we observed 4 lymphosarcomas (*3, 6*) in the WH/J progeny of rabbits treated with NEU, which we attributed to the presence of the inherited condition for lymphosarcoma (*ha/ha*) known to be present in that strain (*6, 13, 14*). In these experiments the presence of the *ha* gene in a homozygous condition is impossible unless the IIIVO/J male used in the cross also carries this gene undetected. To test this hypothesis, we examined other matings that this male had made within the IIIVO/J strain and

[c] *Numbers in parentheses* are numbers of stillborn progeny.

[d] Marked disproportionate miniaturization at birth or a 20% reduction in ear or tail length measured at 4 wk.

[e] Data were based on rabbits necropsied ≤1 mo of age.

[f] Data are means ± SE. Epidermoid cysts appeared and then regressed usually during the first 8 wk of life. They reached a maximum size of 3 mm^3.

found no evidence for lymphosarcoma in any of the progeny or in any animal of that strain in the past 10 years. The male also was bred to 8 of his IIIVO/J daughters, producing 46 progeny for which we have data. The probability of this male being of the +/*ha* genotype and producing 46 normal progeny when bred back to his daughters is $(7/8)^{46}$ or 0.002. The WH/J strain rabbits with lymphosarcoma have a mean age at death of about 8 months, and the 2 hybrids we observed with lymphosarcoma in these data were about 7 months of age. The necropsy information on the 46 progeny of this IIIVO/J male bred back to his daughters was all based on animals over 9 months of age with a mean age of 17.5±1.2 months. We are confident, therefore, that this IIIVO/J male does not carry the *ha* gene. Thus we conclude that either lymphosarcoma is another effect of the NEU treatment or NEU, in conjunction with one dose of the *ha* gene, can work synergistically to produce this pathology.

Table 2 gives detailed information on the tumors observed. From this table, one can make some inferences about the interrelationships of the types of tumors and the possible relationship of teratogenic to carcinogenic effects. If one looks first at the metastases that were observed, the lung was clearly the primary site for metastatic nephroblastomas because the lung was involved in 7 of the 8 cases of metastases. In addition, three other sites were observed. The omentum by itself and two sites, the maxilla and the sacrum, were observed in the same animals where lung metastases were also found. These hybrid progeny appear to be more susceptible to metastases (21% overall) than were their parental strains in which only one case (3% overall) was observed (*3, 4, 6*). For this comparison of the frequency of metastases, the data from the three regimens used to induce renal tumors in the parental strains were combined, since the frequency of induced primary renal tumors depended on the strain of rabbit but not on whether the regimen was either the acute or chronic administration of NEU or its precursors (*3, 4, 6*). That single case of metastatic nephroblastoma in the parental strains, however, did involve the lungs as well as the jaw and liver. The effect of the disproportionate miniaturization on renal tumor development can be inferred, but on the basis of the number of cases we observed, it is hard to state with certainty. However, in all 7 cases in which we observed disproportionate miniaturization in animals that survived, nephroblastomas were observed subsequently. This observation certainly suggests a relationship and is in contrast to any association between the presence of epidermoid cysts, renal tumors, metastases, and neurofibromas, which all appeared independently, except for the obvious relationship of the metastases to the renal tumors.

TABLE 2.—*Teratogenic and carcinogenic effects of acute administration of NEU to pregnant rabbits*

Strain of progeny[a]	Disproportionate miniaturization[b]	Epidermoid cysts[c]	Sex and animal, No.	Initial renal tumor observation		Death of animal		Histopathologic findings
				Method[d]	Age, mo	Mode[e]	Age, mo	
WH/J × IIIVO/J			♂782884			K	7	Lymphosarcoma
		Yes	♀782891	P	2.5	K	3.50	Nephroblastoma on left kidney and vascular bloom and cysts on right kidney (kidney wt: 80.1 g left; 7.8 g right). Metastasis to omentum.
			♂782892	A	8.25	D	8.25	Small nephroblastoma on right kidney, vascular bloom on both kidneys, and cysts on left kidney. Subcutaneous neurofibromatosis on right side at base of rib cage (3×2×0.5 cm).
			♀782893	P	5.25	K	8.75	Nephroblastoma on left kidney and vascular bloom on both kidneys (kidney wt: 242 g left; 5.0 g right). Neurofibromatosis (2.5×2×1 cm) on right scapula.
		Yes	♀782894			K	6.75	Lymphosarcoma
		Yes	♀782895			K	12.75	Vascular bloom on both kidneys. Two neurofibromas [one (2×1.5×1.5 cm) on left posterior midcervical and the other (3.5×3×1 cm) on the posterior hip at junction of femur and pelvis].
			♂783174	P	3.25	K	5.25	Bilateral Wilms'-like renal tumors, nephroblastomas, vascular bloom, and cysts on both kidneys (kidney wt: 28.6 g left; 13.7 g right)
			♀783176	P	11.75	D	15.50	Nephroblastoma on left kidney and vascular bloom and cysts on both kidneys (kidney wt: 129.7 g left; 9.9 g right)
			♂783177	P	5.25	K	12.50	Nephroblastoma on right kidney and vascular bloom on left kidney (kidney wt: 6.7 g left; 458.2 g right). Two neurofibromas [one (6.5×6.5×2 cm) on ventral surface near sternum and the other (1.5×0.5×0.5 cm) in neck muscle at level of sixth nerve].

[a] First strain denotes female parent—only weaned progeny are included in table.
[b] Marked disproportionate miniaturization at birth or a 20% reduction in ear or tail length measured at 4 wk.
[c] Epidermoid cysts appeared and then regressed usually during the first 8 wk of life. They reached a maximum size of 3 mm^3.
[d] P=palpation or elevated packed cell volume. A=autopsy.
[e] D=natural death. K=killed.

TABLE 2 (continued).—*Teratogenic and carcinogenic effects of acute administration of NEU to pregnant rabbits*

Strain of progeny[a]	Disproportionate miniaturization[b]	Epidermoid cysts[c]	Sex and animal No.	Initial renal tumor observation		Death of animal		Histopathologic findings
				Method[d]	Age, mo	Mode[e]	Age, mo	
WH/J × IIIVO/J			♂783179	P	4.5	K	12.50	Nephroblastoma on left kidney and vascular bloom on right kidney (kidney wt: 404.5 g left; 9.2 g right). Neurofibromatosis (1.5×1×0.3 cm) below right scapula near spine.
			♀783180			K	12.50	Vascular bloom and cysts on both kidneys. Neurofibromatosis (2×1.5×1 cm) near right eye.
			♀793685	A	3.25	D	3.25	Nephroblastoma (0.8×0.8×0.5 cm) on right kidney and vascular bloom and cysts on both kidneys
			♂793686	P	4.25	K	8.00	Nephroblastoma on left kidney and vascular bloom and cysts on both kidneys (kidney wt: 161 g left; 9.3 g right)
		Yes	♂800405			K	15.0	Vascular bloom and cysts on both kidneys
	Yes	Yes	♂800406	P	4.25	K	15.0	Nephroblastoma on left kidney and vascular bloom and cysts on both kidneys (kidney wt: 205 g left; right kidney was inadvertently not weighed but appeared normal in size, i.e., ≈7 g). Metastases to lungs. Two neurofibromas with neurilemmal cysts [one (7×5×1.5 cm) on left flank and the other (2.5×1.5×0.5 cm) near right kidney].
	Yes	Yes	♂800408	P	4.25	K	9.0	Nephroblastoma on left kidney and vascular bloom on right kidney (kidney wt: 326.4 g left, 6.5 g right). Neurofibromatosis with neurilemmal cyst on midline in upper lumbar area.
	Yes		♀800409	A	2.75	D	2.75	Nephroblastoma (2×1.5×1.3 cm) on left kidney, vascular bloom on both kidneys, and cysts on right kidney. Two neurofibromas (one on right upper lip and the other on cervical nerve).
			♂800473	P	5.25	K	14.75	Nephroblastoma (1 cm^3) on right kidney and vascular bloom and cysts on both kidneys (kidney wt: 7.9 g left; 8.2 g right)
		Yes	♀800474	P	7.50	K	15.0	Nephroblastoma on right kidney and vascular bloom and cysts on both kidneys (kidney wt: 7.5 g left; 20.2 g right). Three small neurofibromas (1×1×0.2 cm) located subcutaneously and 1 neurofibroma with neurilemmal cyst (3×2.5×1.5 cm) on stomach.
			♂800475	P	4.0	K	10.75	Bilateral nephroblastomas and vascular bloom on both kidneys and cysts on left kidney (kidney wt: 288.5 g left; 722.6 g right). Metastases to lung. Neurofibroma with neurilemmal cysts (1.5×0.5×0.5 cm). Hepatoma beginning.
	Yes		♂800476	P	4.0	K	10.75	Bilateral nephroblastomas (kidney wt: 147.0 g left; 351.7 g right). Metastases to right maxilla and to lungs.
	Yes	Yes	♂800477	P	4.0	K	6.25	Bilateral nephroblastomas and vascular bloom on both kidneys and cysts on right kidney (kidney wt: 118.1 g left; 72.2 g right). Neurofibroma on second cervical nerve.
IIIVO/J × WH/J		Yes	♀800700	P	6.5	K	15.75	Nephroblastoma on right kidney and vascular bloom and cysts on both kidneys (kidney wt: 8.4 g left; 40.0 g right). Neurofibroma with neurilemmal cyst (2×3×1 cm) located subcutaneously between right ear and eye.
			♂800702	P	3.0	K	8.75	Nephroblastoma on left kidney and vascular bloom and cysts on both kidneys (kidney wt: 185.6 g left; 10.7 g right). Two neurofibromas (1.5×1×0.4 cm and 1×0.5×0.3 cm) on ventral internal abdominal wall.
			♀800703			K	16.5	Vascular bloom and cysts on both kidneys
		Yes	♂801078	P	3.25	K	5.5	Bilateral nephroblastomas, vascular bloom, and cysts on both kidneys (kidney wt: 130.7 g left; 74.3 g right)

[a] First strain denotes female parent—only weaned progeny are included in table.

[b] Marked disproportionate miniaturization at birth or a 20% reduction in ear or tail length measured at 4 wk.

[c] Epidermoid cysts appeared and then regressed usually during the first 8 wk of life. They reached a maximum size of 3 mm^3.

[d] P=palpation or elevated packed cell volume. A=autopsy.

[e] D=natural death. K=killed.

TABLE 2 (continued).—*Teratogenic and carcinogenic effects of acute administration of NEU to pregnant rabbits*

Strain of progeny[a]	Disproportionate miniaturization[b]	Epidermoid cysts[c]	Sex and animal No.	Initial renal tumor observation		Death of animal		Histopathologic findings
				Method[d]	Age, mo	Mode[e]	Age, mo	
IIIVO/J × WH/J		Yes	♀801079	P	1.75	D	4.0	Bilateral nephroblastomas, vascular bloom, and cysts on left kidney (kidney wt: 16.8 g left; 213.9 g right). Neurofibromas with neurilemmal cysts on second and sixth cervical nerves.
		Yes	♂801080	P	2.5	K	3.5	Bilateral nephroblastomas, vascular bloom, and cysts on both kidneys (kidney wt: 195.5 g left; 106 g right). Neurofibroma with neurilemmal cyst (1×1×2.5 cm) located subcutaneously in thoracic lymph node on left side.
		Yes	♂801081	P	3.25	K	8.75	Nephroblastoma on right kidney and vascular bloom and cysts on both kidneys (kidney wt: 17.7 g left; 1,123.5 g right). Metastases to lung. Three neurofibromas with neurilemmal cysts [two (6×3×3 cm and 5×3×3 cm) in muscle of left femur and a small one on the stomach].
			♀801787	P	3.75	K	12.0	Nephroblastoma with Wilms'-like features on right kidney and vascular bloom on both kidneys (kidney wt: 6.2 g left; 1,097.5 g right). Neurofibroma with neurilemmal cysts below stomach. Liver hemangioma.
		Yes	♀801788	P	3.75	K	8.25	Bilateral nephroblastomas, vascular bloom, and cysts on left kidney (kidney wt: 215 g left; 332 g right). Neurofibroma mixed in with the nephroblastoma.
		Yes	♂801789	P	3.75	K	6.5	Bilateral nephroblastomas and cysts on both kidneys (kidney wt: 32.6 g left; 231.9 g right). Neurofibroma (0.8×0.8×0.2 cm) on right side ventral to linea alba of abdominal wall.
		Yes	♀801790	P	3.75	K	12.0	Bilateral nephroblastomas with Wilms'-like features, vascular bloom, and cysts on left kidney (kidney wt: 309.9 g left; 711.5 g right). Metastases to lung. Two neurofibromas [one (3.5×2×0.5 cm) on right mandible and a small sublingual one].
			♂801792	A	13.75	K	13.75	Nephroblastoma on left kidney, vascular bloom on both kidneys, and cysts on left kidney (kidney wt: 9.6 g left; 7.1 g right). Two neurofibromas with neurilemmal cysts [one (0.5×0.5×0.1 cm) on left flank and the other (1×1×0.3 cm) on left shoulder].
			♀801794	P	3.0	K	11.0	Bilateral nephroblastomas and vascular bloom on both kidneys and cysts on right kidney (kidney wt: 600.7 g left; 338.4 g right). Neurofibroma with neurilemmal cyst on left hip.
			♀801973	P	3.25	K	3.50	Nephroblastoma on left kidney and vascular bloom and cysts on both kidneys (kidney wt: 22 g left; 7 g right)
			♂801974	P	3.25	K	11.75	Bilateral nephroblastomas and vascular bloom and cysts on both kidneys (kidney wt: 212.5 g left; 95.9 g right). Four neurofibromas with neurilemmal cysts [two (1.5×1.5×0.5 cm and 3.5×2×0.5 cm) in left lower peritoneum, one (2.5×1.5×1 cm) in neck region, and the other (3×2×0.5 cm) in left mandible area].
		Yes	♂801975	A	2.75	D	2.75	Nephroblastoma (1 cm^3) on left kidney and vascular bloom and cysts on both kidneys
			♂801976	P	2.50	K	5.50	Bilateral nephroblastomas and vascular bloom on both kidneys and cysts on right kidney (kidney wt: 247 g left; 55.3 g right)
X/J × IIIVO/J	Yes	Yes	♀801137	A	3.75	D	3.75	Bilateral nephroblastomas (1×1×1 cm on left and 1.5×2.5×1 cm on right)
			♂801138	P	5.0	K	6.50	Nephroblastoma on left kidney and vascular bloom and cysts on both kidneys (kidney wt: 30.4 g left; 7.8 g right)

Meeting Highlights

Job-Exposure Matrices in Occupational Epidemiology

Analyses of occupational hazards are most powerful when subjects are grouped by exposure. However, epidemiologic studies have traditionally been based on job title and industry, which are often poor surrogates for exposure; e.g., persons with the same job title in different industries can have vastly different exposures. Misclassification of exposure status reduces the power of an analysis and dilutes risk estimates. In response to this problem, several researchers developed job-exposure matrices (JEM), which are cross-classifications of industry-specific job titles with agents to which persons in the jobs are exposed. Thus the JEM allow the researchers to translate job and industry data into exposure data. On April 19–21, 1982, the University of Southampton, England, and its Medical Research Council (MRC) Environmental Epidemiology Unit sponsored a meeting of approximately 60 scientists to discuss approaches for developing JEM and and related issues.

Matrices developed before collection of any study data ("a priori") enhance evaluation of routinely collected records such as cancer registry data and death certificates. Researchers from the United States, Italy, and England described their a priori JEM, and persons from Scandinavia and Canada presented some possible applications of JEM to census, pension, employment, morbidity, and mortality files. JEM can be used for both hypothesis generating and testing.

A priori JEM have some limitations. They are based on exposures inferred from job title and industry, not actual exposure histories for individual study subjects. Ambiguous job titles which vary over time and place can result in inaccurate exposure assignment. JEM do not usually contain dose measurements. Often, entire classes of chemicals are indicted when only a few chemicals in the class are hazardous. Also, most of the JEM currently contain only known or suspect chemical carcinogens. Finally, associations observed through the use of JEM may be confounded by nonoccupational factors and other hazardous occupational exposures.

Despite these limitations, JEM are a valuable adjunct to occupational epidemiology. Although JEM do not eliminate misclassification of exposure status, they certainly reduce it. Many of the deficiencies of a priori JEM are due to the pilot nature of the JEM developed thus far and can be corrected by further research. Even restricted to known or suspected carcinogens, JEM can address whether occupational exposure to these chemicals can induce cancer in people.

A different technique for translating occupational histories into exposure profiles involves determining exposures on a case-by-case basis. Canadian investigators proposed that inasmuch as each person's job title, industry, and exposure history are idiosyncratic, the data should be treated as such. Subjects in the Canadian project complete short questionnaires, which are reviewed by chemist-engineers who determine the pertinent detailed questions to be asked in a second interview. Theoretically, the resulting matrix should contain more accurate qualitative and quantitative exposure information for the individual for use in case-control studies. When completed, the results of the Canadian project will need to be evaluated in terms of the extra expenditure of time and money involved. This approach is not feasible for analyzing numerous routinely collected records, such as cancer registry data.

All conference attendees agreed that better characterization of exposure and dose is needed. Industrial hygienists should have a major role in constructing JEM. The variation of exposure by place and time needs to be taken into consideration. The sensitivity and specificity of a job-exposure matrix should be compared to actual exposures as recorded or reported by the study subject.

A discussion developed concerning the advisability of creating internationally standardized occupational and exposure codes comparable to the International Classification of Diseases. The general consensus was that variation in the meaning of job titles makes it impossible to create an international occupational code. The observation also was made that there is no need for such a code because analysis should ultimately be based on chemical and physical exposures, instead of job title. Therefore, the greater need is for a standardized exposure code. Chemical abstract (CAS) numbers are assigned uniquely and recognized internationally but do not facilitate the grouping of chemicals by class. A recommendation was made to use the CAS numbers in conjunction with another system that allowed easy grouping. Route of contact, calendar year, and geographic location at time of use of the agents could be added to JEM in the future.

An interesting proposal was made to use JEM to identify work areas and populations for environmental air and blood and urine sampling. The materials could be collected every 5 years from a large population-based sample and, in conjunction with morbidity and mortality rates, could be used to calculate dose-response data. Technical, political, and ethical considerations and a pilot project were discussed. Arguments against the "biological sample" bank included the need for information on confounding factors, the questionable ability to assay suspected carcinogens in samples collected years earlier, and the possibility that the persons most heavily exposed to a potential carcinogen may refuse to participate in the voluntary sampling program. The suggestion also was made that a national registry of industrial hygiene data and occupational histories should be created before complicated biologic monitoring is attempted.

The conference, like most meetings on occupational hazards, voiced support for legislation requiring employers to retain a minimum data set of employees' demographic characteristics and occupational histories.

Dr. E. Donald Acheson[1], the conference organizer, is preparing the proceedings for publication in approximately 1 year.

Announcements

The Journal will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.

Seventeenth Annual Clinical Symposium of St. Jude Children's Research Hospital

St. Jude Children's Hospital, Memphis, Tennessee, will be the site of this symposium to be held on February 25-26, 1983. The symposium will focus on current results in the treatment of children with cancer and leukemia. Emphasis will be on diagnosis and treatment programs for primary disease as well as the care of complications. There will be discussions of various aspects of supportive care as an essential adjunct to chemotherapy regimens.

The symposium will be open to all physicians who wish to attend. Approximately 200 physicians will be accepted for participation on a first-come basis; there are no registration or other fees.

Physicians may register by writing to the Associate Director for Clinical Research, St. Jude Children's Research Hospital, Box 318, Memphis, Tennessee 38101.

Eighteenth Annual San Francisco Cancer Symposium

"Hyperthermia and Radiation Therapy in the Treatment of Cancer" is the title of this symposium to be held at the Sheraton Palace Hotel, San Francisco, California, on March 5-6, 1983. The symposium is being presented by the West Coast Cancer Foundation in association with the American Cancer Society, California Division, and St. Mary's Hospital and Medical Center, and is open to members of the medical and health communities.

Twelve hours of Category I CMA/AMA credit will be offered to physicians and physicists. Nurses will be offered twelve hours of credit by the California Board of Registered Nursing. There will be a reduction in cost if registration is made before February 1, 1983.

For further information contact the West Coast Cancer Foundation, 50 Francisco Street, Suite 200, San Francisco, California 94133 (telephone: 415-981-4590).

Second Annual A.A.I. Course in Advanced Immunology

The American Association of Immunologists will sponsor this course in advanced immunology entitled "Regulatory Elements of the Immune System" to be held at the Duke Marine Laboratory, Beaufort, North Carolina, on June 5-12, 1983. The course will focus on recent advances in immunobiology, immunogenetics, and molecular and clinical immunology as they relate to immune regulation. Topics will include: MHC gene organization and control, MHC restriction and Ir gene control, regulation by interleukins, T-suppressor cell clones and hybrids, B-cell growth and differentiation, immunoglobulin gene organization and isotype switching, effector mechanisms and immunologic analysis and manipulation in human disease.

This course is intended primarily for advanced graduate students and post-doctoral and clinical fellows who wish to expand their knowledge of modern immunology.

Since space is limited, early application is recommended. To apply for the course, please submit a letter documenting your background in immunology and stating your reasons for wishing to attend, as well as current research/teaching activities and a brief c.v., no later than March 1, 1983 to: Dr. David W. Scott, AAI Course, Box 3010, Division of Immunology, Duke University Medical Center, Durham, North Carolina 27710.

Eleventh International Symposium for Comparative Research on Leukemia and Related Diseases

Cambridge, England, will be the site of this meeting to be held on July 3-8, 1983 at Cambridge University. For additional information, complete program, and registration materials please contact Dr. David S. Yohn, Secretary General, International Association for Comparative Research on Leukemia and Related Diseases, Suite 302, 410 West Twelfth Avenue, Columbus, Ohio 43210.

Eleventh Annual Meeting of the International Society for Oncodevelopmental Biology and Medicine

The Karolinska Institute, Stockholm University, Umeå University, and National Bacteriological Laboratory will sponsor this meeting to be held in Stockholm, Sweden, on September 11-15, 1983. The purpose of this interdisciplinary meeting is to provide a forum for communication of recent advances in basic research on oncofetal proteins and their clinical application as tumor and fetal diagnostic markers. As such, this conference will be of interest to both clinicians and scientists working in areas of oncology, tumor immunobiology, developmental biology, and areas of reproductive medicine related to fetal development and the prenatal detection of birth defects.

Deadline for abstract submissions is April 30, 1983. For additional information contact the Congress Secretariat, ISOBM Congress, % RESO Congress Service, S-10524 Stockholm, Sweden (telephone: +468144910; telex: 17639; telegram: FOLKRESO).

Seventh Meeting of the European Association for Cancer Research (EACR)

The Danish Cancer Society will sponsor this meeting to be held in Copenhagen, Denmark, on September 19-21, 1983. The major theme of this meeting will be "Chemical Carcinogenesis." Plenary sessions will include presentations by invited speakers and selected papers submitted by the participants. Other communications may be presented in parallel sessions or as posters. The topics of these presentations may be related to any field in cancer research although papers closely related to the main subject will be considered for inclusion in plenary sessions. The second Otto Mühlbock Memorial Lecture will be presented.

The meeting is open to members and non-members of the EACR. Papers may be submitted for presentation by non-members only if sponsored by a member. The deadline for submission of abstracts is May 1, 1983.

A satellite meeting on modifiers of carcinogenesis, organized by Dr. E. Thorling, will follow the main meeting on September 22–23, 1983. For further information concerning the meeting please apply to Dr. J. Kieler, The Danish Cancer Society, Laboratory of Environmental Carcinogenesis, Ndr Frihavnsgade 70, DK-2100 Copenhagen Ø, Denmark.

Acknowledgment

The Board of Editors acknowledges with gratitude the generous assistance of the following reviewers who, between August 1, 1981, and August 1, 1982, helped in the evaluation of manuscripts submitted for publication. The Board is especially grateful to the first 41 reviewers, who reviewed five or more papers during the past year.

Permuted Title Index

Volumes 68 and 69
January–December 1982

acetoxime in MRC-Wistar rats /Carcinogenicity test of 69:961
A-chain-anticarcinoembryonic antigen antibody conjugate for human colon adenocarcinoma cell line /Selective cytotoxicity of a ricin 69:799
acid esterase and acid phosphatase in permanent human hematopoietic cell lines /Isozymes of 69:1255
α-1-acid glycoprotein assay in the detection of human colorectal cancer: Comparison with carcinoembryonic antigen /Value of plasma 68:75
(α_1-acid glycoprotein) levels /Mitogen-induced blastogenesis and receptor mobility inhibition by breast cancer serum with elevated 68:779
acid phosphatase in permanent human hematopoietic cell lines /Isozymes of acid esterase and 69:1255
acinar carcinoma /Secretagogue response in rat pancreatic 69:969
ACI rat by 430-keV neutrons, X-rays, and diethylstilbestrol /Induction of mammary neoplasms in the 69:1135
acute leukemia in the United States /No seasonality in the diagnosis of 69:1283
acute leukemia: Possible subsets in childhood leukemia /Changes in clonal expression during the course of 69:393
acute urethan dose and target cell number /Relationship of lung adenoma prevalence and growth rate to 69:851
adenocarcinoma cell lines and tissues /Various isozyme gene expression patterns among human colorectal 68:81
adenocarcinoma cell line /Selective cytotoxicity of a ricin A-chain-anticarcinoembryonic antigen antibody conjugate for human colon 69:799
adenocarcinoma cells: Lack of therapeutic action of supplemental ascorbic acid /Prophylactic and therapeutic actions of supplement- 69:73
adenocarcinoma /Development and biologic properties of malignant cell sublines and clones of a spontaneously metastasizing rat mam- 68:507
adenocarcinoma /Gastrin protection against chemically induced gastric adenocarcinomas in Wistar rats: Histopathology of the gland- 69:59
adenocarcinoma grown in vivo and in vitro /Flow cytometric analysis of R3327 rat prostate 69:79
adenocarcinoma induced by *N*-hydroxy-*N*-2-fluorenylacetamide /Steroid hormone receptors in the rat mammary 69:41
adenocarcinoma in rats: Induction by 3,2′-dimethyl-4-aminobiphenyl /Prostate 68:867
adenocarcinoma of the uterus in androgen-sterilized SD rats /Spontaneous occurrence of atypical hyperplasia and 69:95
adenocarcinoma /Relationship between xenotransplantability and cell surface properties of ascites sublines of a rat mammary 69:33
adenocarcinomas in virus-infected leopard frog tadpoles /Effect of thymectomy on development of Lucké renal 68:133
adenocarcinomas in Wistar rats: Histopathology of the glandular stomach and incidence of gastric adenocarcinoma /Gastrin pro- 69:59
adenocarcinomas xenotransplanted into nude mice /α_1-Protease inhibitor production by human 69:381
adenoma, and carcinoma of the human large bowel /Glycoconjugate with *Ulex europaeus* agglutinin-I-binding sites in normal mucosa, 69:777
adenoma latency: Relevance of tumor growth rate and target cell number /Relationship between urethan dose rate and 69:859
adenoma prevalence and growth rate to acute urethan dose and target cell number /Relationship of lung 69:851
adenomatosis coli /Morphologic transformation and chromosomal changes induced by chemical carcinogens in skin fibroblasts from pa- 68:563
adenosylmethionine decarboxylase levels /Degrees of malignancy in human primary central nervous system tumors: Ornithine decar- 68:751
adherent cell contact-mediated modulation of normal myeloid colony formation /Human 68:35
adjuvant chemotherapy of breast cancer /Intrastage prognostic heterogeneity: Implications for 68:445
adriamycin levels and cytotoxicity in adriamycin-sensitive and adriamycin-resistant P388 mouse leukemia cells /Intracellular 68:1027
aflatoxin B_1 as a measure of hepatocarcinoma initiation in rainbow trout /Liver DNA bound in vivo with 68:623
aflatoxin B_1 in large doses /Cholangiocellular carcinomas induced in Syrian golden hamsters administered 68:271
aflatoxins and related metabolites by radioimmunoassay /Detection of 69:1375
African Burkitt's lymphoma with central nervous system involvement /Cerebrospinal fluid markers in 69:787
agar /Effect of enzymatic disaggregation on proliferation of human tumor cells in soft 68:945
agarose without feeder layers /High cloning efficiency of human lymphoid cells in 68:919
age and anatomical site on ultraviolet carcinogenesis in BALB/c mice /Influences of 68:691
age at diagnosis /Risk factors for breast cancer in women in northern Alberta, Canada, as related to 68:211
age at first and subsequent births: A study in the population of the Estonian Republic /Association of breast cancer risk with 69:1035
age-dependent data on multiple myeloma in Austria /Epidemiologic and 68:729
age, sex, and mammary tumor detection in murine mammary tumor virus-infected mice /Letter to the Editor: Immune alterations re- 69:1208
agglutinin-I-binding sites in normal mucosa, adenoma, and carcinoma of the human large bowel /Glycoconjugate with *Ulex europaeus* 69:777
AKR mice /Spontaneous leukemia viruses: Lymphomagenic ecotropic viruses of 69:1077
Alaskan Natives: 1070–79 /Cancers of the gallbladder and biliary tract in 69:1005
Alberta, Canada, as related to age at diagnosis /Risk factors for breast cancer in women in northern 68:211
albumin /Methylazoxymethanol: Effect on the immune response of rats to human serum 68:651
alcohol, and a retinoid: Association with esophageal cancer in rats /Zinc deficiency, 68:785
allergic, and carcinogenic aspects with emphasis on predicting effects in humans—an introduction /Photochemical toxicity: Toxic, 69:151
Alloantigenic phenotype of radiation-induced thymomas in the mouse 69:619
alloantigen /Modulation of cell-mediated alloimmunity by BCG. II. Induction of specific, nonadherent, non-T-killer cells by BCG and 69:613
alloantigens in mice /Effects of different fractions of *Corynebacterium parvum* on the cytotoxic T-cell response to 69:495
alloimmunity by BCG. I. Antagonism and potentiation of immunosuppression caused by cytarabine /Modulation of cell-mediated 69:607
alloimmunity by BCG. II. Induction of specific, nonadherent, non-T-killer cells by BCG and alloantigen /Modulation of cell-mediated 69:613

Fv-4^r mouse strains /Surface antigen expressed in hematopoietic cells derived from 68:1005

G_2 phase in a line of normal human fibroblasts and its malignant derivative /Repair of chromosome damage induced by X-irradiation 69:409
gallbladder and biliary tract in Alaskan Natives: 1970-79 /Cancers of the 69:1005
gamma interferon /Effect of 7,12-dimethylbenz[*a*]anthracene on production and action of 68:993
Ganglioside changes induced by tumor promoters in promotable JB6 mouse epidermal cells: Antagonism by an antipromoter 68:469
Ganglioside patterns: New biochemical markers for human hematopoietic cell lines 68:203
ganglio-*N*-tetraosylceramide-positive lymphocyte mediators of natural killer activity /Morphology and function of 68:449
Gardner's syndrome /Heterogeneous response to X-ray and ultraviolet light irradiations of cultured skin fibroblasts in two families with 68:697
gastric adenocarcinomas in Wistar rats: Histopathology of the glandular stomach and incidence of gastric adenocarcinoma /Gastrin 69:59
gastric carcinoma /Indirect macrophage migration inhibition response to 3-*M* KCl extract of 69:345
Gastrin protection against chemically induced gastric adenocarcinomas in Wistar rats: Histopathology of the glandular stomach and 69:59
gene expression patterns among human colorectal adenocarcinoma cell lines and tissues /Various isozyme 68:81
gene regulation in cancer? /Guest Editorial: What are isozymes telling us about 68:343
Genetics and epidemiology /Carotid body tumors in humans: 68:573
genetics of malignancy workshop /Meeting Highlights: Cytogenetics and somatic cell 69:543
Genetics of transplacentally induced teratogenic and carcinogenic effects in rabbits treated with *N*-nitroso-*N*-ethylurea 69:1411
Genotoxic effects of sunlight-activated waste water in cultured mammalian cells 69:199
genotypic characteristics of a cell line from a squamous cell carcinoma of human skin /Phenotypic and 68:415
germ cell proliferation in fetal testes in mouse strains with high and low incidences of congenital testicular teratomas /Primordial 69:907
gestational trophoblastic neoplasia /Circulating immune complex levels in patients with 69:23
(GL-13) in guinea pigs /A deletion in chromosome 1 in cells of a transplantable granulocytic leukemia 69:591
gliomas /In vitro studies on the cell-mediated immune response to human brain tumors. I. Requirement for third-party stimulator 69:1245
gliomas /Serologic analysis of nitrosurea-induced rat 68:501
γ-glutamyltransferase of carcinogen-induced preneoplastic hepatocytes of rats /In vitro measurement of resistance to phalloidin and 69:683
γ-glutamyltransferase-positive and nonspecific esterase-positive foci in rat liver by partial hepatectomy following single injection of *N*- 69:1299
Glutathione *S*-transferase activity: Enhancement by compounds inhibiting chemical carcinogenesis and by dietary constituents 68:493
β_1 glycoprotein as a marker in carcinoma of the breast in women /Use of circulating pregnancy-specific 69:1067
glycoprotein assay in the detection of human colorectal cancer: Comparison with carcinoembryonic antigen /Value of plasma α-1-acid 68:75
glycoprotein epiglycanin in the TA3-MM mouse mammary carcinoma ascites cell /Further studies on the relationship between allo- 68:981
glycoprotein expressed by human melanoma and carcinoma cells /A 94,000-dalton 68:761
glycoprotein) levels /Mitogen-induced blastogenesis and receptor mobility inhibition by breast cancer serum with elevated oroso- 68:779
glycoprotein: Major peptide homology exhibited with the nuclear and membrane-associated 94,000-M_r SV40 T-antigen in hamsters 69:839
golden hamsters administrated aflatoxin B_1 in large doses /Cholangiocellular carcinomas induced in Syrian 68:271
golden hamsters treated transplacentally with *N*-nitrosodiethylamine /Electron microscopic autoradiography of the trachea in fetal 69:927
gp70-specific suppressor T-cells in mice inoculated with virus-producing tumor cells /Induction of 69:953
graft acceptance /Successful transplantation of a human leukemia cell into nude mice: Conditions optimizing 68:15
gram-positive bacteria: Expression of antitumor activity according to peptide structure and route of injection /Peptidoglycans extracted 68:657
granulocytic leukemia (GL-13) in guinea pigs /A deletion in chromosome 1 in cells of a transplantable 69:591
Granulopoiesis longevity in continuous bone marrow cultures and factor-dependent cell line generation: Significant variation among 28 68:305
granulopoietic system /5-Fluorouracil, 1,3-bis(2-chloroethyl)-1-nitrosourea, and 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea: 68:541
GR mice /Comparison of biologic behavior and histology of transplanted mammary tumors in 69:933
GR/A mice: An in vitro study /Hormone requirements of the pregnancy-dependent mammary tumor of 69:1391
Guest Editorial: Human retroviruses and adult T-cell leukemia-lymphoma 69:1209
Guest Editorial: Sheep lung carcinoma: An endemic analogue of a sporadic human neoplasm 69:747
Guest Editorial: What are isozymes telling us about gene regulation in cancer? 68:343
guinea pig /Bile acids: Effects on absorption of 1,2-dimethylhydrazine and 7,12-dimethylbenz[*a*]anthracene in the colon of the rat and 68:619
guinea pig cell line /Independent expression of chemical carcinogen-induced phenotypic properties frequently associated with the neo- 69:1175
guinea pig cell tumorigenicity /Plasminogen activator, fibronectin, lymphotoxin sensitivity, and natural skin reactivity relationships to 68:329
guinea pigs /A deletion in chromosome 1 in cells of a transplantable granulocytic leukemia (GL-13) in 69:591
guinea pig tumor. I. Quantitative analysis of adoptive immunity /Mechanisms of immunologic eradication of a syngeneic 68:673; 69:987
gum and mouth, esophagus, larynx, and lung by sex and by income level /Major histologic types of cancers of the 69:773

H-2 expression on a teratocarcinoma-derived cell line, TerC 69:1311

hamster amelanotic melanoma A-Mel-3 /Microcirculatory blood flow, capillary morphology, and local oxygen pressure of the 68:475

hamster cells by putative epoxide metabolites of commercially utilized chloroalkenes /Neoplastic transformation of Syrian 69:531

hamster embryo cells /Equivalency of endothelial cell growth supplement to irradiated feeder cells in carcinogen-induced morpho- 68:127

hamsters administered aflatoxin B_1 in large doses /Cholangiocellular carcinomas induced in Syrian golden 68:271

hamsters: Inhibition by vitamin E /Oral mucosal carcinogenesis in 68:791

hamsters /Simian virus 40 (SV40)-specific isoelectric point-4.7-94,000-M_r membrane glycoprotein: Major peptide homology exhibited 69:839

hamsters treated transplacentally with *N*-nitrosodiethylamine /Electron microscopic autoradiography of the trachea in fetal Syrian 69:927

hamster trachea: Cytokinetic and ultrastructural alterations /Squamous metaplasia in organ cultures of vitamin A-deficient 69:895

heating on lethality due to hyperthermia and selected chemotherapeutic drugs /Effect of rate of 68:487

hematopoietic cell lines /Ganglioside patterns: New biochemical markers for human 68:203

hematopoietic cell lines /Isozymes of acid esterase and acid phosphatase in permanent human 69:1255

hematopoietic cells derived from *Fc-4*^{r} mouse strains[a] /Surface antigen expressed in 68:1005

Hematopoietic precursor cells in mice treated with 4-demethoxydaunorubicin and doxorubicin 68:971

hemolysis in the mouse /2′-Deoxycoformycin-induced 68:1011

hepatectomy, during carcinogenesis, and in transplantable hepatocellular carcinomas /Expression of fibronectin and laminin in the rat 69:1105

hepatectomy following single injection of *N*-nitrosodiethylamine /Induction of γ-glutamyltransferase-positive and nonspecific esterase- 69:1299

hepatectomy /Production of kidney tumors in rats with low dose of dimethylnitrosamine after partial 68:293

hepatitis B surface and core antigens in human liver cell carcinoma and surrounding nontumorous liver /Distribution of 69:565

hepatitis B surface antigen /Primary liver carcinoma and liver cirrhosis in atomic bomb survivors, Hiroshima and Nagasaki, 1961–75, 69:1221

hepatocarcinoma initiation in rainbow trout /Liver DNA bound in vivo with aflatoxin B_1 as a measure of 68:623

hepatocellular carcinomas /Expression of fibronectin and laminin in the rat liver after partial hepatectomy, during carcinogenesis, 69:1105

hepatocytes and hepatoma cells /Effects of nicotinamide, isonicotinamide, and bleomycin on DNA synthesis and repair in rat 69:1353

hepatocytes from livers of carcinogen-treated rats /Purification and transplantation of 68:851

hepatocytes /Isolation, culture, and transplantation of human 68:771

hepatocytes of rats /In vitro measurement of resistance of phalloidin and γ-glutamyltransferase of carcinogen-induced preneoplastic 69:683

hepatoma cells /Effects of nicotinamide, isonicotinamide, and bleomycin on DNA synthesis and repair in rat hepatocytes and 69:1353

hepatomas: Chemotherapy with Lycurim and Pyrazofurin /Rat 68:665

hereditary lymphosarcoma (leukemia) /Causes of death and sex differences in survival times of pigs with untreated 68:239

hereditary neurofibromatosis /Probable clonal origin of neurofibrosarcoma in a patient with 69:1289

heterogeneity of human colorectal cancer cell lines analyzed by a panel of monoclonal antibodies. I. Heterogeneous expression of Ia-like 69:357

hexamethylphosphoramide by inhalation /Induction of nasal tumors in rats exposed to 68:157

Hiroshima and Nagasaki, 1950–76: Relationship to radiation dose absorbed by marrow /Multiple myeloma among atomic bomb 69:323

Hiroshima and Nagasaki, 1961–75, with special reference to hepatitis B surface antigen /Primary liver carcinoma and liver cirrhosis in 69:1221

L-Histidinol protection against cytotoxic action of cytosine arabinoside and 5-fluorouracil in cultured mouse spleen cells 68:279

histiocytomas induced by 4-(hydroxyamino)quinoline 1-oxide in rats /Malignant fibrous 68:859

HLA-like antigenic determinants /Antigenic heterogeneity of human colorectal cancer cell lines analyzed by a panel of monoclonal 69:357

homosexual men /Meeting Highlights: Kaposi's sarcoma in 68:337

hormonal risk factors for breast cancer /Interaction of familial and 69:817

Hormone dependence of 7,12-dimethylbenz[*a*]anthracene-induced mammary tumor growth: Correlation with prostaglandin E_2 content 69:443

hormone receptor binding in rat mammary tumors /Effects of dietary lipids on lactogenic 68:319

hormone receptors in the rat mammary adenocarcinoma induced by *N*-hydroxy-*N*-2-fluorenylacetamide /Steroid 69:41

Hormone requirements of the pregnancy-dependent mammary tumor of GR/A mice: An in vitro study 69:1391

hormone treatment /Growth of mouse mammary glands after neonatal sex 69:1347

human adenocarcinomas xenotransplanted into nude mice /α_1-Protease inhibitor production by 69:381

human adenovirus 5 propagated in Burkitt's lymphoma cells /Changes in 69:1215

Human adherent cell contact-mediated modulation of normal myeloid colony formation 68:35

human B-lymphoblast tumorigenicity in nude mice /Effect of type C viral expression and cellular karyotype on 69:435

human brain tumors. I. Requirement for third-party stimulator lymphocytes in the induction of cell-mediated cytotoxic responses to al- 69:1245

human breast cyst fluids /Androgen conjugates in 69:1055

human breast tumors /Characterization of a monoclonal antibody reactive with a subset of 68:719

human breast tumors /Prolactin receptors in 68:381

human carcinogenesis /Meeting Highlights: Host factors in 68:173

human colon adenocarcinoma cell line /Selective cytotoxity of a ricin A-chain–anticarcinoembryonic antigen antibody conjugate for 69:799

human colon carcinomas and its relationship to clinical behavior /DNA distribution in 69:15

human colon mucosa /Epithelial line from normal 69:1271

human colon tumor cell lines by feeder layers of murine fibroblasts /Enhancement of growth of 69:767

human colony-stimulating factor-producing cell line from a squamous cell carcinoma of the thyroid gland /Establishment and charac- 69:1235

human colorectal adenocarcinoma cell lines and tissues /Various isozyme gene expression patterns among 68:81

human colorectal cancer cell lines analyzed by a panel of monoclonal antibodies. I. Heterogeneous expression of Ia-like and HLA-like 69:357

human colorectal cancer: Comparison with carcinoembryonic antigen /Value of plasma α-1-acid glycoprotein assay in the detection 68:75

human fibroblasts and its malignant derivative /Repair of chromosome damage induced by X-irradiation during G_2 phase in a line of 69:409

human fibroblasts /Basis for the differential action of aminonucleoside on normal and transformed 68:407

human granulopoietic system /5-Fluorouracil, 1,3-bis(2-chloroethyl)-1-nitrosourea, and 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1-nitro- 68:541

human hematopoietic cell lines /Ganglioside patterns: New biochemical markers for 68:203

human hematopoietic cell lines /Isozymes of acid esterase and acid phosphatase in permanent 69:1255

human hepatocytes /Isolation, culture, and transplantation of 68:771

human hyperplastic foci /DNA content of liver cell nuclei of *N*-2-fluorenylacetamide-induced altered foci and neoplasms in rats and 69:1277

human large bowel /Glycoconjugate with *Ulex europaeus* agglutinin-I-binding sites in normal mucosa, adenoma, and carcinoma of the 69:777

human leukemia cell into nude mice: Conditions optimizing graft acceptance /Successful transplantation of a 68:15

human leukocyte interferon to melanoma patients. I. Effects on natural killer function and cell populations /Systemic administration of 68:703

human leukocyte interferon to melanoma patients. II. Cellular events associated with changes in natural killer cytotoxicity /Sys- 68:711

human liver cell carcinoma and surrounding nontumorous liver /Distribution of hepatitis B surface and core antigens in 69:565

Human lymphoblastoid cell lines /Tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate: Effect on complement and Epstein-Barr 68:385

human lymphoid cells in agarose without feeder layers /High cloning efficiency of 68:919

human lymphoid cells /In vitro assay of the effects of psoralens plus ultraviolet radiation on 69:219

Human lymphoma-lymphoma hybrids and lymphoma-leukemia hybrids. I. Isolation, characterization, cell surface markers, and B-cell 68:179

Human lymphoma-lymphoma hybrids and lymphoma-leukemia hybrids. II. Epstein-Barr virus induction patterns 68:197

human mammary carcinomas /T-Lymphocyte and B-lymphocyte subpopulations infiltrating 69:1

human melanoma and carcinoma cells /A 94,000-dalton glycoprotein expressed by 68:761

human melanoma cells by interferon /Enhanced expression of melanoma-associated antigens and β_2-microglobulin on cultured 68:19

human melanoma xenografts in nude mice with a radiolabeled monoclonal antibody /Imaging of 69:823

human metastatic breast carcinoma /Isolation and partial characterization of surface components of cell line MDA-MB-231 derived 69:371

Human models for identification of photosensitizing chemicals 69:269

human natural and lectin-induced cytotoxicity /Interferon and prostaglandins: Effects on 69:339

human natural killer cell activity by a streptococcal preparation, OK-432: Interferon and interleukin-2 participation in the stimulation with 69:807

human neoplasm /Guest Editorial: Sheep lung carcinoma: An endemic analogue of a sporadic 69:747

human neuroblastoma cells in vitro /Retinoic acid-induced growth inhibition and morphologic differentiation of 68:589

human oral mucosa treated with chemical carcinogens in short-term organ culture /Unscheduled DNA synthesis in 69:557

human osteosarcoma /Collagen polymorphism in extracellular matrix of 69:1009

human ovarian cancer cells by xenogeneic peritoneal macrophages /In vitro growth stimulation of 69:1039

human ovarian carcinoma cells /Interferon effect on cytotoxicity of peripheral blood and tumor-associated lymphocytes against 68:555

human pancreatic tumor /Coproduction of carcinoembryonic antigen and nonspecific cross-reacting antigen by a continuous cell line 69:401

human primary central nervous system tumors: Ornithine decarboxylase levels as better indicators than adenosylmethionine decarbox- 68:757

human prostate cancer with the use of tissue-specific antigens /Multiple marker evaluation in 68:99

human prostate. II. Long-term explant culture of normal prostate and benign prostatic hyperplasia: Light microscopy /Studies on 69:751

human prostate. III. Long-term explant culture of normal prostate and benign prostatic hyperplasia: Transmission and scanning elec- 69:757

Human retroviruses and adult T-cell leukemia-lymphoma /Guest Editorial: 69:1209

human retrovirus /Meeting Highlights: Adult T-cell leukemia-lymphoma: Role of a 69:981

humans—an introduction /Photochemical toxicity: Toxic, allergic, and carcinogenic aspects with emphasis on predicting effects in 69:151

humans /Chemical phototoxicity in 69:265

humans /Current status of predictive animal models for drug photoallergy and their correlation with drug photoallergy in 69:237

human serum albumin /Methylazoxymethanol: Effect on the immune response of rats to 68:651

humans: Genetics and epidemiology /Carotid body tumors in 68:573

human skin /Phenotypic and genotypic characteristics of a cell line from a squamous cell carcinoma of 68:415

humans: Relationship to plasma lipids and relative weight /Cancer incidence in 68:915

humans: Stage-dependent blood levels of substance(s) immunologically cross-reactive with insulin /Carcinomas of the cervix and corpus 68:891

humans /Therapeutic in vivo photochemistry: Photochemical toxicity studies in 69:273

humans /Transforming growth factors in the urine of normal, pregnant, and tumor-bearing 69:793

humans with leukemias, lymphomas, or soft tissue sarcomas /Search for evidence of feline leukemia virus infection in 69:333

human thymoma lymphocytes: Role of subcellular factors in blastic activation /Functional properties of 69:827

human T-lymphocytes. XIX. T-cells and T-cells with receptors for IgMFc (Tμ), IgGFc (Tγ), or IgAFc (Tα) in the peripheral blood and re- 69:1261

human tumor cells in soft agar /Effect of enzymatic disaggregation on proliferation of 68:945

human tumors heterotransplanted in nude mice /Calorie restriction: Effect on growth of 68:249

human urinary bladder in vitro /*N*-Methyl-*N*-nitrosourea and saccharin: Effects on epithelium of normal 69:577

hybrid murine tumor cells: Requirements for optimal immunization /Antitumor immunity induced by 69:647

hybrid /Nonimmunogenic radiation-induced lymphoma: Immunity induction by a somatic cell 68:841

hybrids. I. Isolation, characterization, cell surface markers, and B-cell markers /Human lymphoma-lymphoma hybrids and lympho- 68:179

hybrids. II. Epstein-Barr virus induction patterns /Human lymphoma-lymphoma hybrids and lymphoma-leukemia 68:197

hybrids /Inheritance of cellular reistance to the antitumor agent ICRF 159 in somatic cell 68:977

hydrogen chloride induction of nasal cancer in the rat /Gaseous formaldehyde and 68:597
4-(hydroxyamino)quinoline 1-oxide in rats /Malignant fibrous histiocytomas induced by 68:859
N-hydroxy-*N*-2-fluorenylacetamide /Steroid hormone receptors in the rat mammary adenocarcinoma induced by 69:41
hyperthermia and selected chemotherapeutic drugs /Effect of rate of heating on lethality due to 68:487

Ia-like and HLA-like antigenic determinants /Antigenic heterogeneity of human colorectal cancer cell lines analyzed by a panel of 69:357
ICRF 159 in somatic cell hybrids /Inheritance of cellular resistance to the antitumor agent 68:977
IgMFc (Tμ), IgGFc (Tγ), or IgAFc (Tα) in the peripheral blood and regional lymph nodes of patients with untreated breast cancer 69:1261
Immune alterations related to age, sex, and mammary tumor detection in murine mammary tumor virus-infected mice /Letter to the 69:1208
immune complex levels in patients with gestational trophoblastic neoplasia /Circulating 69:23
immune response of rats to human serum albumin /Methylazoxymethanol: Effect on the 68:651
immune response to human brain tumors. I. Requirement for third-party stimulator lymphocytes in the induction of cell-mediated cyto- 69:1245
immunity /Immunomodulation of the lymphoresponsive phases of carcinogenesis: Mechanisms of natural 69:737
immunity induced by hybrid murine tumor cells: Requirements for optimal immunization /Antitumor 69:647
Immunity induction by a somatic cell hybrid /Nonimmunogenic radiation-induced lymphoma: 68:841
immunity to mouse mammary tumor virus antigens by patients with hyperplastic benign breast disease /Cell-mediated 68:935
Immunity to tumor-associated antigens in vasectomized men 69:551
Immunization against transplantable leukemia impaired in copper-deficient mice 69:489
immunization /Anterior immunity induced by hybrid murine tumor cells: Requirements for optimal 69:647
Immunoadjuvant effects of *Blastomyces dermatitidis* against EL 4 lymphoma in C57BL/6J mice 69:1337
immunoglobulins that specifically inhibit DNA synthesis of mouse tumor cells /Platinum-complexed antitumor 69:47
immunoglobulin to Fcγ receptors on macrophages in 3-methylcholanthrene-induced murine tumors /Exclusive binding of 69:1163
immunologic characterization of 3-methylcholanthrene-induced sarcoma cell lines metastasizing widely in mice and exhibiting distinct 69:595
immunologic eradication of a syngeneic guinea pig tumor. I. Quantitative analysis of adoptive immunity /Mechanisms of 68:673; 69:987
immunologic reactivity to Moloney murine sarcoma virus-induced tumors. III. Further characterization of tumor-specific serum block- 69:939
Immunologic relatedness of intracisternal A-particles in mouse embryos and neoplastic cell lines 68:643
Immunomodulation of the lymphoresponsive phases of carcinogenesis: Mechanisms of natural immunity 69:737
immunomodulation on the fate of tumor cells in the central nervous system and systemic organs of mice. Distribution of [^{125}I]5-iodo- 69:465
immunosuppression caused by cytarabine /Modulation of cell-mediated alloimmunity by BCG. I. Antagonism and potentiation of 69:607
Immunosuppressive effects of ultraviolet (280–320 nm) radiation and psoralen plus ultraviolet (320–400 nm) radiation in mice 69:171
Immunotherapeutic effects of partially purified tumor-specific transplantation antigens on pulmonary metastases of a 3-methylcholan- 69:1121
Immunotherapy by intralesional injection of BCG cell walls or live BCG in bovine ocular squamous cell carcinoma: A prelimary report 69:1095
immunotherapy /Development of resistance to MOPC-315 plasmacytoma after intralesional and intraperitoneal melphalan therapy of 68:963
Immunotherapy of a murine leukemia virus-infected, chemically induced murine sarcoma with antiviral antibodies 69:509
immunotherapy of a murine lymphoma antigenically alteraed by drug treatment in vivo /Intracerebral adoptive 68:817
income level /Major histologic types of cancers of the gum and mouth, esophagus, larynx, and lung by sex and by 69:773
inhalation /Induction of nasal tumors in rats exposed to hexamethylphosphoramide by 68:157
inhibitors of carcinogenesis: Effect on azoxymethane-induced intestinal cancer in rats /Combined 69:103
insulin /Carcinomas of the cervix and corpus uteri in humans: Stage-dependent blood levels of substance(s) immunologically cross- 68:891
Interferon and interleukin-2 participation in the stimulation with OK-432 /In vitro potentiation of human natural killer cell activity 69:807
Interferon and prostaglandins: Effects on human natural and lectin-induced cytotoxicity 69:339
interferon /Effect of 7,12-dimethylbenz[*a*]anthracene on production and action of gamma 68:993
Interferon effect on cytotoxicity of peripheral blood and tumor-associated lymphocytes against human ovarian carcinoma cells 68:555
interferon /Enhanced expression of melanoma-associated antigens and β_2-microglobulin on cultured human melanoma cells by 68:19
interferon inducers. I. Effect against artificial and spontaneous lung metastases of murine tumors /Studies on the antitumor activi- 68:139
interferon on the growth of spontaneous mammary tumors in mice /Inhibitory effect of 69:653
interferon to melanoma patients. I. Effects on natural killer function and cell populations /Systemic administration of human leukocyte 68:703
interferon to melanoma patients. II. Cellular events associated with changes in natural killer cytotoxicity /Systemic administration of 68:711
interleukin-2 participation in the stimulation with OK-432 /In vitro potentiation of human natural killer cell activity by a strepto- 69:807
intestinal cancer in rats /Combined inhibitors of carcinogenesis: Effect on azoxymethane-induced 69:103
Intestinal metaplasia in Japan: Association with diet 68:401
intracardial injection /Effect of immunomodulation on the fate of tumor cells in the central nervous system and systemic organs of 69:465
Intracerebral adoptive immunotherapy of a murine lymphoma antigenically altered by drug treatment in vivo 68:817
intracisternal A-particles in mouse embryos and neoplastic cell lines /Immunologic relatedness of 68:643
iodinated nerve growth factor binding by the suspected tumor promoters saccharin and cyclamate /Inhibition of 68:299
[^{125}I]5-iodo-2′-deoxyuridine-labeled KHT tumor cells after left intracardial injection /Effect on immunomodulation on the fate of tumor 69:465
irradiated feeder cells in carcinogen-induced morphologic transformation of Syrian hamster embryo cells /Equivalency of endothelial 68:127

irradiation during G_2 phase in a line of normal human fibroblasts and its malignant derivative /Repair of chromosome damage in- 69:409
β-irradiation in rats /Enhancement of skin tumorigenesis by cigarette smoke condensate following 68:605
irradiation of the nasopharynx /Neoplasms following childhood radium 68:3
irradiation on changes in crypts of the mouse colon during treatment with 1,2-dimethylhydrazine /Effects of sublethal 69:693
irradiations of cultured skin fibroblasts in two families with Gardner's syndrome /Heterogeneous response to X-ray and ultraviolet light ... 68:697
isoelectric point-4.7–94,000-M_r membrane glycoprotein: Major peptide homology exhibited with the nuclear and membrane-associated 69:839
isonicotinamide, and bleomycin on DNA synthesis and repair in rat hepatocytes and hepatoma cells /Effects of nicotinamide, ... 69:1353
isoproterenol on mammary gland tumor induced by *N*-nitroso-*N*-methylurea and salivary gland tumors induced by 7,12-dimethylbenz- 69:1115
isozyme gene expression patterns among human colorectal adenocarcinoma cell lines and tissues /Various 68:81
Isozymes of acid esterase and acid phosphatase in permanent human hematopoietic cell lines 69:1255

Temperature gradients and local perfusion in a mammary carcinoma ... 68:519
teratocarcinoma-derived cell line, TerC /*H-2* expression on a ... 69:1311
teratogenic and carcinogenic effects in rabbits treated with *N*-nitroso-*N*-ethylurea /Genetics of transplacentally induced ... 69:1411
teratomas /Primordial germ cell proliferation in fetal testes in mouse strains with high and low incidences of congenital testicular ... 69:907
TerC /*H-2* expression on a teratocarcinoma-derived cell line, ... 69:1311
testicular teratomas /Primordial germ cell proliferation in fetal testes in mouse strains with high and low incidences of congenital ... 69:907
12-*O*-tetradecanoylphorbol 13-acetate: Effect of complement and Epstein-Barr virus receptors in human lymphoblastoid cell lines ... 68:385
12-*O*-tetradecanoylphorbol 13-acetate on cell interactions in vitro /Some effects of the tumor promoter ... 69:721
T_G cell involvement in the leukocyte adherence inhibition phenomenon ... 68:549

Thermotolerance in the murine jejunum 68:1033
thioguanine-platinum(II) and selenoguanine-platinum(II) /Murine lymphoma L5178Y cells resistant to purine antagonists: Differ- 68:287
Thy-1 antigen on normal and neoplastic rat mammary tissues: Changes in location and amount of antigen during differentiation of cul- 68:799
thymectomy on development of Lucké renal adenocarcinomas in virus-infected leopard frog tadpoles /Effect of 68:133
thymic epithelial reticular cells /Formation of symbiotic complex by microenvironment-dependent mouse leukemias and 69:627
thymidine on L1210 leukemia in mice /Comparison of in vitro and in vivo effects of 68:875; 69:547
thymoma lymphocytes: Role of subcellular factors in blastic activation /Functional properties of human 69:827
thymomas in the mouse /Alloantigenic phenotype of radiation-induced 69:619
thymosin-treated bone marrow cell injection /Decrease of tumor growth in mice after intravenous 69:27
thyroid gland /Establishment and characterization of a human colony-stimulating factor-producing cell line from a squamous cell carci- 69:1235
T-Lymphocyte and B-lymphocyte subpopulations infiltrating human mammary carcinomas 69:1
T-lymphocyte function in the peripheral blood of brain tumor patients /In vitro reversal of depressed 68:27
T-lymphocytes. XIX. T-cells and T-cells with receptors for IgMFc (Tμ), IgGFc (Tγ), or IgAFc (Tα) in the peripheral blood and regional 69:1261
T-lymphoid cell lines with specific cytotoxic reactivity for a syngeneic murine lymphoma /Generation of long-term 69:109
tobacco smoke inhalation /Pathogenesis of lesions induced in rat lung by chronic 69:117
trachea: Cytokinetic and ultrastructural alterations /Squamous metaplasia in organ cultures of vitamin A-deficient hamster 69:895
trachea in fetal Syrian golden hamsters treated transplacentally with *N*-nitrosodiethylamine /Electron microscopic autoradiography of 69:927
transformation and chromosomal changes induced by chemical carcinogens in skin fibroblasts from patients with familial adenomatosis coli 68:563
transformation in C3H/10T½ cells /Resting state depth and saturation density as modulated by tumor promoters and culture condi- 68:259
transformation in culture with associated advances in culture technology /A quest for the mechanism of "spontaneous" malignant 68:895
transformation of mouse salivary gland epithelium in vitro /Chromosome changes associated with the progression of cell lines 69:425
transformation of Syrian hamster cells by putative epoxide metabolites of commercially utilized chloroalkenes /Neoplastic 69:531
transformation of Syrian hamster embryo cells /Equivalency of endothelial cell growth supplement to irradiated feeder cells in car- 68:127
transformed cells in culture /Methionine regulation of *N*-5-methyltetrahydrofolate:homocysteine methyltransferase and its influence on 69:9
transformed human fibroblasts /Basis for the differential action of aminonucleoside on normal and 68:407
transforming and nontransforming Epstein-Barr virus in high passages of P3HR-1 cell lines /Persistence of 69:585
transplacentally induced teratogenic and carcinogenic effects in rabbits treated with *N*-nitroso-*N*-ethylurea /Genetics of 69:1411
transplantable 7,12-dimethylbenz[*a*]anthracene-induced chicken fibrosarcoma lines: Differences in metastatizing properties and organ 69:535
transplantable granulocytic leukemia (GL-13) in guinea pigs /A deletion in chromosome 1 in cells of a 69:591
transplantable hepatocellular carcinomas /Expression of fibronectin and laminin in the rat liver after partial hepatectomy, during car- 69:1105
transplantable leukemia impaired in copper-deficient mice /Immunization against 69:489
transplantable mammary tumor in the rat /Androgen control of cytosol progesterone receptor levels in the MT-W9B 69:673
transplantation antigens on pulmonary metastases of a 3-methylcholanthrene-induced sarcoma in mice: A preliminary report /Immu- 69:1121
transplantation antigens with the nonionic detergent octyl-β-D-glucopyranoside /Noncytolytic extraction of murine tumor-specific 69:131
transplantation of a human leukemia cell into nude mice: Conditions optimizing graft acceptance /Successful 68:15
transplantation of hepatocytes from livers of carcinogen-treated rats /Purification and 68:851
transplantation of human hepatocytes /Isolation, culture, and 68:771
transplantation of murine skin cancers induced by methoxsalen plus ultraviolet (320-400 nm) radiation /Induction and 68:685
transplanted mammary tumors in GR mice /Comparison of biologic behavior and histology of 69:933
transplants of normal, hyperplastic, and tumor tissues exposed to X-rays /Survival of mouse mammary gland 68:613
Trisomy 15 and other nonrandom chromosome changes in Rauscher murine leukemia virus-induced leukemia cell lines 69:945
trophoblastic neoplasia /Circulating immune complex levels in patients with gestational 69:23
tubular cell tumors in rats treated with *N*-ethyl-*N*-hydroxyethylnitrosamine /β-Cyclodextrin: Promoting effect on the development of 69:963
tumor-associated antigens. I. Characterization of the cell components for induction of suppression /Tumor cell-triggered macrophage- 69:867
tumor-associated antigens. II. Mechanisms for induction of suppression /Tumor cell-triggered macrophage-mediated suppression of the 69:873
tumor-associated antigens in spleens of syngeneic mouse mammary tumor systems with low and high oncogenic potentials /Anal- 69:1403
tumor-associated antigens in vasectomized men /Immunity to 69:551
Tumor-associated antigens produced by mouse mammary tumor cells in artificial capillary culture 69:1359
tumor-associated lymphocytes against human ovarian carcinoma cells /Interferon effect on cytotoxicity of peripheral blood and 68:555
tumor-bearing BALB/c mice. I. Enhancement of in vivo rejection responses by combined chemotherapy-immunotherapy /Develop- 68:963
tumor-bearing humans /Transforming growth factors in the urine of normal, pregnant, and 69:793
tumor-bearing mice and effects of *Corynebacterium parvum* /Accessory of cell function in 69:1293
tumor cell invasion in vitro /Effect of natural protease inhibitors and a chemoattractant on 69:1049
Tumor cell-triggered macrophage-mediated suppression of the T-cell cytotoxic response to tumor-associated antigens. I. Characterization 69:867
Tumor cell-triggered macrophage-mediated suppression of the T-cell cytotoxic response to tumor-associated antigens. II. Mechanisms for in- 69:873
tumor development /Letter to the Editor: *Trans* fatty acids in 69:319
tumor growth in mice after intravenous thymosin-treated bone marrow cell injection /Decrease of 69:27
tumor growth rate and target cell number /Relationship between urethan dose rate and adenoma latency: Relevance of 69:859
tumoricidal macrophages from lung melanoma metastases of mice treated systemically with liposomes containing a lipophilic deriva- 69:1189

tumorigenesis by cigarette smoke condensate following β-irradiation in rats /Enhancement of skin 68:605

tumorigenicity in nude mice /Effect of type C viral expression and cellular karyotype on human B-lymphoblast 69:435

tumorigenicity of untransformed mouse cell lines /Role of anchorage in the expression of 69:415

tumorigenicity /Plasminogen activator, fibronectin, lymphotoxin sensitivity, and natural skin reactivity relationships to guinea pig cell 68:329

tumorigenic phenotype during transformation of mouse salivary gland epithelium in vitro /Chromosome changes associated with 69:425

Tumor-induced neovascularization in the mouse eye 69:699

tumor-initiating activity of complex mixtures from environmental particulate emissions on SENCAR mouse skin /Comparative 68:829

Tumor lysis mechanism involving target cell-binding proteases /Inducible macrophage cytotoxins. II. 69:889

tumor necrosis-inducing factor: Purification and effects on myelomonocytic leukemia cells /Murine 68:997

tumor promoters and culture conditions: Relationship to chemical transformation in C3H/10T½ cells /Resting state depth and satu- 68:259

tumor promoters in promotable JB6 mouse epidermal cells: Antagonism by an antipromoter /Ganglioside changes induced by 68:469

tumor promoters saccharin and cyclamate /Inhibition of iodinated nerve growth factor binding by the suspected 68:299

Tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate: Effect on complement and Epstein-Barr virus receptors in human lymphoblas- 68:385

tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate on cell interactions in vitro /Some effects of the 69:721

tumor-promoting phorbol esters of procollagen synthesis in promotable JB6 mouse epidermal cells /Inhibition by 69:1147

tumor-specific cell surface antigen identified by monoclonal antibody on a Rous sarcoma virus-induced mouse tumor /Individually dis- 69:527

tumor-specific serum blocking factors /Regulation of cell-mediated immunologic reactivity to Moloney murine sarcoma virus-induced 69:939

tumor-specific transplantation antigens on pulmonary metastases of a 3-methylcholanthrene-induced sarcoma in mice: A preliminary report 69:1121

tumor-specific transplantation antigens with the nonionic detergent octyl-β-D-glucopyranoside /Noncytolytic extraction of murine 69:131

tumor stem-cell line /Prostaglandin-induced differentiation or dimethyl sulfoxide-induced differentiation: Reduction of the neoplastic 69:1083

tumor suppression in mice /Evidence for involvement of mast cells in 69:1305

tumor virus antigens by patients with hyperplastic benign breast disease /Cell-mediated immunity to mouse mammary 68:935

Tumor virus induction and host cell capacity inactivation: Possible in vitro tests for photosensitizing chemicals 69:183

type C viral expression and cellular karyotype on human B-lymphoblast tumorigenicity in nude mice /Effect of 69:435

Ulex europaeus agglutinin-I-binding sites in normal mucosa, adenoma, and carcinoma of the human large bowel /Glycoconjugate with 69:777

ultraviolet carcinogenesis in BALB/c mice /Influences of age and anatomical site on 68:691

ultraviolet light irradiations of cultured skin fibroblasts in two families with Gardner's syndrome /Heterogeneous response to X-ray and 68:697

ultraviolet light on melanocytes: Use of animal models in pigment research /Toxic effect of 69:245

ultraviolet (280–320 nm) radiation and psoralen plus ultraviolet (320–400 nm) radiation in mice /Immunosuppressive effects of 69:171

ultraviolet (320–400 nm) radiation /Induction and transplantation of murine skin cancers induced by methoxsalen plus 68:685

ultraviolet radiation on human lymphoid cells /In vitro assay of the effects of psoralens plus 69:219

ultraviolet radiation: Role of DNA–protein cross-links /Cell damage by near 69:177

ultraviolet radiation (320–400 nm) therapy: An experimental and clinical evaluation /Ocular phototoxicity and psoralen plus 69:287

United States–Japan Cooperative Cancer Research Program on cell interactions and cancer /Meeting Highlights: Brief summary of the 69:544

United States /No seasonality in the diagnosis of acute leukemia in the 69:1283

United States: Sources and uses of data /Measurement of cancer incidence in the 68:743

urethan dose and target cell number /Relationship of lung adenoma prevalence and growth rate to acute 69:851

urethan dose rate and adenoma latency: Relevance of tumor growth rate and target cell number /Relationship between 69:859

urinary bladder in vitro /*N*-Methyl-*N*-nitrosourea and saccharin: Effects on epithelium of normal human 69:577

urinary bladder tumors in male F344 rats /Organ-specific promoting effects of phenobarbital sodium and sodium saccharin in the in- 68:497

urinary tract /Coffee drinking and cancer of the lower 68:91

urine of normal, pregnant, and tumor-bearing humans /Transforming growth factors in the 69:793

uterine cervix and penis in China /Correlation between cancers of the 69:1063

uterus in androgen-sterilized SD rats /Spontaneous occurrence of atypical hyperplasia and adenocarcinoma of the 69:95

V_2 carcinoma implanted in the nude mouse /Collagenolytic activity of rabbit 69:1329

vasectomized men /Immunity to tumor-associated antigens in 69:551

Vasopressin: Action in WRK-1 rat mammary tumor cells 68:267

vinblastine, vindesine, and bis(*N*-ethylidene vindesine) disulfide, disulfate /Cross-resistance of cultured murine leukemia vincristine-re- 68:1023

vincristine-resistant P388 cells to vinblastine, vindesine, and bis(*N*-ethylidene vindesine) disulfide, disulfate /Cross-resistance of cul- 68:1023

vindesine, and bis(*N*-ethylidene vindesine) disulfide, disulfate /Cross-resistance of cultured murine leukemia vincristine-resistant P388 68:1023

viral components in modifying erythroid differentiation in mice /Friend erythroleukemia virus complex: Role of 68:457

virus- and tumor-associated antigens in spleens of syngeneic mouse mammary tumor systems with low and high oncogenic potentials 69:1402

virus antigens by patients with hyperplastic benign breast disease /Cell-mediated immunity to mouse mammary tumor 68:935

virus complex: Role of viral components in modifying erythroid differentiation in mice /Friend erythroleukemia 68:457
viruses of AKR mice /Spontaneous leukemia viruses: Lymphomagenic ecotropic 69:1077
virus expressions in two NZB mouse breeding lines that differ in chromosome breakage /Diverse xenotropic 68:951
virus-induced leukemia cell lines /Trisomy 15 and other nonrandom chromosome changes in Rauscher murine leukemia 69:945
virus-induced mouse tumor /Individually distinct tumor-specific cell surface antigen identified by monoclonal antibody on a Rous sar- 69:527
virus-induced tumors. III. Further characterization of tumor-specific serum blocking factors /Regulation of cell-mediated immuno- 69:939
virus induction and host cell capacity inactivation: Possible in vitro tests for photosensitizing chemicals /Tumor 69:183
virus induction patterns /Human lymphoma-lymphoma hybrids and lymphoma-leukemia hybrids. II. Epstein-Barr 68:197
virus-infected, chemically induced murine sarcoma with antiviral antibodies /Immunotherapy of a murine leukemia 69:509
virus-infected leopard frog tadpoles /Effect of thymectomy on development of Lucké renal adenocarcinomas in 68:133
virus-infected mice /Letter to the Editor: Immune alterations related to age, sex, and mammary tumor detection in murine mammary 69:1208
virus infection in humans with leukemias, lymphomas, or soft tissue sarcomas /Search for evidence of feline leukemia 69:333
virus in high passages of P3HR-1 cell lines /Persistence of transforming and nontransforming Epstein-Barr 69:585
virus /In vitro infection of lymphocytes with Marek's disease 69:709
virus-producing tumor cells /Induction of gp70-specific suppressor T-cells in mice inoculated with 69:953
virus receptors in human lymphoblastoid cell lines /Tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate: Effect on complement 68:385
virus tumors in CBA/J mice: Chemopreventive and chemotherapeutic actions of supplemental β-carotene /Moloney murine sarcoma 68:835
vitamin A and 5-fluorouracil and the growth of allotransplantable and syngeneic tumors in mice /Combined treatments with 68:823
vitamin A-deficient hamster trachea: Cytokinetic and ultrastructural alterations /Squamous metaplasia in organ cultures of 69:895
vitamin E /Oral mucosal carcinogenesis in hamsters: Inhibition by 68:791
vomiting in chemotherapy patients /Prevalence and correlates of anticipatory nausea and 68:585

Wales; 1950–79: Are the changes real? /Increasing trends of multiple myeloma mortality in England and 69:387
water in cultured mammalian cells /Genotoxic effects of sunlight-activated waste 69:199
weight /Cancer incidence in humans: Relationship to plasma lipids and relative 68:915
West Virginia /Mortality among workers in a nickel refinery and alloy manufacturing plant in 68:925
Wilms' tumor: Results of the National Wilms' Tumor Study /Epidemiological features of 68:429
Wistar rats: Histopathology of the glandular stomach and incidence of gastric adenocarcinoma /Gastrin protection against chemically 69:59
women in northern Alberta, Canada, as related to age at diagnosis /Risk factors for breast cancer in 68:211
women /Parity and colorectal cancer risk in 69:1059
women /Single oblique-view mammography for periodic screening for breast cancer in 68:351
women /Smoking history and lung cancer survival in 68:395
women /Use of circulating pregnancy-specific β_1 glycoprotein as a marker in carcinoma of the breast in 69:1067
women with benign breast diseases /Exogenous estrogens and other risk factors for breast cancer in 69:1017
WRK-1 rat mammary tumor cells /Vasopressin: Action in 68:267

xenografts /Growth and characterization of childhood rhabdomyosarcomas as 68:437
xenografts in nude mice with a radiolabeled monoclonal antibody /Imaging of human melanoma 69:823
xenotransplantability and cell surface properties of ascites sublines of a rat mammary adenocarcinoma /Relationship between 69:33
xeromammograms /Observer variation in the interpretation of 68:357
X-irradiation during G_2 phase in a line of normal human fibroblasts and its malignant derivative /Repair of chromosome damage in- 69:409
X-ray and ultraviolet light irradiations of cultured skin fibroblasts in two families with Gardner's syndrome /Heterogeneous response to 68:697
X-rays, and diethylstilbestrol /Induction of mammary neoplasms in the ACI rat by 430-keV neutrons, 69:1135
X-rays /Survival of mouse mammary gland transplants of normal, hyperplastic, and tumor tissues exposed to 68:613

Zinc deficiency, alcohol, and a retinoid: Association with esophageal cancer in rats 68:785

blank page

Table of Contents

Volumes 68–69
January–December 1982

Vol 68, No.1—JANUARY 1982

1 Howard Bancroft Andervont, *D.Sc*—A Tribute

Investigations on Man

3	Neoplasms following childhood radium irradiation of the nasopharynx	*Dale P. Sandler, George W. Comstock, Genevieve M. Matanoski*
9	Epithelial dysplasia in nipple aspirates of breast fluid: Association with family history and other breast cancer risk factors	*Nicholas L. Petrakis, Virginia L. Ernster, Eileen B. King, Susan T. Sacks*
15	Successful transplantation of a human leukemia cell into nude mice: Conditions optimizing graft acceptance	*H. W. (Löms) Ziegler, Glauco Frizzera, Fritz H. Bach*
19	Enhanced expression of melanoma-associated antigens and β_2-microglobulin on cultured human melanoma cells by interferon	*Shuen-Kuei Liao, Pak C. Kwong, Mohammed Khosravi, Peter B. Dent*
27	In vitro reversal of depressed T-lymphocyte function in the peripheral blood of brain tumor patients	*Gary W. Wood, Robert A Morantz*
35	Human adherent cell contact-mediated modulation of normal myeloid colony formation	*Gary Spitzer, Dharmvir S. Verma, Miloslav Beran, Axel R. Zander, Kenneth B. McCredie, Karel A. Dicke*
43	Pathology panel for lymphoma clinical studies: A comprehensive analysis of cases accumulated since its inception	*Hun Kim, Ronald J. Zelman, Michael A. Fox, John M. Bennett, Costan W. Berard, James J. Butler, Gerald E. Byrne, Jr., Ronald F. Dorfman, Robert J. Hartsock, Robert J. Lukes, Risa B. Mann, Richard S. Neiman, John W. Rebuck, William W. Sheehan, Daina Variakojis, John F. Wilson, Henry Rappaport*
69	Maximizing differences in the concanavalin A-induced blastogenic responses of lymphocytes from breast cancer patients and controls by the use of α-methyl-D-mannoside	*John A. Distasio, David A. Cheresh, Russel J. Schilder, Charles L. Vogel, Michael A. Silverman, Diana M. Lopez*
75	Value of plasma α-1-acid glycoprotein assay in the detection of human colorectal cancer: Comparison with carcinoembryonic antigen	*Clement Y-T. Chu, Lilian T-Y. Lai, Hari P. Pokala*
81	Various isozyme gene expression patterns among human colorectal adenocarcinoma cell lines and tissues	*Lynne P. Rutzky, Michael J. Siciliano*
91	Coffee drinking and cancer of the lower urinary tract	*Alan S. Morrison, Julie E. Buring, Wendy G. Verhoek, Kunio Aoki, Ian Leck, Yoshiyuki Ohno, Koji Obata*
95	Noncontraceptive estrogen use and the occurrence of ovarian cancer	*Noel S. Weiss, J. Lynn Lyon, Sarala Krishnamurthy, Scott E. Dietert, Jonathan M. Liff, Janel R. Daling*
99	Multiple marker evaluation in human prostate cancer with the use of tissue-specific antigens	*M. Kuriyama, M. C. Wang, C. L. Lee, C. S. Killian, L. D. Papsidero, H. Inaji, R. M. Loor, M. F. Lin, T. Nishiura, N. H. Slack, G. P. Murphy, T. M. Chu*
107	Environmental factors in the etiology of rhabdomyosarcoma in childhood	*Seymour Grufferman, Helen H. Wang, Elizabeth R. DeLong, Sue Y. S. Kimm, Elizabeth S. Delzell, John M. Falletta*
115	Anticancer drugs: Effect on the cloning of Raji lymphoma cells in soft agar	*Pao-Chen Wu, Robert F. Ozols, Masakazu Hatanaka, Charles W. Boone*

Investigations on Nonhuman Systems

123	Antitumor activity of picolinic acid in CBA/J mice	*Susan W. C. Leuthauser, Larry W. Oberley, Terry D. Oberley*

127 Equivalency of endothelial cell growth supplement to irradiated feeder cells in carcinogen-induced morphologic transformation of Syrian hamster embryo cells — *Charles H. Evans, Joseph A. DiPaolo*

133 Effect of thymectomy on development of Lucké renal adenocarcinomas in virus-infected leopard frog tadpoles — *Louise A. Rollins-Smith, Nicholas Cohen*

139 Studies on the antitumor activities of pyrimidinone-interferon inducers. I. Effect against artificial and spontaneous lung metastases of murine tumors — *Luka Milas, Evan M. Hersh, Dale A. Stringfellow, Nancy Hunter*

147 Rat mammary tumor classification: Notes on comparative aspects — *Dymitr Komitowski, Bernard Sass, Walter Laub*

157 Induction of nasal tumors in rats exposed to hexamethylphosphoramide by inhalation — *Ki P. Lee, Henry J. Trochimowicz*

Meeting Highlights

173 Host factors in human carcinogenesis — *John J. Mulvihill*

Announcements

175 Sixteenth Annual Clinical Symposium

175 Thirty-Second Annual Conference of The National Council on the Aging, Inc.

175 Oncology Update 1982

175 North American Society for Cardiac Radiology—1982 Postgraduate Course

175 Second Annual Washington Imaging Conference

175 Fourth Annual Course in Flow Cytometry

175 Educational Video Cassettes

Vol 68, No. 2—FEBRUARY 1982

177 Obituary—Herbert Joseph Rapp — *Tibor Borsos*

Investigations on Man

179 Human lymphoma-lymphoma hybrids and lymphoma-leukemia hybrids. I. Isolation, characterization, cell surface markers, and B-cell markers — *Jesper Zeuthen, George Klein, Rosalie Ber, Giuseppe Masucci, Susanne Bisballe, Susan Povey, Paul Terasaki, Peter Ralph*

197 Human lymphoma-lymphoma hybrids and lymphoma-leukemia hybrids. II. Epstein-Barr virus induction patterns — *George Klein, Jesper Zeuthen, Rosalie Ber, Ingemar Ernberg*

203 Ganglioside patterns: New biochemical markers for human hematopoietic cell lines — *Günter Rosenfelder, Andreas Ziegler, Peter Wernet, Dietmar G. Braun*

211 Risk factors for breast cancer in women in northern Alberta, Canada, as related to age at diagnosis — *Jay H. Lubin, Patricia E. Burns, William J. Blot, Alan W. Lees, Carol May, Linda E. Morris, Joseph F. Fraumeni, Jr.*

219 Cancer incidence in the Republic of Panama, 1974-78 — *William C. Reeves, Plinio F. Valdés, María M. Brenes, Rosa C. de Britton, Claire F. B. Joplin*

227 Phase I–Phase II trial of *N*-phosphonacetyl-L-aspartic acid given by intravenous infusion and 5-fluorouracil given by bolus injection — *Charles Erlichman, Ross C. Donehower, James L. Speyer, Ray Klecker, Bruce A. Chabner*

233 Phytohemagglutinin or pokeweed mitogen induction of in vitro colony formation by T-cells from patients with chronic lymphocytic leukemia — *Vito Pistoia, Arcangelo Nocera, Riccardo Ghio, Paola Minale, Manlio Ferrarini*

Investigations on Nonhuman Systems

239 Causes of death and sex differences in survival times of pigs with untreated hereditary lymphosarcoma (leukemia) — *H. S. McTaggart, P. Imlah, K. W. Head*

249 Calorie restriction: Effect on growth of human tumors heterotransplanted in nude mice — *Beppino C. Giovanella, Randall C. Shepard, John S. Stehlin, John M. Venditti, Betty J. Abbott*

259 Resting state depth and saturation density as modulated by tumor promoters and culture conditions: Relationship to chemical transformation in C3H/10T½ cells — *David Miska, H. Bruce Bosmann*

267 Vasopressin: Action in WRK-1 rat mammary tumor cells — *M. E. Monaco, P. H. Kohn, W. R. Kidwell, J. S. Strobl, M. E. Lippman*

271 Cholangiocellular carcinomas induced in Syrian golden hamsters administered aflatoxin B_1 in large doses — *Michael R. Moore, Henry C. Pitot, Elizabeth C. Miller, James A. Miller*

279 L-Histidinol protection against cytotoxic action of cytosine arabinoside and 5-fluorouracil in cultured mouse spleen cells — *Robert C. Warrington, Wei D. Fang*

287 Murine lymphoma L5178Y cells resistant to purine antagonists: Differences in cross-resistance to thioguanine–platinum(II) and selenoguanine–platinum(II) — *Fumihiko Kanzawa, Mitsuaki Maeda, Takuma Sasaki, Akio Hoshi, Kazuo Kuretani*

293 Production of kidney tumors in rats with low dose of dimethylnitrosamine after partial hepatectomy — *Ritva P. Evarts, Carolyn A. Brown, Mostafa Hassan Mostafa*

299 Inhibition of iodinated nerve growth factor binding by the suspected tumor promoters saccharin and cyclamate — *Douglas N. Ishii*

305 Granulopoiesis longevity in continuous bone marrow cultures and factor-dependent cell line generation: Significant variation among 28 inbred mouse strains and outbred stocks — *Mary Ann Sakakeeny, Joel S. Greenberger*

319 Effects of dietary lipids on lactogenic hormone receptor binding in rat mammary tumors — *William T. Cave, Jr., Marsha J. Erickson-Lucas*

325 Lipopolysaccharide and pristane-induced peritoneal exudate requirements for plasma tumor cell colony formation — *Micsunica Platica, Catherine Bojko, Radu Clincea, Vincent Hollander*

329 Plasminogen activator, fibronectin, lymphotoxin sensitivity, and natural skin reactivity relationships to guinea pig cell tumorigenicity — *Richard P. McCabe, Charles H. Evans*

Meeting Highlights

337 Kaposi's sarcoma in homosexual men — *John L. Ziegler*

338 Monoclonal antibodies and breast cancer — *Marianne L. Egan, Donald E. Henson*

Announcements

341 National Toxicology Program Conference

341	Latest NCI Monographs Published	
341	Other Monographs Available	

Vol 68, No. 3—MARCH 1982

Guest Editorial

343	What are isozymes telling us about gene regulation in cancer?	*Sidney Weinhouse*

Investigations on Man

351	Single oblique-view mammography for periodic screening for breast cancer in women	*Bengt Lundgren, Anders Helleberg*
357	Observer variation in the interpretation of xeromammograms	*Norman F. Boyd, Christina Wolfson, Myron Moskowitz, Thomas Carlile, Michel Petitclerc, Helen A. Ferri, Eve Fishell, Andre Gregoire, Matthew Kiernan, J. Donald Longley, Imre S. Simor, Anthony B. Miller*
365	Multiple cell lines from patients with malignant melanoma: Morphology, karyology, and biochemical analysis	*Toni U. Semple, George E. Moore, Robert T. Morgan, Linda K. Woods, Laurie A. Quinn*
381	Prolactin receptors in human breast tumors	*Lucile Turcot-Lemay, Paul A. Kelly*
385	Tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate: Effect on complement and Epstein-Barr virus receptors in human lymphoblastoid cell lines	*Naoki Yamamoto, Takashi Mitsuma, Arnold Vogt*
391	Cerebrospinal fluid levels of 2′-deoxycoformycin after systemic administration in monkeys	*Julie Blatt, Peter M. Venner, Riccardo Riccardi, Lawrence F. Cohen, Daimon Gangji, Robert I. Glazer, David G. Poplack*
395	Smoking history and lung cancer survival in women	*M. Ward Hinds, Hong-Yi Yang, Grant Stemmermann, James Lee, Laurence N. Kolonel*
401	Intestinal metaplasia in Japan: Association with diet	*Abraham Nomura, Hiroshi Yamakawa, Takuzo Ishidate, Sigetosi Kamiyama, Hisayuki Masuda, Grant N. Stemmermann, Lance K. Heilbrun, Jean H. Hankin*
407	Basis for the differential action of aminonucleoside on normal and transformed human fibroblasts	*Ernest A. Albanese, George P. Studzinski*
415	Phenotypic and genotypic characteristics of a cell line from a squamous cell carcinoma of human skin	*Petra Boukamp, Wolfgang Tilgen, Rule T. Dzarlieva, Dirk Breitkreutz, Dietrich Haag, Rüdiger K. Riehl, Axel Bohnert, Norbert E. Fusenig*
429	Epidemiological features of Wilms' tumor: Results of the National Wilms' Tumor Study	*Norman E. Breslow, J. Bruce Beckwith*
437	Growth and characterization of childhood rhabdomyosarcomas as xenografts	*J. A. Houghton, P. J. Houghton, B. L. Webber*
445	Intrastage prognostic heterogeneity: Implications for adjuvant chemotherapy of breast cancer	*Maurice M. Black, Benjamin F. Hankey, Thomas H. C. Barclay*

Investigations on Nonhuman Systems

449	Morphology and function of ganglio-*N*-tetraosylceramide-positive lymphocyte mediators of natural killer activity	*Kazuo Shimamura, Sonoko Habu, Hiroyasu Fukui, Akira Akatsuka, Ko Okumura, Norikazu Tamaoki*
457	Friend erythroleukemia virus complex: Role of viral components in modifying erythroid differentiation in mice	*Barbara Fagg, Wolfram Ostertag*
461	Growth and spontaneous regression of swine melanoma: Relationship of in vitro leukocyte reactivity	*Jane Berkelhammer, Bonnie M. Ensign, Reuel R. Hook, Jr., Cynthia J. Hecker, Gerald D. Smith, Ronald W. Oxenhandler*

469	Ganglioside changes induced by tumor promoters in promotable JB6 mouse epidermal cells: Antagonism by an antipromoter	*Leela Srinivas, Nancy H. Colburn*
475	Microcirculatory blood flow, capillary morphology, and local oxygen pressure of the hamster amelanotic melanoma A-Mel-3	*Bernhard Endrich, Frithjof Hammersen, Alwin Götz, Konrad Messmer*
487	Effect of rate of heating on lethality due to hyperthermia and selected chemotherapeutic drugs	*Terence S. Herman, Cynthia C. Sweets, David M. White, Eugene W. Gerner*
493	Glutathione *S*-transferase activity: Enhancement by compounds inhibiting chemical carcinogenesis and by dietary constituents	*Velta L. Sparnins, Plarida L. Venegas, Lee W. Wattenberg*
497	Organ-specific promoting effects of phenobarbital sodium and sodium saccharin in the induction of liver and urinary bladder tumors in male F344 rats	*Keisuke Nakanishi, Shoji Fukushima, Akihiro Hagiwara, Seiko Tamano, Nobuyuki Ito*
501	Serologic analysis of nitrosourea-induced rat gliomas	*Michael Pfreundschuh, Humberto Cravioto, Gerald Hochwald, Joseph Ransohoff*
507	Development and biologic properties of malignant cell sublines and clones of a spontaneously metastasizing rat mammary adenocarcinoma	*Anthny Neri, Dan Welch, Takanori Kawaguchi, Garth L. Nicolson*
519	Temperature gradients and local perfusion in a mammary carcinoma	*Pietro M. Gullino, Rakesh K. Jain, Flora H. Grantham*

Correction

535	November 1981, Vol 67, No. 5, page 991: "Letters to the Editor, BCG and Cancer" (reply)	*George W. Comstock*

Announcements

535 Harvard Medical School Continuing Education Program

535 Aspirin Foundation of America

535 Cancer Management 1982

535 World Symposium on Asbestos

535 Fist International Symposium on the Endocrine Lung in Health and Disease

535 World Congress of Gastroenterology, Digestive Endoscopy, and Colo-Proctology

536 Annual Course in Advanced Immunology

536 First Conference on Radioprotectors and Anticarcinogens

536 Design and Analysis of Scientific Experiments

536 Veterinary Cancer Society

Vol 68, No. 4—APRIL 1982

Investigations on Man

537	Oral contraceptive use and malignant melanoma	*Christopher Bain, Charles H. Hennekens, Frank E. Speizer, Bernard Rosner, Walter Willett, Charlene Belanger*

541	5-Fluorouracil, 1,3-bis(2-chloroethyl)-1-nitrosourea, and 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea: Effect on the human granulopoietic system	*Hans-Peter Lohrmann, Karin A. Lepp, Wolfgang Schreml*
549	T_G cell involvement in the leukocyte adherence inhibition phenomenon	*S. G. Taylor IV, Patricia C. Saffold, Donald P. Braun, Jules E. Harris*
555	Interferon effect on cytotoxicity of peripheral blood and tumor-associated lymphocytes against human ovarian carcinoma cells	*Paola Allavena, Martino Introna, Cristiana Sessa, Costantino Mangioni, Alberto Mantovani*
563	Morphologic transformation and chromosomal changes induced by chemical carcinogens in skin fibroblasts from patients with familial adenomatosis coli	*Michiko Miyaki, Noriko Akamatsu, Tetsuo Ono, Akira Tonomura, Joji Utsunomiya*
573	Carotid body tumors in humans: Genetics and epidemiology	*Dilys M. Parry, Frederick P. Li, Louise C. Strong, J. Aidan Carney, David Schottenfeld, Ronald R. Reimer, Seymour Grufferman*
579	Lymphocyte fluorescence polarization changes after phytohemagglutinin stimulation in the diagnosis of colorectal carcinoma	*Glenn R. Hocking, Jennifer M. Roland, Richard C. Nairn, Eric Pihl, Alan M. Cuthbertson, Edward S. R. Hughes, William R. Johnson*
585	Prevalence and correlates of anticipatory nausea and vomiting in chemotherapy patients	*Gary R. Morrow*
589	Retinoic acid-induced growth inhibition and morphologic differentiation of human neuroblastoma cells in vitro	*Neil Sidell*

Investigations on Nonhuman Systems

597	Gaseous formaldehyde and hydrogen chloride induction of nasal cancer in the rat	*Roy E. Albert, Arthur R. Sellakumar, Sidney Laskin, Marvin Kuschner, Norton Nelson, Carroll A. Snyder*
605	Enhancement of skin tumorigenesis by cigarette smoke condensate following β-irradiation in rats	*John F. McGregor (with revisions by D. K. Myers)*
613	Survival of mouse mammary gland transplants of normal, hyperplastic, and tumor tissues exposed to X-rays	*Leslie J. Faulkin, Dan J. Mitchell, Robert D. Cardiff, Marvin Goldman*
619	Bile acids: Effects on absorption of 1,2-dimethylhydrazine and 7,12-dimethylbenz[*a*]anthracene in the colon of the rat and guinea pig	*Richard C. Rose, David L. Nahrwold*
623	Liver DNA bound in vivo with aflatoxin B_1 as a measure of hepatocarcinoma initiation in rainbow trout	*Mark Whitham, Joseph E. Nixon, R. O. Sinnhuber*
629	B16 melanoma cell variants: Irreversible inhibition of growth and induction of morphologic differentiation by anthracycline antibiotics	*Avraham Raz*
639	Differing stem cell self-renewal of lectin-separated murine bone marrow fractions	*Andrew L. Salner, Jane E. Obbagy, Samuel Hellman*
643	Immunologic relatedness of intracisternal A-particles in mouse embryos and neoplastic cell lines	*Thomas T. F. Huang, Jr., Patricia G. Calarco*
651	Methylazoxymethanol: Effect on the immune response of rats to human serum albumin	*Ahmed F. S. A. Habeeb, Alan M. Preston, Priscila Sanabria, Nelson Escobales*
657	Peptidoglycans extracted from gram-positive bacteria: Expression of antitumor activity according to peptide structure and route of injection	*Anne-François Goguel, Geneviève Lespinats, Charles Nauciel*
665	Rat hepatomas: Chemotherapy with Lycurim and Pyrazofurin	*May S. Lui, Robert C. Jackson, Ronald J. Harkrader, George Weber*
669	Liver tumors induced by a new beta-adrenoreceptor blocking agent in female rats	*Giovanni Ragnotti, Marco Presta, Laura Riboni, Teresa Zavanella*

673 Mechanisms of immunologic eradication of a syngeneic guinea pig tumor. I. Quantitative analysis of adoptive immunity *Suyu Shu, James T. Hunter, Herbert J. Rapp, Leila S. Fonseca*

681 Esophageal carcinogenesis in F344 rats by nitrosomethylethylamines substituted in the ethyl group *William Lijinsky, Joseph E. Saavedra, Melvin D. Reuber, Sandra S. Singer*

685 Induction and transplantation of murine skin cancers induced by methoxsalen plus ultraviolet (320-400 nm) radiation *M. L. Kripke, W. L. Morison, J.A. Parrish*

691 Influences of age and anatomical site on ultraviolet carcinogenesis in BALB/c mice *Peter Ebbesen, Margaret L. Kripke*

Announcements

695 American Cancer Society National Conference—The Primary Care Physician and Cancer

695 Eleventh Annual Meeting of the International Society for Experimental Hematology

695 Workshop on "Coagulation, Cancer, and Inflammation"

695 Approaches to the Management of Pain

695 Eighth Biannual Morris Hepatoma Symposium

695 Fourteenth Meeting of the International Society for Pediatric Oncology (SIOP)

695 Second International Congress of the T. and L. de Beaumont Bonelli Foundation for Cancer Research

695 Large Bowel Cancer: Biology and Control

Vol 68, No. 5—MAY 1982

Investigations on Man

---

697 Heterogeneous response to X-ray and ultraviolet light irradiations of cultured skin fibroblasts in two families with Gardner's syndrome *Timothy J. Kinsella, John B. Little, John Nove, Ralph R. Weichselbaum, Frederick P. Li, Robert J. Meyer, David J. Marchetto, W. Bradford Patterson*

703 Systemic administration of human leukocyte interferon to melanoma patients. I. Effects on natural killer function and cell populations *Sidney H. Golub, Fred Dorey, Dean Hara, Donald L. Morton, Martyn W. Burk*

711 Systemic administration of human leukocyte interferon to melanoma patients. II. Cellular events associated with changes in natural killer cytotoxicity *Sidney H. Golub, Paula D'Amore, Marcia Rainey*

719 Characterization of a monoclonal antibody reactive with a subset of human breast tumors *Dorothy Yuan, Fred J. Hendler, Ellen S. Vitetta*

729 Epidemiologic and age-dependent data on multiple myeloma in Austria *Heinz Ludwig, Elke Fritz, Hans P. Friedl*

735 Generation of suppressor cells for natural killer activity in cancer patients after surgery *Atsushi Uchida, Roland Kolb, Michael Micksche*

743 Measurement of cancer incidence in the United States: Sources and uses of data *E. Robert Greenberg, Theodore Colton, Curtis Bagne*

751 Degrees of malignancy in human primary central nervous system tumors: Ornithine decarboxylase levels as better indicators than adenosylmethionine decarboxylase levels *Giuseppe Scalabrino, Daniela Modena, Maria Elena Ferioli, Mirella Puerari, Giovanni Luccarelli*

755	An increased risk for lung cancer mortality associated with sugarcane farming	*Henry Rothschild, James J. Mulvey*
761	A 94,000-dalton glycoprotein expressed by human melanoma and carcinoma cells	*Kohzoh Imai, Barry S. Wilson, Aldo Bigotti, Pier G. Natali, Soldano Ferrone*
771	Isolation, culture, and transplantation of human hepatocytes	*S. C. Strom, R. L. Jirtle, R. S. Jones, D. L. Novicki, M. R. Rosenberg, A. Novotny, G. Irons, J. R. McLain, G. Michalopoulos*
779	Mitogen-induced blastogenesis and receptor mobility inhibition by breast cancer serum with elevated orosomucoid (α_1-acid glycoprotein) levels	*David A. Cheresh, John A. Distasio, Charles L. Vogel, Diana M. Lopez*

Investigations on Nonhuman Systems

785	Zinc deficiency, alcohol, and a retinoid: Association with esophageal cancer in rats	*Gamal N. Gabrial, Thomas F. Schrager, Paul M. Newberne*
791	Oral mucosal carcinogenesis in hamsters: Inhibition by vitamin E	*Gerald Shklar*
799	Thy-1 antigen on normal and neoplastic rat mammary tissues: Changes in location and amount of antigen during differentiation of cultured stem cells	*Philip S. Rudland, Michael J. Warburton, Paul Monaghan, Mary A. Ritter*
813	Surgical resection of the rat colon: Effects on carcinogenesis by 1,2-dimethylhydrazine	*C. A. Rubio, G. Nylander*
817	Intracerebral adoptive immunotherapy of a murine lymphoma antigenically altered by drug treatment in vivo	*L. Romani, M. C. Fioretti, R. Bianchi, B. Nardelli, E. Bonmassar*
823	Combined treatments with vitamin A and 5-fluorouracil and the growth of allotransplantable and syngeneic tumors in mice	*Yoshifumi Tomita, Kunisuke Himeno, Kikuo Nomoto, Hideya Endo, Tomio Hirohata*
829	Comparative tumor-initiating activity of complex mixtures from environmental particulate emissions on SENCAR mouse skin	*Stephen Nesnow, Larry L. Triplett, Thomas J. Slaga*
835	Moloney murine sarcoma virus tumors in CBA/J mice: Chemopreventive and chemotherapeutic actions of supplemental β-carotene	*Eli Seifter, Giuseppe Rettura, Jacques Padawer, Stanley M. Levenson*
841	Nonimmunogenic radiation-induced lymphoma: Immunity induction by a somatic cell hybrid	*Eitan Yefenof, Mira Goldapfel, Rosalie Ber*
851	Purification and transplantation of hepatocytes from livers of carcinogen-treated rats	*Steven B. Miller, Theresa P. Pretlow, Joe A. Scott, Thomas G. Pretlow II*
859	Malignant fibrous histiocytomas induced by 4-(hydroxyamino)quinoline 1-oxide in rats	*Yoichi Konishi, Hiroshi Maruyama, Yoshio Mii, Yoshizumi Miyauchi, Yoshihiko Yokose, Kenji Masuhara*
867	Prostate adenocarcinoma in rats: Induction by 3,2′-dimethyl-4-aminobiphenyl	*Shoichi Katayama, Emerich Fiala, Bandaru S. Reddy, Abraham Rivenson, Jerald Silverman, Gary M. Williams, John H. Weisburger*
875	Comparison of in vitro and in vivo effects of thymidine on L1210 leukemia in mice	*Daniel S. Zaharko, Lori M. Ramonas*

Letters to the Editor

883	Cartesian reductionism and cancer	*Harry Rubin*
884	Spontaneous liver tumors in laboratory rats	*Morris Pollard*

Investigations on Man

885	Breast cancer and serum cholesterol	*Robert A. Hiatt, Gary D. Friedman, Richard D. Bawol, Hans K. Ury*
891	Carcinomas of the cervix and corpus uteri in humans: Stage-dependent blood levels of substance(s) immunologically cross-reactive with insulin	*K. Pavelić, M. Bolanča, N. Veček, J. Pavelić, T. Marotti, S. Vuk-Pavlović*
895	A quest for the mechanism of "spontaneous" malignant transformation in culture with associated advances in culture technology	*Katherine K. Sanford, Virginia J. Evans*
915	Cancer incidence in humans: Relationship to plasma lipids and relative weight	*R. B. Wallace, C. Rost, L. F. Burmeister, P. R. Pomrehn*
919	High cloning efficiency of human lymphoid cells in agarose without feeder layers	*Kathleen N. Ayres*
925	Mortality among workers in a nickel refinery and alloy manufacturing plant in West Virginia	*Philip E. Enterline, Gary M. Marsh*
935	Cell-mediated immunity to mouse mammary tumor virus antigens by patients with hyperplastic benign breast disease	*G. B. Cannon, S. H. Barsky, T. C. Alford, L. F. Jerome, V. Tinley, J. L. McCoy, J. H. Dean*
945	Effect of enzymatic disaggregation on proliferation of human tumor cells in soft agar	*Anne W. Hamburger, Christine P. White, Kathleen Tencer*

Investigations on Nonhuman Systems

951	Diverse xenotropic virus expressions in two NZB mouse breeding lines that differ in chromosome breakage	*Carmen Bernard, Ingrid Emerit*
957	Phenotypic stability of murine tumor cells in vitro and in vivo	*James Varani, Edmund J. Lovett*
963	Development of resistance to MOPC-315 plasmacytoma after intralesional and intraperitoneal melphalan therapy of tumor-bearing BALB/c mice. I. Enhancement of in vivo rejection responses by combined chemotherapy-immunotherapy	*Aliza Adler, Irit Altbaum*
971	Hematopoietic precursor cells in mice treated with 4-demethoxydaunorubicin and doxorubicin	*Giulio Massa, Giuseppe Bogliolo, Francesco D'Amore, Carlo Muzzulini, Riccardo Ghio, Ivo Pannacciulli*

977	Inheritance of cellular resistance to the antitumor agent ICRF 159 in somatic cell hybrids	*David H. Edgar, Andrew M. Creighton*
981	Further studies on the relationship between allotransplantability and the presence of the cell surface glycoprotein epiglycanin in the TA3-MM mouse mammary carcinoma ascites cell	*Scott C. Miller, John F. Codington, George Klein*
989	Carcinogenesis by isomers of *N*-nitroso-3,5-dimethylpiperidine	*W. Lijinsky, M. D. Reuber, Sandra S. Singer, George M. Singer*
993	Effect of 7,12-dimethylbenz[*a*]anthracene on production and action of gamma interferon	*Karen A. Golemboski, Debra K. D. DeLor, Uldis N. Streips, Gerald Sonnenfeld*
997	Murine tumor necrosis-inducing factor: Purification and effects on myelomonocytic leukemia cells	*Saul Green, Areta Dobrjansky, Mary Ann Chiasson*
1005	Surface antigen expressed in hematopoietic cells derived from $Fv\text{-}4^r$ mouse strains	*Hiroshi Yoshikura, Takeshi Odaka*
1011	2′-Deoxycoformycin-induced hemolysis in the mouse	*Ellen Spremulli, Gerald W. Crabtree, Daniel L. Dexter, Israel Diamond, Paul Calabresi*
1015	Carcinogen-induced DNA damage and cellular alterations in F344 rat colon organ cultures	*Nitin T. Telang, Gary M. Williams*
1023	Cross-resistance of cultured murine leukemia vincristine-resistant P388 cells to vinblastine, vindesine, and bis(*N*-ethylidene vindesine) disulfide, disulfate	*Lee J. Wilkoff, Elizabeth A. Dulmadge*
1027	Intracellular adriamycin levels and cytotoxicity in adriamycin-sensitive and adriamycin-resistant P388 mouse leukemia cells	*Ram Ganapathi, William Reiter, Awtar Krishan*
1033	Thermotolerance in the murine jejunum	*Kurt J. Henle*
1037	Detection of acquired provirus sequences in mammary tumors from low-expressor, low-risk mice	*Bruce W. Altrock, Robert D. Cardiff, John P. Puma, Judi K. Lund*

Announcements

1043 Laser, Microwaves, Ultraviolet, and Ultrasound: Biophysical and Biological Basis, Applications, and Hazards in Medicine in Industry Program

1043 Fourth Annual Pharmacy Symposium on Cancer Chemotherapy

1043 A New Organization—American College of Epidemiology

1043 Annual Meeting of the American College of Epidemiology

1043 International Cancer Symposium

1043 Symposium on Application of Biological Markers to Carcinogen Testing

1044 A New Journal—Survey of Immunologic Research

1044 Eighth FDA Science Symposium

Vol 69, No. 1—JULY 1982

Investigations on Man

1	T-Lymphocyte and B-lymphocyte subpopulations infiltrating human mammary carcinomas	*Oleg Eremin, Robin R. A. Coombs, Terence D. Prospero, David Plumb*

9	Methionine regulation of *N*-5-methyltetrahydrofolate:homocysteine methyltransferase and its influence on the growth and protein synthesis in normal, neoplastic, and transformed cells in culture	*Jadwiga W. Tautt, Elżbieta L. Anuszewska, Jadwiga H. Koziorowska*
15	DNA distribution in human colon carcinomas and its relationship to clinical behavior	*R. C. Wolley, K. Schreiber, L. G. Koss, M. Karas, A. Sherman*
23	Circulating immune complex levels in patients with gestational trophoblastic neoplasia	*Anthony A. Rayner, Ross Berkowitz, Glenn Steele, Jr., Peter H. Schur, Mary L. Rodrick, Donald P. Goldstein, Paul J. Harte, Richard E. Wilson, Norman Zamcheck, Alelia E. Munroe*

Investigations on Nonhuman Systems

27	Decrease of tumor growth in mice after intravenous thymosin-treated bone marrow cell injection	*Didier Cupissol, Augustin Rey, Allan L. Goldstein, Bernard Serrou*
33	Relationship between xenotransplantability and cell surface properties of ascites sublines of a rat mammary adenocarcinoma	*Susan C. Howard, Steven R. Hull, John W. Huggins, Coralie A. Carothers Carraway, Kermit L. Carraway*
41	Steroid hormone receptors in the rat mammary adenocarcinoma induced by *N*-hydroxy-*N*-2-fluorenylacetamide	*Sara Antonia Li, Danuta Malejka-Giganti, Jonathan J. Li*
47	Platinum-complexed antitumor immunoglobulins that specifically inhibit DNA synthesis of mouse tumor cells	*Esther Hurwitz, Rina Kashi, Meir Wilchek*
53	Differences in spleen suppressor cell content in rats with progressing and regressing tumors	*Michael A. Hollingsworth, Donald L. Evans*
59	Gastrin protection against chemically induced gastric adenocarcinomas in Wistar rats: Histopathology of the glandular stomach and incidence of gastric adenocarcinoma	*Massaharu Tatsuta, Hisako Yamamura, Haruo Taniguchi, Hiroshi Tamura*
67	Subcutaneously injected radiolabeled liposomes: Transport to the lymph nodes in mice	*Vasily I. Kaledin, Nellie A. Matienko, Valery P. Nikolin, Yevgeny V. Gruntenko, Vladimir G. Budker, Tamara E. Vakhrusheva*
73	Prophylactic and therapeutic actions of supplemental β-carotene in mice inoculated with C3HBA adenocarcinoma cells: Lack of therapeutic action of supplemental ascorbic acid	*Giuseppe Rettura, Francis Stratford, Stanley M. Levenson, Eli Seifter*
79	Flow cytometric analysis of R3327 rat prostate adenocarcinoma grown in vivo and in vitro	*Alice J. Claflin, Alan Pollack, Theodore Malinin, Norman L. Block, George L. Irvin*
89	Depression of natural antitumor resistance of C57BL/6 mice by leukemogenic doses of radiation and restoration of resistance by transfer of bone marrow or spleen cells from normal, but not beige, syngeneic mice	*E. Gorelik, R. B. Herberman*
95	Spontaneous occurrence of atypical hyperplasia and adenocarcinoma of the uterus in androgen-sterilized SD rats	*Shinichi Morikawa, Souei Sekiya, Masabumi Naitoh, Hiroshi Iwasawa, Bin Takeda, Hiroyoshi Takamizawa*
103	Combined inhibitors of carcinogenesis: Effect on azoxymethane-induced intestinal cancer in rats	*Norman D. Nigro, Arthur W. Bull, Paulette S. Wilson, Barbara K. Soullier, Majid A. Alousi*
109	Generation of long-term T-lymphoid cell lines with specific cytotoxic reactivity for a syngeneic murine lymphoma	*Timothy J. Eberlein, Maury Rosenstein, Paul J. Spiess, Steven A. Rosenberg*
117	Pathogenesis of lesions induced in rat lung by chronic tobacco smoke inhalation	*Carol A. Heckman, Walden E. Dalbey*
131	Noncytolytic extraction of murine tumor-specific transplantation antigens with the nonionic detergent octyl-β-D-glucopyranoside	*Stephen J. LeGrue, Catherine M. Macek, Barry D. Kahan*
137	Use of young nude mice for selection of subpopulations of cells with increased metastatic potential from nonsyngeneic neoplasms	*Vincent A. Pollack, Isaiah J. Fidler*

Photochemical Toxicity—Proceedings of the seventh in the series of Food and Drug Administration Science Symposia

Introduction

151 Photochemical toxicity: Toxic, allergic, and carcinogenic aspects with emphasis on predicting effects in humans—an introduction *F. Alan Andersen*

Basic Chemistry, Physics, and Biology Relating to Photosensitization

155 Optical radiation measurements: Instrumentation and sources of error *Robert J. Landry, F. Alan Andersen*
163 Molecular aspects of drug photosensitivity with special emphasis on psoralen photosensitization reaction *Madhu A. Pathak*
171 Immunosuppressive effects of ultraviolet (280–320 nm) radiation and psoralen plus ultraviolet (320–400 nm) radiation in mice *Margaret L. Kripke*

Cellular Assay Systems

177 Cell damage by near ultraviolet radiation: Role of DNA–protein cross-links *A. Eisenstark, S. Kovacs, J. Terry*
183 Tumor virus induction and host cell capacity inactivation: Possible in vitro tests for photosensitizing chemicals *L. E. Bockstahler, T. P. Coohill, C. D. Lytle, S. P. Moore, J. M. Cantwell, B. J. Schmidt*
189 Comparative photobiology of psoralens *M. J. Ashwood-Smith, A. T. Natarajan, G. A. Poulton*
199 Genotoxic effects of sunlight-activated waste water in cultured mammalian cells *Gary F. Strniste, David J. Chen, Richard T. Okinaka*
205 Interaction of oxygen and oxy-radicals with carotenoids *Norman I. Krinsky, Susan M. Deneke*
211 A method to quantify the potency of photosensitizers that modify cell membranes *John P. Pooler, Dennis P. Valenzeno*

Experimental Animal Systems

219 In vitro assay of the effects of psoralens plus ultraviolet radiation on human lymphoid cells *Kenneth H. Kraemer*
229 Modification of photocarcinogenesis by chemical agents *Frederick Urbach, P. Donald Forbes, Ronald E. Davies*
237 Current status of predictive animal models for drug photoallergy and their correlation with drug photoallergy in humans *Leonard C. Harber, Robert B. Armstrong, Hideyuki Ichikawa*
245 Toxic effect of ultraviolet light on melanocytes: Use of animal models in pigment research *George Szabo, Frederick B. Blog, Andrija Kornhauser*

Animal Photochemical Toxicity Effects

253 Toxicologic aspects of photosensitization in livestock *A. Earl Johnson*
259 Chemical and biochemical aspects of photosensitization in livestock and poultry *G. Wayne Ivie*

Human Photochemical Toxicity Effects

265 Chemical phototoxicity in humans *John H. Epstein*

269 Human models for identification of photosensitizing chemicals *Albert M. Kligman, Kays H. Kaidbey*

273 Therapeutic in vivo photochemistry: Photochemical toxicity studies in humans *John A. Parrish*

279 Photosensitization by porphyrins and prevention of photosensitization by carotenoids *Micheline M. Mathews-Roth*

287 Ocular phototoxicity and psoralen plus ultraviolet radiation (320–400 nm) therapy: An experimental and clinical evaluation *Sidney Lerman*

Summary and Conclusions

303 Concluding remarks *Constantine Zervos*

Investigations on Man

323	Multiple myeloma among atomic bomb survivors in Hiroshima and Nagasaki, 1950–76: Relationship to radiation dose absorbed by marrow	*Michito Ichimaru, Toranosuke Ishimaru, Motoko Mikami, Masako Matsunaga*
329	Possible association of radioprotective and chemoprotective aminophosphorothioate drug activity with polyamine oxidase susceptibility	*Joseph M. Gaugas*
333	Search for evidence of feline leukemia virus infection in humans with leukemias, lymphomas, or soft tissue sarcomas	*Peter P. Sordillo, R. Pincow Markovich, William D. Hardy, Jr.*
339	Interferon and prostaglandins: Effects on human natural and lectin-induced cytotoxicity	*Nicholas P. Lang, John R. Ortaldo, Guy D. Bennard, Ronald B. Herberman*
345	Indirect macrophage migration inhibition response to 3-*M* KCl extract of gastric carcinoma	*Tsuyoshi Akiyoshi, Fumio Koba, Michihiro Kawaguchi, Soichiro Miyazaki, Hideo Tsuji*
349	Ten- to fourteen-year effect of screening on breast cancer mortality	*Sam Shapiro, Wanda Venet, Philip Strax, Louis Venet, Ruth Roeser*
357	Antigenic heterogeneity of human colorectal cancer cell lines analyzed by a panel of monoclonal antibodies. I. Heterogeneous expression of Ia-like and HLA-like antigenic determinants	*Grant D. MacLean, Jutta Seehafer, Andrew R. E. Shaw, Mark W. Kieran, B. Michael Longenecker*
365	Changes in skin cancer morbidity between 1971–72 and 1977–78	*Thomas R. Fears, Joseph Scotto*
371	Isolation and partial characterization of surface components of cell line MDA-MB-231 derived from a human metastatic breast carcinoma	*Evelyne Walker-Nasir, John F. Codington, Marianne R. Jahnke, Thomas C. Fuller, Roger W. Jeanloz*
381	α_1-Protease inhibitor production by human adenocarcinomas xenotransplanted into nude mice	*Dorothy Lee, Dan Shochat, David V. Gold*
387	Increasing trends of multiple myeloma mortality in England and Wales; 1950–79: Are the changes real?	*Ramon Velez, Valerie Beral, Jack Cuzick*
393	Changes in clonal expression during the course of acute leukemia: Possible subsets in childhood leukemia	*Hie-Won L. Hann, Peter C. Nowell, Penelope Koch, Jun Minowada, John E. Leitmeyer, Charles S. August*
401	Coproduction of carcinoembryonic antigen and nonspecific cross-reacting antigen by a continuous cell line from a human pancreatic tumor	*Masahide Kuroki, Sadanori Ichiki, Motomu Kuroki, Yuji Matsuoka*
409	Repair of chromosome damage induced by X-irradiation during G_2 phase in a line of normal human fibroblasts and its malignant derivative	*Ram Parshad, Raymond Gantt, Katherine K. Sanford, Gary M. Jones, Robert E. Tarone*

Investigations on Nonhuman Systems

415	Role of anchorage in the expression of tumorigenicity of untransformed mouse cell lines	*Robert S. Wells, Evelyn W. Campbell, Douglas E. Swartzendruber, Lawrence M. Holland, Paul M. Kraemer*
425	Chromosome changes associated with the progression of cell lines from preneoplastic to tumorigenic phenotype during transformation of mouse salivary gland epithelium in vitro	*John K. Cowell, Caroline B. Wigley*
435	Effect of type C viral expression and cellular karyotype on human B-lymphoblast tumorigenicity in nude mice	*Anton F. Steuer, Robert C. Ting, Phillip D. Markham, Zaki Salahuddin, Robert C. Gallo*
443	Hormone dependence of 7,12-dimethylbenz[*a*]anthracene-induced mammary tumor growth: Correlation with prostaglandin E_2 content	*M. Katherine Foecking, William E. Kibbey, Hussein Abou-Issa, Richard H. Matthews, John P. Minton*
447	Comparison of ovariectomy and retinyl acetate on the growth of established 7,12-dimethylbenz[*a*]anthracene-induced mammary tumors in the rat	*Philippe Gandilhon, Réjean Melancon, Jean Djiane, Paul A. Kelly*

453	Growth and differentiation of hyperplastic outgrowths derived from mouse mammary epithelial cells transformed in organ culture	*Nivedita Ganguly, Ranjan Ganguly, Nozer M. Mehta, Mihir R. Banerjee*
465	Effect of immunomodulation on the fate of tumor cells in the central nervous system and systemic organs of mice. Distribution of $[^{125}\text{I}]$5-iodo-2′-deoxyuridine-labeled KHT tumor cells after left intracardial injection	*Frances K. Conley*
475	Role of prostaglandin E_1 and copper in angiogenesis	*Marina Ziche, John Jones, Pietro M. Gullino*
483	Angiogenesis and neoplastic progression in vitro	*Marina Ziche, Pietro M. Gullino*
489	Immunization against transplantable leukemia impaired in copper-deficient mice	*Omelan A. Lukasewycz, Joseph R. Prohaska*
495	Effects of different fractions of *Corynebacterium parvum* on the cytotoxic T-cell response to alloantigens in mice	*Alan Lichtenstein, Richard Tuttle, John Cantrell, Jacob Zighelboim*
503	Chemical cocarcinogenesis with the use of a subclone derived from Balb/3T3 cells with catechol as cocarcinogen	*Mahalakshmi Atchison, Ching-shan Chu, Takeo Kakunaga, Benjamin L. Van Duuren*
509	Immunotherapy of a murine leukemia virus-infected, chemically induced murine sarcoma with antiviral antibodies	*Edward C. Ward, J. Dirk Iglehart, Kent J. Weinhold, Dani P. Bolognesi*
517	Proliferation of ductal outgrowths by carcinogen-induced rat mammary tumors in gland-free mammary fat pads	*Evelyn M. Rivera, Srinivasan Vijayaraghavan*
527	Individually distinct tumor-specific cell surface antigen identified by monoclonal antibody on a Rous sarcoma virus-induced mouse tumor	*Noboru Kuzumaki, Hidetaka Minakawa, Takashige Miyazaki, Soichi Haraguchi, Tetsumichi Matsuo, Takato O. Yoshida*
531	Neoplastic transformation of Syrian hamster cells by putative epoxide metabolites of commercially utilized chloroalkenes	*Joseph A. DiPaolo, Jay Doniger*
535	Derivation of transplantable 7,12-dimethylbenz[*a*]anthracene-induced chicken fibrosarcoma lines: Differences in metastasizing properties and organ specficity	*J. E. Galton, B. Xue, G. M. Hochwald, G. J. Thorbecke*

Meeting Highlights

543	Cytogenetics and somatic cell genetics of malignancy workshop	*Warren W. Nichols, Alfred G. Knudson, Louis Siminovitch*
544	Brief summary of the third joint meeting of the United States–Japan Cooperative Cancer Research Program on cell interactions and cancer	*Ira Pastan, Yoji Ikawa*

Corrections

547	May 1982, Vol 68, No. 5, page 878: "Comparison of In Vitro and In Vivo Effects of Thymidine on L1210 Leukemia in Mice"	*Daniel S. Zaharko, Lori M. Ramonas*

Letters to the Editor

549 Morbidity versus mortality *Johannes Clemmesen, Arne Nielsen*

550 Reply *Richard Doll, Richard Peto*

Investigations on Man

551 Immunity to tumor-associated antigens in vasectomized men *Deborah J. Anderson, Nancy J. Alexander, David L. Fulgham, Arthur A. Vandenbark, Denis R. Burger*

557 Unscheduled DNA synthesis in human oral mucosa treated with chemical carcinogens in short-term organ culture *Fumio Ide, Takatoshi Ishikawa, Minoru Takagi, Shinichiro Umemura, Shozo Takayama*

565 Distribution of hepatitis B surface and core antigens in human liver cell carcinoma and surrounding nontumorous liver *Setsuo Hirohashi, Yukio Shimosato, Yoshinori Ino, Kiyozo Kishi*

569 Elevated dTTPase activities in sera of patients with advanced cancer *Nicolaus Dahlmann*

573 Breath methane excretion in patients with unresected colorectal cancer *David A. Karlin, R. D. Jones, John R. Stroehlein, Anthony J. Mastromarino, Gregory D. Potter*

577 *N*-Methyl-*N*-nitrosourea and saccharin: Effects on epithelium of normal human urinary bladder in vitro *Shadia El-Gerzawi, Barry M. Heatfield, Benjamin F. Trump*

585 Persistence of transforming and nontransforming Epstein-Barr virus in high passages of P3HR-1 cell lines *Paul Gerber, Dharam Ablashi, Ian Magrath, Gary Armstrong, Philip Andersen, Luba Trach*

Investigations on Nonhuman Systems

591 A deletion in chromosome 1 in cells of a transplantable granulocytic leukemia (GL-13) in guinea pigs *Dorothy E. Moore, Warren H. Evans, Michael G. Mage*

595 Establishment and immunologic characterization of 3-methylcholanthrene-induced sarcoma cell lines metastasizing widely in mice and exhibiting distinct and selective propensities for the mode of metastasis *Yuso Kodama, Toshio Seyama, Kenji Kamiya, Kenjiro Yokoro*

607 Modulation of cell-mediated alloimmunity by BCG. I. Antagonism and potentiation of immunosuppression caused by cytarabine *Richard I. Murahata, Malcolm S. Mitchell*

613 Modulation of cell-mediated alloimmunity by BCG. II. Induction of specific, nonadherent, non-T-killer cells by BCG and alloantigen *Richard I. Murahata, Malacolm S. Mitchell*

619 Alloantigenic phenotype of radiation-induced thymomas in the mouse *P. Mark Hogarth, Margaret M. Henning, Ian F. C. McKenzie*

627 Formation of symbiotic complex by microenvironment-dependent mouse leukemias and thymic epithelial reticular cells *Yoshimi Nishi, Kazuhiro Yoshikawa, Hiroshi Hiai, Kunihiro Notake, Hayase Shisa, Yasuaki Nishizuka*

639	A high-tumor-incidence subline of the D1 mouse mammary hyperplastic outgrowth line: Effect of carcinogens	*Rhoda L. Ashley, Robert D. Cardiff, Terry S. Pratt, Leslie J. Faulkin*
647	Antitumor immunity induced by hybrid murine tumor cells: Requirement for optimal immunization	*Craig S. McCune, Robert W. O'Donnell, Paul K. Horan, Hollis S. Budd, Janice L. Spennacchio, Christy Chuang, Edgard C. Henshaw*
653	Inhibitory effect of interferon on the growth of spontaneous mammary tumors in mice	*Erik De Clercq, Zhen-Xi Zhang, Kris Huygen, Roger Leyten*
659	Influence of cause-of-death assignment on time-to-tumor analyses in animal carcinogenesis studies	*Ralph L. Kodell, John H. Farmer, David W. Gaylor, Alexander M. Cameron*
665	Murine lymph node natural killer cells: Regulatory mechanisms of activation or suppression	*Goro Hisano, Nabil Hanna*
673	Androgen control of cytosol progesterone receptor levels in the MT-W9B transplantable mammary tumor in the rat	*Margot M. Ip, Richrad J. Milholland, Untae Kim, Fred Rosen*
683	In vitro measurement of resistance to phalloidin and γ-glutamyltransferase of carcinogen-induced preneoplastic hepatocytes of rats	*Norimasa Sawada, Kazunori Furukawa, Hideyuki Tsukada*
687	Chicken resistance to dimethylnitrosamine acute effects on the liver: A comparative study with other species	*H. M. Godoy, M. I. Díaz Gómez, A. Marzi, E. C. de Ferreyra, O. M. de Fenos, J. A. Castro*
693	Effects of sublethal irradiation on changes in crypts of the mouse colon during treatment with 1,2-dimethylhydrazine	*Thomas C. Richards, David E. Tacha*
699	Tumor-induced neovascularization in the mouse eye	*V. R. Muthukkaruppan, L. Kubai, R. Auerbach*
709	In vitro infection of lymphocytes with Marek's disease virus	*Bruce W. Calnek, Karel A. Schat, William R. Shek, Chen-Lo H. Chen*
715	Surface antigens on Marek's disease lymphoblastoid tumor cell lines	*Karel A. Schat, Chen-Lo H. Chen, William R. Shek, Bruce W. Calnek*
721	Some effects of the tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate on cell interactions in vitro	*David E. Maslow, Eric G. Mayhew, Charles E. Wenner*
725	Mouse skin tumor-initiating activity of 5-, 7-, and 12-methyl- and fluorine-substituted benz[α]anthracenes	*Alexander W. Wood, Wayne Levin, Richard L. Chang, Allan H. Conney, Thomas J. Slaga, Robert F. O'Malley, Melvin S. Newman, Donald R. Buhler, Donald M. Jerina*
729	Free amino acid pools of rodent mammary tumors	*Martin J. Pine, Untae Kim, Clement Ip*
737	Immunomodulation of the lymphoresponsive phases of carcinogenesis: Mechanisms of natural immunity	*Charles H. Evans, Joseph A. DiPaolo, Jeffrey A. Heinbaugh, Anthony J. DeMarinis*
741	Lymphotoxin prevention of diethylnitrosamine carcinogenesis in vivo	*Janet H. Ransom, Charles H. Evans, Joseph A. DiPaolo*

Guest Editorial

747	Sheep lung carcinoma: An endemic analogue of a sporadic human neoplasm	*K. Perk, I. Hod*

Investigations on Man

751	Studies on carcinogenesis of human prostate. II. Long-term explant culture of normal prostate and benign prostatic hyperplasia: Light microscopy	*Hayato Sanefuji, Barry M. Heatfield, Benjamin F. Trump, John D. Young, Jr.*
757	Studies on carcinogenesis of human prostate. III. Long-term explant culture of normal prostate and benign prostatic hyperplasia: Transmission and scanning electron microscopy	*Barry M. Heatfield, Hayato Sanefuji, Benjamin F. Trump*
767	Enhancement of growth of human colon tumor cell lines by feeder layers of murine fibroblasts	*M. G. Brattain, D. E. Brattain, A. M. Sarrif, L. J. McRae, W. D. Fine, J. G. Hawkins*
773	Major histologic types of cancers of the gum and mouth, esophagus, larynx, and lung by sex and by income level	*V. L. Ernster, S. Selvin, S. T. Sacks, D. W. Merrill, E. A. Holly*
777	Glycoconjugate with *Ulex europaeus* agglutinin-I-binding sites in normal mucosa, adenoma, and carcinoma of the human large bowel	*Suguru Yonezawa, Takao Nakamura, Sadao Tanaka, Eiichi Sato*
787	Cerebrospinal fluid markers in African Burkitt's lymphoma with central nervous system involvement	*William C Wallen, Robert J. Biggar, Paul H. Levine, Janet Neequaye, Francis K. Nkrumah*
793	Transforming growth factors in the urine of normal, pregnant, and tumor-bearing humans	*Daniel R. Twardzik, Stephen A. Sherwin, Jane Ranchalis, George J. Todaro*
799	Selective cytotoxicity of a ricin A-chain–anticarcinoembryonic antigen antibody conjugate for human colon adenocarcinoma cell line	*Thomas W. Griffin, Linda R. Haynes, Julie A. DeMartino*
807	In vitro potentiation of human natural killer cell activity by a streptococcal preparation, OK-432: Interferon and interleukin-2 participation in the stimulation with OK-432	*Hiro Wakasugi, Tadashi Kasahara, Nagahiro Minato, Junji Hamuro, Michio Miyata, Yasuhiko Morioka*
813	Carcinoembryonic antigen: Usefulness as a postsurgical method in the detection of recurrence in Dukes stage B_2 and C colorectal cancers	*Maria Koch, Graeme Washer, Herta Gaedke, Thomas A. McPherson*
817	Interaction of familial and hormonal risk factors for breast cancer	*Louis A. Brinton, Robert Hoover, Joseph F. Fraumeni, Jr.*
823	Imaging of human melanoma xenografts in nude mice with a radiolabeled monoclonal antibody	*Tarun Ghose, Soldano Ferrone, Kohzoh Imai, Stevens T. Norvell, Jr., Steven J. Luner, Robert H. Martin, A. Huntley Blair*
827	Functional properties of human thymoma lymphocytes: Role of subcellular factors in blastic activation	*Piero Musiani, Libero Lauriola, Nicola Maggiano, Pietro Tonali, Mauro Piantelli*
833	Changes in lung cancer incidence and mortality rates among Americans: 1969–78	*John W. Horm, Ardyce J. Asire*

Investigations on Nonhuman Systems

839	Simian virus 40 (SV40)-specific isoelectric point-4.7–94,000-M_r membrane glycoprotein: Major peptide homology exhibited with the nuclear and membrane-associated 94,000-M_r SV 40 T-antigen in hamsters	*Rupert Schmidt-Ullrich, W. Scott Thompson, Stuart J. Kahn, Maureen T. Monroe, Donald F. H. Wallach*
851	Relationship of lung adenoma prevalence and growth rate to acute urethan dose and target cell number	*Michael L. Dourson, Ellen J. O'Flaherty*
859	Relationship between urethan dose rate and adenoma latency: Relevance of tumor growth rate and target cell number	*Ellen J. O'Flaherty, Michael L. Dourson*
867	Tumor cell-triggered macrophage-mediated suppression of the T-cell cytotoxic response to tumor-associated antigens. I. Characterization of the cell components for induction of suppression	*Chou-Chik Ting, Dennis Rodrigues*

873 Tumor cell-triggered macrophage-mediated suppression of the T-cell cytotoxic response to tumor-associated antigens. II. Mechanisms for induction of suppression — *Chou-Chik Ting, Myrthel E. Hargrove*

879 Inducible macrophage cytotoxins. I. Biokinetics of activation and release in vitro — *Thomas H. Reidarson, Walter E. Levy III, Jim Klostergaard, Gale A. Granger*

889 Inducible macrophage cytotoxins. II. Tumor lysis mechanism involving target cell-binding proteases — *Thomas H. Reidarson, Gale A. Granger, Jim Klostergaard*

895 Squamous metaplasia in organ cultures of vitamin A-deficient hamster trachea: Cytokinetic and ultrastructural alterations — *Dharam P. Chopra*

907 Primordial germ cell proliferation in fetal testes in mouse strains with high and low incidences of congenital testicular teratomas — *Takehiko Noguchi, Leroy C. Stevens*

915 Epizootic neoplasms in fishes from a lake polluted by copper mining wastes — *John J. Black, Elwin D. Evans, John C. Harshbarger, Robert F. Zeigel*

927 Electron microscopic autoradiography of the trachea in fetal Syrian golden hamsters treated transplacentally with *N*-nitrosodiethylamine — *Hildegard M. Reznik-Schüller*

933 Comparison of biologic behavior and histology of transplanted mammary tumors in GR mice — *Dean H. Percy, Vincent L. Morris, Janet I. MacInnes*

939 Regulation of cell-mediated immunologic reactivity to Moloney murine sarcoma virus-induced tumors. III. Further characterization of tumor-specific serum blocking factors — *William J. Halliday, Thelma A. Koppi, Ian F. C. McKenzie*

945 Trisomy 15 and other nonrandom chromosome changes in Rauscher murine leukemia virus-induced leukemia cell lines — *Anne Hagemeijer, Elisabeth M. E. Smit, Francine Govers, Nico J. de Both*

953 Induction of gp70-specific suppressor T-cells in mice inoculated with virus-producing tumor cells — *Jeffrey A. Bluestone, Carlos Lopez*

961 Carcinogenicity test of acetoxime in MRC-Wistar rats — *Sidney S. Mirvish, Shahrokh Salmasi, Richard G. Runge*

963 *β*-Cyclodextrin: Promoting effect on the development of renal tubular cell tumors in rats treated with *N*-ethyl-*N*-hydroxyethylnitrosamine — *Yoshio Hiasa, Masato Ohshima, Yoshiteru Kitahori, Noboru Konishi, Toyohisa Fujita, Takashi Yuasa*

969 Secretagogue response in rat pancreatic acinar carcinoma — *John R. Warren*

975 Enhanced metastatic potential of tumor cells harvested from spontaneous metastases of heterogeneous murine tumors — *James E. Talmadge, Isaiah J. Fidler*

Meeting Highlights

981 Adult T-cell leukemia-lymphoma: Role of a human retrovirus — *Max Essex*

Corrections

987 December 1981, Vol 67, No. 6 page 1328: "Enhancement of Experimental Pancreatic Cancer in Syrian Golden Hamsters by Dietary Fat" — *Diane F. Birt, Sharokh Salmasi, Parviz M Pour*

987 April 1982, Vol 68, No. 4, page 678: "Mechanisms of Immunologic Eradication of a Syngeneic Guinea Pig Tumor" — *Suyu Shu, James T. Hunter, Herbert J. Rapp, Leila S. Fonesca*

1207 Noncontraceptive estrogen use and the occurrence of ovarian cancer — *Carlos La Vecchia, Allesandro Liberati, Silvia Franceschi*

1208 Immune alterations related to age, sex, and mammary tumor detection in murine mammary tumor virus-infected mice — *Hervé Benoist, Jean Dufer, Cécile Bouchet, Andrée Desplaces*

Guest Editorial

1209 Human retroviruses and adult T-cell leukemia–lymphoma — *Robert C. Gallo, Marvin S. Reitz, Jr.*

Investigations on Man

1215 Changes in human adenovirus 5 propagated in Burkitt's lymphoma cells — *Nicole Faucon, Georges Ogier, Yvette Chardonnet*

1221 Primary liver carcinoma and liver cirrhosis in atomic bomb survivors, Hiroshima and Nagasaki, 1961–75, with special reference to hepatitis B surface antigen — *Masahide Asano, Hiroo Kato, Keiko Yoshimoto, Shinichi Seyama, Hideyo Itakura, Tadao Hamada, Soichi Iijima*

1229 Epidemiology of familial predisposition for breast cancer in Japan — *Motoi Murata, Keijiro Kuno, Atsuo Fukami, Goi Sakamoto*

1235 Establishment and characterization of a human colony-stimulating factor-producing cell line from a squamous cell carcinoma of the thyroid gland — *Tetsuro Okabe, Hitoshi Nomura, Nakaaki Oshawa*

1245 In vitro studies on the cell-mediated immune response to human brain tumors. I. Requirement for third-party stimulator lymphocytes in the induction of cell-mediated cytotoxic responses to allogeneic cultured gliomas — *Maurice K. Gately, Moshe Glaser, Steven J. Dick, Ray W. Mettetal, Jr., Paul L. Kornblith*

1255 Isozymes of acid esterase and acid phosphatase in permanent human hematopoietic cell lines — *Christer Sundström, Heinz J. Radzun, Mohammad R. Parwaresch*

1261 Subpopulations of human T-lymphocytes. XIX. T-cells and T-cells with receptors for IgMFc (Tμ), IgGFc (Tγ), or IgAFc (Tα) in the peripheral blood and regional lymph nodes of patients with untreated breast cancer — *Sudhir Gupta, Susanna Cunningham-Rundles*

1265 Epidemic curve of respiratory cancer due to chloromethyl ethers — *William Weiss*

1271 Epithelial line from normal human colon mucosa — *B. Shannon Danes, E. Sutanto*

1277 DNA content of liver cell nuclei of *N*-2-fluorenylacetamide-induced altered foci and neoplasms in rats and human hyperplastic foci — *Hideki Mori, Takuji Tanaka, Shigeyuki Sugie, Masayoshi Takahashi, Gary M. Williams*

1283 No seasonality in the diagnosis of acute leukemia in the United States — *Alexander M. Walker, Paulus A. H. van Noord*

1289 Probable clonal origin of neurofibrosarcoma in a patient with hereditary neurofibromatosis — *Jan M. Friedman, Philip J. Fialkow, Claudia L. Greene, Michael N. Weinberg*

Investigations on Nonhuman Systems

1293 Accessory cell function in tumor-bearing mice and effects of *Corynebacterium parvum* — *Seiya Okuda, Kazuto Taniguchi, Chiharu Kubo, Kikuo Nomoto*

1299	Induction of γ-glutamyltransferase-positive and nonspecific esterase-positive foci in rat liver by partial hepatectomy following single injection of *N*-nitrosodiethylamine	*Norio Hirota, Shinichi Moriyama, Takeshi Yokoyama*
1305	Evidence for involvement of mast cells in tumor suppression in mice	*Hiroshi Tanooka, Yukihiko Kitamura, Toshihiko Sado, Kazuhiko Tanaka, Mizue Nagase, Sohei Kondo*
1311	*H-2* expression on a teratocarcinoma-derived cell line, TerC	*David B. Searls, Michael Edidin*
1317	Inhibitory effect of fumaric acid on forestomach and lung carcinogenesis by a 5-nitrofuran naphthyridine derivative in mice	*Keiko Kuroda, Masayoshi Kanisawa, Mitsutaro Akao*
1321	Characterization of anti-inflammatory factors produced by murine tumor cells in culture	*S. J. Normann, J. Cornelius*
1329	Collagenolytic activity of rabbit V_2 carcinoma implanted in the nude mouse	*Chitra Biswas, Kurt J. Bloch, Jerome Gross*
1337	Immunoadjuvant effects of *Blastomyces dermatitidis* against EL 4 lymphoma in C57BL/6J mice	*L. Scott McDaniel, George C. Cozad*
1343	Suppression of 7,12-dimethylbenz[*a*]anthracene-induced chromosome aberrations in rat bone marrow cells after treatment with Sudan III and related azo dyes	*Yoshiaki Ito, Sakan Maeda, Tetsuo Fujihara, Norifumi Ueda, Taketoshi Sugiyama*
1347	Growth of mouse mammary glands after neonatal sex hormone treatment	*Yasuhiro Tomooka, Howard A. Bern*
1353	Effects of nicotinamide, isonicotinamide, and bleomycin on DNA synthesis and repair in rat hepatocytes and hepatoma cells	*Rosemary Barra, Verrell Randolph, MariaElaina Sumas, Kevin Lanighan, Michael A. Lea*
1359	Tumor-associated antigens produced by mouse mammary tumor cells in artificial capillary culture	*Jean C. Hager, S. Spiegelman, M. Ramanarayanan, James Bausch, Pierre M. Galletti, Paul Calabresi*
1367	Glycosylated podophyllotoxin congeners: Loss of microtubule inhibition and permission of invasion in vitro	*Marc M. Mareel, Christian H. Dragonetti, Georges K. De Bruyne, Rita M.-L. Van Cauwenberge*
1375	Detection of aflatoxins and related metabolites by radioimmunoassay	*Philippe Sizaret, Christian Malaveille, Ruggero Montesano, Charles Frayssinet*
1383	Carcinogenic effect of carbazole in the liver of (C57BL/6N × C3H/HeN)F_1 mice	*Hiroyuki Tsuda, Akihiro Hagiwara, Michiko Shibata, Masato Ohshima, Nobuyuki Ito*
1391	Hormone requirements of the pregnancy-dependent mammary tumor of GR/A mice: An in vitro study	*John W. Harbell, Jackie S. Papkoff, Charles W. Daniel*
1403	Analysis of lymphoid cells responding to virus- and tumor-associated antigens in spleens of syngeneic mouse mammary tumor systems with low and high oncogenic potentials	*Diana M. Lopez, Ronald D. Paul*
1411	Genetics of transplacentally induced teratogenic and carcinogenic effects in rabbits treated with *N*-nitroso-*N*-ethylurea	*R. R. Fox, H. Meier, H. G. Bedigian, D. D. Crary*

Meeting Highlights

1419	Job-exposure matrices in occupational epidemiology	*Shelia K. Hoar*

Announcements

1421 Seventeenth Annual Clinical Symposium of St. Jude Children's Research Hospital

1421 Eighteenth Annual San Francisco Cancer Symposium

1421 Second Annual A.A.I. Course in Advanced Immunology

1421 Eleventh International Symposium for Comparative Research on Leukemia and Related Diseases

1421 Eleventh Annual Meeting of the International Society for Oncodevelopmental Biology and Medicine

1421 Seventh Meeting of the European Association for Cancer Research (EACR)

1423 **Acknowledgement**

1429 **Index of Authors**

1435 **Permuted Title Index**

1463 **1982 Table of Contents**
